PREFACE.

THIS SUPPLEMENT brings the Record of Chemical Discovery down to the end of the year 1872, including some of the more important discoveries which have appeared in 1873 and 1874.

The Author has much pleasure in stating that he has been favoured with the assistance of two of the former Contributors to the Dictionary, and of three other gentlemen, who have contributed articles of great interest and importance. The following is a list of the Contributors and of the Articles which they have written :—

H. E. ARMSTRONG, PH.D., F.C.S., PROFESSOR OF CHEMISTRY AT THE LONDON INSTITUTE:

Phenols.—Sulphur Chlorides.

G. C. FOSTER, B.A., F.R.S., PROFESSOR OF PHYSICS AT UNIVERSITY COLLEGE:

Magnetism.

H. NEWELL MARTIN, M.B., D.Sc., B.A., FELLOW AND LECTURER OF CHRIST'S COLLEGE, CAMBRIDGE:

Digestion.—Gastric Juice.—Glycogen.—Muscular Tissue.—Proteids, Respiration.—Urine.

H. E. ROSCOE, PH.D., F.R.S., PROFESSOR OF CHEMISTRY AT THE OWENS COLLEGE, MANCHESTER:

Light, Chemical Action of.—Spectral Analysis.

ROBERT WARINGTON, ESQ., F.C.S.

Fodder.—Maize.—Malt.—Manure.—Millet.—Oats.—Root-crops.

DICTIONARY OF CHEMISTRY.

SECOND SUPPLEMENT.

A

ARIETENE. A hydrocarbon obtained by distilling the resinous exudation of the nut-pine (*Pinus sabiniana*), indigenous in California. It has a specific gravity of 0.691 at 15°; distils almost constantly at about 101°; is nearly insoluble in water, but dissolves in 5 parts of alcohol of 95 p. c. It burns with a white smokeless flame, and dissolves fixed and volatile oils, except castor-oil. It has a pungent odour like that of orange-oil, and its vapour possesses powerful anæsthetic properties. It is attacked by boiling nitric acid, and gives substitution-products with chlorine. It has not been analysed (Wenzell, *Pharm. J. Trans.* [3] ii. 789).

ARIETIC ACID. See **COLOPHONY.**

ACACIA. The seeds of the *Acacia nilotica*, an arborescent leguminous plant, common in Egypt, have been examined by O. Popp (*Arch. Pharm.* [2] cxlv. 140). The tree produces innumerable leathery pods, which ripen in March. The ripe seeds are extremely hard and horny, but become soft by soaking in hot water. They are similar in composition to beans and peas, and might probably be used for food; in the dry state they yield from 5.3 to 5.5 p. c. nitrogen. The unripe pods give 1.8 to 2.0 p. c., the ripe pods 1.0 p. c. The ash of the seed has the following composition:—

K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ²	SrO ²	Cl	CO ²
33.39	5.36	14.21	12.10	0.61	16.23	3.65	1.81	0.35	12.11 = 99.82

ACEDIAMINE. This name was given by Strecker to a base the hydrochloride of which was said to be produced by the action of gaseous hydrogen chloride on fused acetamide (i. 2). Tawildkrow, however (*Deut. Chem. Ges. Ber.* v. 477), obtained by this reaction nothing but a mixture of sal-ammoniac and hydrochloride of diacetamide; neither did he succeed in forming acediamine by the action of sal-ammoniac on acetamide, or of ammonia or ammonium iodide on acetonitril.

ACENAPHTHENE. See **NAPHTHALENE.**

ACETAL, $\text{CH}^2\text{—CH}(\text{OC}^2\text{H}^5)^2$.—When bromine is added by drops to acetal in a cooled vessel, and the product washed with water and alkalis, a heavy, extremely pungent oil is obtained, which, when purified by fractional distillation, yields monobromacetal, $\text{CH}^2\text{Br.CH}(\text{OC}^2\text{H}^5)^2$. This compound in the pure state has a not unpleasant odour; it is insoluble in water, and boils, with slight decomposition, at 170°. Treated with alcoholic potash at 160°–180° for twelve hours, it is converted into hydroxyl-acetal, or glycolacetal, $\text{CH}^2(\text{OH}).\text{CH}(\text{OC}^2\text{H}^5)^2$, a colourless, fragrant liquid, boiling, without decomposition, at 167°. Vapour-density, obs. = 66.61 ($\text{H} = 1$), calc. = 67.

Glycolacetal is completely destroyed at common temperatures by strong sulphuric acid and by gaseous hydrochloric acid; glacial acetic acid does not act upon it in the cold; but at 100° slight browning takes place, and at 120° the decomposition is complete in a few hours. The product contains a body which has the odour of aldehyde, gives a specular deposit with silver nitrate, and, when treated with hydrogen sulphide, forms oily drops having the characteristic smell of sulphaldehyde; but it has not been obtained in sufficient quantity for satisfactory investigation.

Ethylie Glycolacetal, or *Glycolacetal ether*, $\text{CH}^2(\text{OC}^2\text{H}^5)^2$, obtained by the action of a concentrated solution of sodium ethylate at 160° on bromacetal, is a

2nd Sup.

B

liquid having an agreeable odour, boiling at 164° , and entirely destroyed by strong acids.

Diethyl Glycolacetal, $\text{CH}(\text{OC}^2\text{H}^5)^2 \cdot \text{CH}(\text{OC}^2\text{H}^5)^2$, corresponding to glyoxal, is obtained in like manner by the action of sodium ethylate on dichloroacetal; it boils at about 180° without decomposition, and is entirely destroyed by strong acids (Pinner, *Deut. Chem. Ges. Ber.* v. 147).

Trichloroacetal, $\text{C}^1\text{H}^1\text{Cl}^3\text{O}$.—Of this compound there are two modifications: one of which, solid at ordinary temperatures and melting at about 72° , was obtained by Paternò, in 1868, as a secondary product in the preparation of dichloroacetal by the action of chlorine upon alcohol (1st *Suppl.* 4); while the other, which is liquid at ordinary temperatures, is obtained by heating tetrachloroethyl oxide, $\text{CCl}^3\text{CH}(\text{OC}^2\text{H}^5)\text{Cl}$, with alcohol in sealed tubes (Wurtz a. Vogt, *Compt. rend.* lxxiv. 277.—Paternò a. Pisati, *Gazzetta chimica italiana*, ii. 333). This latter modification is a transparent, colourless liquid, having a pleasant odour, much like that of dichloroacetal, boiling at 199° – 201° (Wurtz a. Vogt); at 204.8° (corr.), under a pressure of 758.9 mm. Sp. gr. 1.2813 at 0° ; 1.2655 at 22.2° ; 1.617 at 99.96° (Paternò a. Pisati).

The mode of formation of the liquid trichloroacetal shows that it has the constitution $\text{CCl}^3\text{CH}(\text{OC}^2\text{H}^5)^2$:

which is confirmed by the mode of decomposition of the compound when heated with water or with sulphuric acid, the products of which, according to Wurtz a. Vogt, are alcohol and chloral:

The solid trichloroacetal appears also to yield chloral when heated with sulphuric acid; at all events, the distillate, when heated with potash and a small quantity of aniline, gives off the characteristic odour of the carbamides (isocyanides), a result which indicates the formation of chloroform, and thereby tends to show that the product of the action of sulphuric acid on trichloroacetal is really chloral. Nevertheless, Paternò a. Pisati do not regard their experiments (which were made on a small quantity of substance) as quite conclusive on this point, but think it possible that the product of this reaction may be dichloraldehyde, $\text{C}^2\text{Cl}^2\text{H}_2\text{CHO}$. In this case, the constitution of solid trichloroacetal might be represented by the formula:

Tetrachloroethyl oxide is transformed into trichloroacetal, not only by alcohol, but likewise, though much less completely, by sodium ethylate, or a very strong alcoholic solution of potash. If, however, the same compound be treated with a 10 p. c. solution of potassium hydrate in absolute alcohol, a totally different reaction takes place, a molecule of hydrochloric acid being eliminated, and a compound being formed which appears to have the constitution $\text{CCl}^2\text{—CCl—OC}^2\text{H}^5$. The reaction takes place at ordinary temperatures, with abundant deposition of potassium chloride. On dissolving out this salt by water, an oily liquid separates, which, when dried and purified by fractional distillation, boils at 154.8° (corr.) under the pressure of 755 mm., has a density of 1.5725 at 0° and 1.2354 at 99.9° , and gives by analysis 26.45 to 27.53 p. c. carbon, 2.93 to 2.98 hydrogen, and 59.55 to 60.59 chlorine; the formula $\text{C}^1\text{H}^1\text{Cl}^2\text{O}$ requiring 27.35 p. c. C., 2.85 H. and 60.68 Cl.

This compound unites directly with *bromine*, the combination being attended with rise of temperature, and forms a liquid which, after washing with water and sodium carbonate, is perfectly colourless; it is much heavier than water, is decomposed by distillation under ordinary pressure, but distils without alteration under a pressure of 4 centimeters, and boils at about 135° ; in a mixture of snow and salt it solidifies to a crystalline mass which melts at the temperature of the air.

This chlorobrominated compound probably has the constitution represented by the formula $\text{CCl}^2\text{Br—CClBr.O.C}^2\text{H}^5$. It is violently attacked by concentrated alcoholic potash, yielding a heavy oil, which may be separated by distillation with aqueous vapour into the original chlorinated compound, and a substance which is solid at the ordinary temperature (24°), and well crystallised (Paternò a. Pisati).

ACETAMIDE. $\text{C}^2\text{H}^3\text{ONH}^2$.—This compound is formed when acetic acid is boiled with potassium sulphocyanate; but prolonged heating is necessary to complete the reaction, which mainly takes place as represented by the equation:

At the same time, however, acetonitril, carbon dioxide and hydrogen sulphide are formed in small quantity by a secondary reaction (Letts, *Deut. Chem. Ges. Ber.* v. 669).

Acetamide is easily converted into acetonitril, C^2H^3N , by the action of *phosphorus pentasulphide*. The decomposition begins at ordinary temperatures, but heat is required to complete it. Hydrogen sulphide is given off, and a blackish tumented mass remains in the retort. Similar reactions take place with other amides (L. Henry, *Compt. rend.* lxxiii. 1273).

When acetamide is heated to 180° in sealed tubes with *orthoformic ether*, alcohol is formed, together with needle-shaped crystals of methenyl-diacetyl-diamino, a base analogous to Hofmann's methenyl-diphenyl-diamino:

At the same time another reaction takes place, yielding acetic ether and methenyl-diamino, CH^2N^2 , which may be separated as a platinum salt from the mother-liquor of the crystals above mentioned:

Acetamide heated in sealed tubes with *benzoic aldehyde* is converted into benzylene diacetamide, $C^{11}H^{11}N^2O$.

(E. Roth, *Zeitschr. f. Chem.* [2] vi. 680).

A precisely similar reaction takes place with *acetic aldehyde*, yielding the compound $C^{11}H^5.CH(NH.C^2H^3O)^2$, which crystallises in large prisms melting at 169° and distilling with partial decomposition. On heating it with acids, the aldehyde is set free (Tawildarow, *Deut. Chem. Ges. Ber.* v. 477).

Acetamide heated for some time to 128° – 180° with *anisaldehyde*, yields a compound, $C^{12}H^{11}N^2O^3$, which forms nodular groups of needles melting at 180° , soluble in water, insoluble in alcohol and ether, decomposed by hydrochloric acid, with separation of anisaldehyde, not altered by potash-ley, even at boiling heat (A. Schuster, *Zeitschr. f. Chem.* [2] vi. 681).

Acetamide heated with *salicylöl* in various proportions, yields a yellow neutral substance insoluble in alcohol, and containing, after washing with alcohol, from 63.3 to 68.5 p.c. carbon, and 5.7 to 8.1 hydrogen; it is soluble in aqueous and alcoholic potash, and hydrochloric acid added to the solution throws down a reddish-brown spongy substance. Strong hydrochloric acid decomposes it with red coloration (B. Credner, *Zeitschr. f. Chem.* [2] vi. 80).

Acetamide unites directly with *chloral*, forming the crystalline compound C^2H^3NO . $CHCl^3O$. (See *CHLORAL*).

When acetamide is heated with *sodium ethylate*, both being perfectly dry, ammonia is given off, and a crystalline residue is left, which is decomposed by water, yielding ammonia and acetate of sodium. When a solution of acetamide in slightly warm, absolute alcohol is added to a cold viscid solution of sodium ethylate, large plates of sodium ethylate are deposited, enclosing feathery crystals of acetamide (W. N. Hartley, *Chem. Soc. J.* [2] xi. 991).

Diacetamide, $(C^2H^3O)^2NH$, is formed by heating equivalent quantities of acetonitril and acetic acid to 250° , or by heating acetamide with acetic anhydride to 250° for six hours. It melts at 59° – 60° , and boils at 215° . By heating with zinc chloride it is resolved, without evolution of gas, into acetonitril and acetic acid:

(Linnemann, *Wien. Akad. Ber.* lx. [2] 44; *Jahresb.* 1869, p. 601).

According to Wichelhaus (*Deut. Chem. Ges. Ber.* iii. 847; *Chem. Soc. J.* [2] ix. 407), triacetamide is also formed in small quantity when a mixture of acetic anhydride and acetonitril is heated above 200° , and may be dissolved out by ether, after the excess of acetic anhydride has been removed by distillation. It crystallises in small white flexible needles, very much like diacetamide, and melts at 78° – 79° (diacetamide at 74° – 75° , acetamide at 78°). Diacetamide and acetamide treated with silver oxide in the cold, dissolve and form peculiar salts; whereas triacetamide at first forms no such compound; when gently warmed, however, all three yield silver acetate. Acetamide retains its odour when dissolved; diacetamide, under

the same circumstances, gives an acid reaction, and triacetamide is neutral. Diacetamide-treated with phosphoric anhydride, yields acetoneitril and acetic acid or anhydride.

Chlorinated Acetamides are prepared by allowing the ethylic ether of the corresponding chloroacetic acid to remain for some days in contact with aqueous ammonia. The amides thus produced are but slightly soluble in water, their solubility decreasing as the degree of chlorination becomes greater. By distillation with phosphoric anhydride they are converted into the corresponding chloroaceto-nitrils: e.g. $\text{C}^2\text{HCl}^2\text{O.NH}^2 - \text{H}^2\text{O} = \text{C}^2\text{HCl}^2\text{N}$ (L. Bisschoppinck, *Deut. Chem. Ges. Ber.* vi. 731).

Monochloroacetamide, $\text{C}^2\text{H}^2\text{ClO.NH}^2$, melts at 116° , and when subjected to a pressure of 743 mm. boils, with partial decomposition, at 224° – 225° (Bisschoppinck). According to Menschutkin a. Jermolowew (*Zeitschr. f. Chem.* [2] vii. 5), it crystallises in thick prisms, easily soluble in alcohol and water, especially when boiling. It melts at 119.5° and solidifies at about 116° ; sublimes very easily, even at the temperature of the water-bath, in broad, large needles; and distils in very small quantity, apparently undecomposed. Alkalis and baryta-water readily evolve ammonia from it on warming.

The *mercury-compound*, $(\text{C}^2\text{H}^2\text{ClO.NH})^2\text{Hg}$, is formed by adding precipitated mercuric oxide to an aqueous solution of chloroacetamide so long as the colour changes to white, then adding a large quantity of water, boiling, filtering, and exhausting the residue with boiling water. The air-dried compound does not lose weight over oil of vitriol, but begins to decompose at 100° . The compound is deposited from solution in fine needles or in warty masses made up of small needles. It dissolves with great difficulty in boiling water, and is nearly insoluble in cold water. When it is heated to 170° , a violent reaction occurs; chloroacetamide sublimes, and mercury and carbon are left behind. The *silver-compound* cannot be obtained on account of its instability (Menschutkin a. Jermolowew).

Dichloroacetamide, $\text{C}^2\text{HCl}^2\text{O.NH}^2$, melts at 96° , and, under a pressure of 745 mm., distils without change at 233° – 234° . *Trichloroacetamide*, $\text{C}^2\text{Cl}^3\text{O.NH}^2$, melts at 136° and boils at 238° – 239° under a pressure of 476 mm. (Bisschoppinck).

Iodoacetamide, $\text{C}^2\text{H}^2\text{IO.NH}^2$, is obtained by treating an alcoholic solution of chloroacetamide with solid potassium iodide for a day at the ordinary temperature, with frequent agitation, and then evaporating the alcoholic solution. The amide crystallises from water, in which it is easily soluble, in fine colourless opaque prisms. When heated it melts, turns yellow, and decomposes, evolving fumes of iodine (Menschutkin a. Jermolowew).

Ethylacetamide, $\text{C}^2\text{H}^5\text{O.NHC}^2\text{H}^5$, obtained by dehydration of ethylamine acetate, boils at 203° – 204° , and is resolved by fusion with zinc chloride into carbon monoxide, hydrocarbons, and ammonia (Linneemann).

Phenyl-acetamide, or *Acetanilide*, $\text{C}^2\text{H}^5\text{O.NHC}^6\text{H}^5$, prepared from pure aniline and glacial acetic acid, crystallises in very thin rhombohedral laminae, melting between 112° and 113° . It is easily decomposed by boiling dilute sulphuric acid, with formation of acetic acid and aniline sulphate.

To detect *tolylacetamide* (acetoluide) in acetanilide, the compound may be dissolved in 4 parts glacial acetic acid and the liquid diluted with about 80 parts of water, whereupon nearly all the acetanilide remains dissolved, while the acetoluide separates and may be purified by a second crystallisation from a small quantity of glacial acetic acid, or by one or two crystallisations from hot water. Acetoluide melts at a temperature above 140° (Merz a. Weith, *Zeitschr. f. Chem.* [2] v. 699).

Sodium-acetanilide, $\text{C}^6\text{H}^5\text{NaNO}$, is produced by the action of sodium on a hot solution of acetanilide in xylene (Bunge, *ibid.* vi. 119).

ACETAMIDE-CHLORAL. See CHLORAL.

ACETIC ACID, $\text{C}^2\text{H}^4\text{O}^2$.—*Formation*.—1. By direct oxidation of acetylene. When a mixture of 1 vol. acetylene and 20 vols. air is exposed to diffused daylight at ordinary temperatures in contact with dilute potash-solution, the greater part of the acetylene disappears in the course of six months, together with a volume of oxygen equal to half that of the acetylene, and about half the acetylene thus consumed is converted into acetic acid: $\text{C}^2\text{H}^2 + \text{O} + \text{KHO} = \text{C}^2\text{H}^3\text{KO}^2$, the remainder being condensed to a bituminous substance, also containing carbon, hydrogen, and oxygen.—The conversion of the acetylene into acetic acid is more complete when pure chromic acid is used as the oxidising agent. If only a little water is present, the reaction is sudden, violent, and attended with considerable evolution of heat, the products being carbonic, formic, and a variable quantity of acetic acid. To obtain the acetic acid

pure chromic anhydride must be added to an aqueous solution of acetylene, and the solution left to itself at the temperature of the air. The liquid then gradually turns brown and the acetylene disappears, and on distilling and saturating the distillate with barium carbonate, perfectly pure barium acetate is obtained (Berthelot, *Compt. rend.* lxx. 256; *Ann. Ch. Phys.* [4] xxiii. 212).—2. Together with carbonic acid, when essential oil of orange-peel is oxidised by boiling with a mixture of potassium dichromate and sulphuric acid (Wright a. Piesse, *Chem. Soc. J.* [2] ix. 118, 7).—3. Together with several of its homologues, by saponifying croton-oil with caustic soda (Gauthier a. Fröhlich, *Zeitschr. f. Chem.* [2] vi. 549).

Solidification.—Glacial acetic acid melts at 16.7° , and boils under the normal atmospheric pressure at 117.8° . By slow cooling it may be cooled to 10° – 8° without solidifying even on agitation. Solidification, however, takes place immediately when a granule of the solid acid is thrown into the liquid cooled to below 16.7° , the temperature at the same time rising to 16.7° . If the solidified acid be slowly fused by immersing the vessel in water of about 25° , an immersed thermometer exhibits the temperature of 16.7° so long as any considerable quantity of the solid acid remains unmelted: the melting and solidifying points of the glacial acid are therefore identical.

When a mixture of glacial acetic acid and water is cooled, it does not solidify as a whole, but the acetic acid crystallises out, leaving the water liquid, just as a salt separates on cooling from a saline solution. In determining the solidifying point of aqueous acetic acid of given strength, it is necessary—since the separation of a large quantity of acetic acid would alter the proportion between the acid and water—to take care that only a small portion of acetic acid separates out. The best way of ensuring this condition is to cool the liquid about a degree below the approximately determined solidifying point, then throw in a granule of the glacial acid, and stir with a delicate thermometer. The temperature then rises to the solidifying point of the mixture. The results of experiments made in this manner are given in the following table:—

100 parts, by weight, of Acetic Acid mixed with :	100 parts, by weight, of the mixture contain :	Temperature of Solidification :
0.0 Water,	0.0 Water.	16.7° C.
0.5 "	0.497 "	15.65
1.0 "	0.990 "	14.8
1.5 "	1.477 "	14.0
2.0 "	1.961 "	13.25
3.0 "	2.912 "	11.95
4.0 "	3.846 "	10.5
5.0 "	4.761 "	9.4
6.0 "	5.660 "	8.2
7.0 "	6.542 "	7.1
8.0 "	7.407 "	6.25
9.0 "	8.257 "	5.3
10.0 "	9.090 "	4.3
11.0 "	9.910 "	3.6
12.0 "	10.774 "	2.7
15.0 "	13.043 "	0.2
18.0 "	15.324 "	2.6
21.0 "	17.355 "	5.1
24.0 "	19.354 "	7.4

This table shows that the proportion of acetic acid, especially in the more highly concentrated aqueous acid, may be determined, by means of the solidifying point, to within 1–10th p.c.—a degree of accuracy not attainable by any other method yet proposed. Other substances act like water in lowering the solidifying point of acetic acid, e.g. sulphuric acid, alcohol, and certain salts which dissolve in the acid. From a mixture of 100 parts acetic acid ($C^2H^4O^2$) and 0.5 sulphuric acid (H^2SO^4), the acetic acid solidifies at 16.4° ; from a mixture of 100 acetic acid and 1.8 alcohol, at 15.25° . The action of water may, however, be partly counteracted by addition of sulphuric acid. Thus, from a mixture of 100 parts acetic acid and 10 parts water, the acetic acid separates at 4.3° ; but if 2 parts of sulphuric acid are added, solidification takes place at 5.8° ; and from a mixture of 100 acetic acid, 10 water, and 20 sulphuric acid, the acetic acid solidifies at 10.7° .

The solidification of pure acetic acid may be exhibited with certainty, even in summer; namely, by immersing the vessel in cold water at about 10° or 12° , throwing in a fragment of the glacial acid, and agitating, whereupon the acid immediately

solidifies. A small quantity of the solid acid is very easily obtained by stirring a mixture of cold water and sal-ammoniac ammonium nitrate, or potassium sulphocyanate, with a test-tube containing a few drops of the liquid acid. The low temperature thereby produced causes the acetic acid to solidify (F. Rüdorff, *Deut. Chem. Ges. Ber.* iii. 390).

Vapour-density.—Horstmann (*Deut. Chem. Ges. Ber.* iii. 78) has determined the density of saturated acetic acid vapour by calculations based upon the weight of acetic acid which can be taken up by an uncondensable gas at a given temperature. Let V be the volume of the gas at 0° and 760 mm. At the temperature t° and barometric pressure P , this volume, after the gas has become saturated with acetic acid, vapour of tension p , becomes

$$V = V_0 \cdot \frac{273+t}{273} \cdot \frac{760}{p}$$

V is also the volume of the vapour taken up at t under the partial pressure p . If, then, d denotes the specific gravity of this vapour, its weight W will be given by the formula :

$$\begin{aligned} W &= V \cdot \frac{273}{273+t} \cdot \frac{p}{760} \cdot 0.001293 d \\ &= V_0 \cdot \frac{p}{P-p} \cdot 0.001293 d \end{aligned}$$

$$\text{whence } d = \frac{W(P-p)}{V_0 \cdot p \cdot 0.001293}$$

The mode of experimenting was as follows:—A measured volume of dry air was passed first through a flask containing acetic kept at a temperature somewhat above that at which the observation was to be made, then through a long tube containing glass beads moistened with acetic acid. This tube was laid in a large water-bath with several walls, the temperature of which could easily be regulated and kept constant. The temperature of the stream of gas was measured at the point where the gas, while still within the bath, passed over into the absorption apparatus, where the acetic acid was taken up by potash. Any water-vapour that might be given off from the potash solution was stopped by calcium chloride. In calculating the results of the experiments, the determinations of the vapour-tension of acetic acid made by Landolt (*Ann. Ch. Pharm. Suppl.* vi. 157) were made use of. These determinations refer to acetic acid evaporating in a vacuum, whereas Horstmann's refer to evaporation in air; but direct experiments showed that the errors thence arising were inconsiderable.

Density of Saturated Acetic Acid Vapour.

Temperature	Tension	Density	Temperature	Tension	Density
12.4°	13.5 mm.	1.89	27.6°	26.5 mm.	2.46
12.7	13.7	1.96	33.3	33.4	2.58
14.7	15.1	1.78.	38.5	41.5	2.72
15.6	15.6	1.98	38.5	41.5	2.79
17.4	16.8	2.09	41.6	53.1	2.75
20.2	19.0	2.28	48.7	63.0	2.98
21.5	20.4	2.24	51.1	69.0	3.16
22.6	21.2	2.29	59.9	97.0	3.72
25.0	23.5	2.42	62.9	109.2	3.11
26.1	25.0	2.32	63.1	100.0	3.19

Hence it appears that for a pressure of about 20 mm., acetic acid has, even at ordinary temperatures, nearly its normal density (2.08). The lower values obtained in a few cases arise from uncertainty in the measurement of the tension. Below 17° the results were vitiated by the solidification of the acetic acid, and above 60° constancy of temperature could not be effectually maintained. For the boiling point (120°) Horstmann, from former experiments (*Ann. Ch. Pharm. Suppl.* vi. 66), had estimated the density of saturated acetic acid vapour at about 3.3. It does not therefore appear to increase much after 60° .

A. Naumann has also examined the vapour-density of acetic acid vapour with the following results:—1. At a constant temperature the quantities of acetic acid contained in the unit of volume increase in greater proportion than the pressures.—2. The density of

acetic acid vapour, referred to that of air at the same pressure and temperature, decreases for a given quantity of the vapour in the unit of volume, as the temperature rises. Now, as this density must be the same for different temperatures if the vapour of acetic acid at those different temperatures were composed of similar molecules, it follows from the second of the preceding propositions: 3. That the molecules of acetic acid vapour are not similarly constituted at all temperatures, but that a given quantity of acetic acid forms a smaller number of molecules at low than at high temperatures.—4. It must also be supposed that, as the mean distances between the molecules increase, the attraction between them likewise diminishes (*Ann. Ch. Pharm.* clv. 325); (*Deut. Chem. Ges. Ber.* iii. 702).

Reactions.—Acetic acid and phosgene act on one another at 110–120°, producing acetyl chloride:

(Kempff, *J. pr. Chem.* [2] i. 402.)

Acetic acid heated under pressure to 130°–140° with *phenyl sulphocyanate*, forms phenyl-diacetamido, together with carbon dioxide and hydrogen sulphide:

(Hofmann, *Deut. Chem. Ges. Ber.* iii. 770.)

When acetic acid and *benzoic aldehyde* are heated in a sealed tube to 160°, the tube then opened and hydrochloric acid gas passed into the liquid, or zinc chloride added to it, the sides of the tube become covered with small shining crystals of cinnamic acid, another portion of which remains in solution:

The quantity of cinnamic acid thus obtained is, however, but small, part of it being decomposed by the further action of the hydrochloric acid or zinc chloride, with formation of metacinnamone (Schiff, *Deut. Chem. Ges. Ber.* iii. 412).

Metallic Acetates. Respecting the action of acetates upon lead-salts, see LEAD.

Potassium Acetate, decomposed by the electric current, yields at the positive pole—besides dimethyl or ethane, and carbon dioxide—ethylene (formerly mistaken for methyl oxide, i. 17) and a mixture of the vapours of methyl formate, acetate, and carbonate, which condense when the dried gaseous mixture is passed through a tube cooled by a freezing mixture. The ethylene appears to be formed by oxidation of the ethane, according to the equation $\text{C}^2\text{H}^4 + \text{O} = \text{C}^2\text{H}^2 + \text{H}^2\text{O}$. The hydrogen evolved at the negative pole burns with a distinctly luminous flame, possibly due to the presence of traces of acetylene (Kempt & Kolbe, *J. pr. Chem.* [2] iv. 46).

Sodium Acetate.—When crystallised sodium acetate, $\text{C}^2\text{H}^3\text{NaO}_2 + 3\text{H}^2\text{O}$, is melted in a flask and the liquid heated to its boiling point (120°–123°), the flask closed with cotton-wool while the liquid is boiling, and then left to cool, crystallisation takes place when the liquid is nearly cold, the crystals, when drained from the mother-liquor, having the composition $2\text{C}^2\text{H}^3\text{NaO}_2 + 5\text{H}^2\text{O}$. These crystals melt at about 126°, and the liquid on cooling yields crystals which, after draining, consist of the monohydrate, $\text{C}^2\text{H}^3\text{NaO}_2 + \text{H}^2\text{O}$. Sodium acetate, melted and boiled for a few seconds only, yielded, on cooling, crystals, which gave by analysis numbers agreeing with the formula $4\text{C}^2\text{H}^3\text{NaO}_2 + 9\text{H}^2\text{O}$; and by a second melting crystals were formed containing $4\text{C}^2\text{H}^3\text{NaO}_2 + 5\text{H}^2\text{O}$ (Zettnow, *Pogg. Ann.* cxlii. 306).

When an aqueous solution of sodium acetate turns mouldy, oxygen is absorbed and a small quantity of alcohol is formed. A solution of 300 grains of pure crystallised sodium acetate, left to itself from Feb. 4, 1864, to May 20, 1868, had lost 6·85 grains of acetic acid, and yielded 0·6 cub. cent. of (pure) alcohol. A small quantity of formic acid was also produced (Béchamp, *Zeitschr. f. Chem.* vi. 438).

Uranium Acetates.—*Uranio-cobaltous acetate*, $\text{Co}''(\text{C}^2\text{H}^3\text{O}_2)^2 \cdot 2(\text{UO}^2)'(\text{C}^2\text{H}^3\text{O}_2)^2 + 6 \text{ aq.}$, forms small yellow-brown dimetric crystals, which at 130° give off all their water and turn violet (Rammelsberg, *Pogg. Ann.* cxlv. 158).

Uranio-cuprio Acetate, $\text{Cu}''(\text{C}^2\text{H}^3\text{O}_2)^2 \cdot 2(\text{UO}^2)'(\text{C}^2\text{H}^3\text{O}_2)^2 + 4 \text{ aq.}$, is precipitated from a mixture of the two salts in green crystals belonging to the hexagonal system (Rammelsberg).

Alcoholic Acetates. *Acetio Ethers.*—*Ethyl Acetate.*—The statement of Wanklyn (1st Suppl. 16) that the action of sodium on ethyl acetate is not accompanied by evolution of hydrogen, is corroborated by the experiments of Ladenburg (*Deut. Chem. Ges. Ber.* iii. 305). He finds that acetic ether prepared in the ordinary way, then left for several weeks over calcium chloride, and distilled over recently fused calcium chloride

—whereupon it passes over at 72° – 74° —is not pure, inasmuch as when heated in sealed tubes to 200° and then distilled, it leaves a residue which boils above 80° , has a sour taste, a distinct odour of vinegar, and effervesces with sodium carbonate. Acetic ether, purified in the ordinary way, is attacked by silicium chloride only on first contact, and the mixture may then be heated to 120° without any further action taking place. Acetic ether which is no longer altered by silicium chloride is likewise not attacked by (metallically bright) sodium at ordinary temperatures, and only a few white specks are observed on the sodium even after several hours' boiling. When sodium is heated to 100° in a flask with acetic ether (purified as above, and freed by distillation from the greater part of the silicium chloride), the action begins only after several hours' heating, and only once in several experiments was a very small quantity of combustible gas obtained. Acetic ether freed from water and alcohol by means of phosphorous trichloride is likewise not attacked by sodium till heated nearly to 100° , and no gas is evolved. Hence it is inferred that the action of sodium on acetic ether takes place only at a temperature much higher than is generally supposed, and is not attended with evolution of hydrogen.

Tribasic Acetic Ether, $\text{C}^3\text{H}^3(\text{OC}^2\text{H}^3)^3$, is formed when sodium ethylate, free from alcohol, is mixed with the calculated quantity of dichloroethyl chloride, $\text{C}^2\text{H}^2\text{Cl}^2$ (boiling at 72° – 75°), and a volume of anhydrous ether at least equal to that of the sodium ethylate, and heated to 100° – 120° in a sealed tube till the solid sodium ethylate is converted into pulverulent sodium chloride (in about 12 hours). On opening the tube a gas escaped, probably $\text{C}^2\text{H}^2\text{Cl}$, and on dissolving out the sodium salts with water, shaking the ethereal layer with twice its volume of water, drying with calcium chloride, and distilling, there were obtained—together with ordinary acetic ether—*monochloroethyl-ethylene*, $\text{C}^2\text{H}^2\text{Cl}(\text{OC}^2\text{H}^2)^2$, boiling at about 123° , and *tribasic acetic ether*, $\text{C}^2\text{H}^2(\text{OC}^2\text{H}^2)^3$, boiling at 142° .

The monochloroethylene (not quite pure) had a specific gravity of 1.02 at 22° . It is a colourless combustible liquid, insoluble in water, and having a peculiar agreeable odour.

The tribasic acetic ether, still containing 10.2 p. c. of monochloroethyl-ethylene, had a sp. gr. of 0.94 at 22° . It is a colourless combustible liquid, having a peculiar agreeable, ethereal odour, not like that of ordinary ethyl acetate. Heated with water to 120° – 130° , it is decomposed into alcohol and acetic acid (Genther, *Jenaische Zeitschrift*, iv. 221; *Jahresb.* 1870, 636).

Propyl Acetate (normal), $\text{C}^3\text{H}^4\text{O}^2 = \text{CH}^3\text{CH}^2\text{CH}^3.\text{C}^2\text{H}^3\text{O}^2$, obtained by digesting the iodide with silver acetate, boils at 102° (bar. at 750 mm.), and has a specific gravity of 0.913 at 0° (Rossi, *Ann. Ch. Pharm.* clix. 79).

Amyl Acetate (normal), $\text{C}^5\text{H}^{10}\text{O}^2 = \text{CH}^3\text{CH}^2\text{CH}^2\text{CH}^2\text{CH}^3.\text{C}^2\text{H}^3\text{O}^2$, was prepared by mixing normal amyl iodide with silver acetate and glacial acetic acid in a flask cooled with ice, the reaction which takes place spontaneously on removing the vessel from the ice-bath being completed by application of a gentle heat. The resulting amyl acetate, after purification in the usual way, had a sp. gr. of 0.8963 at 0° , 0.8793 at 20° , 0.8635 at 40° , and boiled at 148.4° (observed: correction for mercury-column = 0.75°) under a barometric pressure of 737 mm. (Lieben u. Rossi, *Ann. Ch. Pharm.* clix. 70).

Tolylene Acetate, $\text{C}^8\text{H}^8(\text{C}^2\text{H}^3\text{O}^2)^2$, produced by heating an alcoholic solution of sodium acetate with tolylene chloride to 150° , forms hard shining laminae, having a hot camphorous taste, easily soluble in alcohol and ether. By distillation it appears to yield the monoacetate (Grignaux, *Compt. rend.* lxx. 1363).

Substitution-derivatives of Acetic Acid.

Bromacetic Acid, $\text{C}^2\text{H}^3\text{BrO}^2$, is formed when monobromacetylene, mixed with an indifferent gas, comes in contact with moist air, or when its alcoholic solution is exposed to the air: $\text{C}^2\text{HBr} + \text{H}^2\text{O} + \text{O} = \text{C}^2\text{H}^3\text{BrO}^2$.

Dibromacetic Acid, $\text{C}^2\text{H}^2\text{Br}^2\text{O}^2$, is produced by the action of bromine on ethyl acetate at 130° , much more easily than by treating acetic acid with bromine. The reaction is:

(Carius, *Deut. Chem. Ges. Ber.* iii. 336.)

Chloracetic Acid, $\text{C}^2\text{H}^3\text{ClO}^2$.—This acid, when heated with water, gradually decomposes, the more quickly as the quantity of water is greater and the temperature higher. A solution of the acid containing 0.324 gram $\text{C}^2\text{H}^3\text{ClO}^2$ in 10 c.c. of liquid,

and corresponding with the formula $C^2H^3ClO^2 + 164aq.$, was found to remain unaltered for four months at ordinary temperature; but, when it was enclosed in a sealed tube, plunged into boiling water for various times, and then cooled as quickly as possible, it was found, by trituration with a standard solution of soda or baryta, to have undergone decomposition to the extent shown in the following table.

I. represents the number of hours the solution was heated; II. the percentage of $C^2H^3ClO^2$ decomposed:—

I.	0	2	4	6	11	14	16	18	21	24	27	30
II.	0.0	6.0	11.0	14.5	23.0	28.0	31.5	35.0	38.0	42.5	45.0	51.5
I.	33	37	43	48	72	96	120	144	192	332	430	
II.	53.5	56.0	62.5	66.0	76.5	82.0	87.5	90.5	93.0	97.0	97.5	

(Buchanan, *Deut. Chem. Ges. Ber.* iv. 340).

Phenyl chloracetate, $C^6H^5.C^2H^3ClO^2$, is obtained by heating phenol with chloracetyl chloride; it forms silky glistening needles, melting at 40.2° , insoluble in water, soluble in alcohol and ether. Heated with alcoholic ammonia in a sealed tube, it is converted into phenyl amidacetate, $C^6H^5.C^2H^3(NH^2)O^2$, which crystallises in white needles, soluble in water, almost insoluble in alcohol and ether (E. W. Prevost, *J. pr. Chem.* [2] iv. 379).

When an alcoholic solution of *ethyl chloracetate* is heated with potassium nitrite, potassium ethyloxalate is formed according to the equation:

(Steiner, *Deut. Chem. Ges. Ber.* v. 333).

Dichloroacetic Acid, $C^2H^2Cl^2O^2$.—When ethyl dichloroacetate is digested at a temperature below 100° with a solution of potassium cyanide in dilute alcohol till it no longer smells of hydrocyanic acid, the filtered liquid, after separation of the alcohol, shaken up with ether, and the ethereal solution evaporated, a substance is left which, after crystallisation from alcohol and water, is scentless and tasteless; melts at 190° – 191° ; has a neutral reaction; is very soluble in ether, moderately soluble in alcohol; dissolves readily in hot, slightly in cold water, and crystallises from the solution in prisms. Its aqueous solution is decomposed by potash in the cold, with evolution of ammonia.

The crystalline compound has the composition $C^4H^4N^2O^4$, and may be regarded as an amidated ether, $CH(CONH^2)^2.COOC^2H^3$, derived from an unknown acid, $CH(COOH)^2$. It is probably formed by the action of water in presence of excess of acetic acid on ethyl dicyanacetate, produced in the first instance by the action of potassium cyanide on ethyl dichloroacetate in presence of alcohol:

The ether treated with potash yields oxalic, malonic, and glycollic acids, which are also found in the aqueous liquid separated from the ethereal solution of the amidated ether in the course of its preparation (Amato, *Gazzetta chimica italiana*, i. 690).

Trichloroacetic Acid, $CCl^3.COOH$. (De Clermont, *Compt. rend.* lxxiii. 112, 501; lxxiv. 942; Judson, *Zeitschr. f. Chem.* [2] vii. 40).—This acid is easily prepared by the action of nitric acid on chloral or its hydrate. When chloral hydrate is put into a flask with three times its weight of fuming nitric acid, and the mixture left to itself in the sun, a continuous disengagement of nitrogen tetroxide ensues, which ceases at the end of three or four days. On distilling the mixture, the temperature rises rapidly to 123° , at which point a mixture of nitric acid and water distils over; it then rises gradually to 195° , and the distillate consists of the last portion of the nitric acid, together with a small quantity of trichloroacetic acid; the temperature then remains steady at 195° , and the distillation proceeds regularly so long as any acid remains in the retort; the product is a colourless, transparent liquid, which crystallises at 44.8° . In one operation, 300 grams of trichloroacetic acid may be produced from 480 grams of chloral hydrate (De Clermont).

Trichloroacetic acid boils at 195° (Judson).

The trichloroacetates of *barium*, *strontium* and *calcium*, prepared by adding an excess of trichloroacetic acid to the corresponding carbonates, and evaporating at ordinary temperatures over lime, have a composition represented by the general formula $M^2(C^2Cl^3O^2)^2 + 6H^2O$. The *sodium salt*, similarly prepared, consists of $NaC^2Cl^3O^2 + 3H^2O$ (De Clermont).

The *lead salt*, $\text{Pb}(\text{C}^2\text{Cl}^3\text{O}^2)^2 + \text{H}^2\text{O}$, crystallises in large rhombic prisms, easily soluble in water, less soluble in alcohol, and only sparingly in ether. The *copper salt*, $\text{Cu}(\text{C}^2\text{Cl}^3\text{O}^2)^2 + 6\text{H}^2\text{O}$, forms fine crystals, resembling copper sulphate. In preparing it an excess of copper carbonate must be avoided, or else the acid will be decomposed, with production of chloroform (Judson).

The following trichloroacetates have likewise been analysed by De Clermont:—

Acid potassium salt	$\text{KC}^2\text{Cl}^3\text{O}^2 \cdot \text{C}^2\text{Cl}^3\text{HO}^2$
Lithium salt	$\text{LiC}^2\text{Cl}^3\text{O}^2 \cdot 2\text{H}^2\text{O}$
Magnesium salt	$\text{Mg}(\text{C}^2\text{Cl}^3\text{O}^2)^2 \cdot 4\text{H}^2\text{O}$
Nickel salt	$\text{Ni}(\text{C}^2\text{Cl}^3\text{O}^2)^2 \cdot 4\text{H}^2\text{O}$

These salts crystallise from solutions of the respective carbonates in trichloroacetic acid. The magnesium and lithium salts require several months for crystallisation; the crystals of both are deliquescent, and those of the latter can be kept only in sealed tubes.

Isobutyl Trichloroacetate, $\text{CH}^3\text{CH}(\text{CH}^3)^2 \cdot \text{C}^2\text{Cl}^3\text{O}^2$, obtained by prolonged digestion of 2 mol. isobutyl alcohol, 2 mol. trichloroacetic acid, and 1 mol. sulphuric acid, distilling, washing with sodium carbonate and water, and drying over calcium chloride, is a colourless liquid of agreeable odour, heavier than water, boiling at $187^\circ\text{--}189^\circ$ (Judson).

Trichloroacetanilide, $\text{C}^6\text{H}^5 \cdot \text{C}^2\text{Cl}^3\text{O} \cdot \text{HN}$, may be obtained by gradually mixing ethereal solutions of trichloroacetyl chloride and aniline; it is insoluble in cold water and dissolves very sparingly in boiling water, but easily in alcohol and ether; it crystallises in silvery scales which melt at 82° . *Trichloroacetobutidide*, prepared by an analogous process from toluidine, crystallises in fine six-sided prisms, which are often an inch long and melt at 102° (Judson).

When trichloroacetic acid is gradually added to a solution of *potassium sulphate*, sulphurous oxide is first given off, then carbon dioxide and chloroform. The solution, boiled till it ceases to smell of chloroform, contains, besides sulphate and hyposulphate of potassium, a very soluble salt, $\text{CHCl}(\text{SO}^2\text{K})\text{CO}^2\text{K} + 12\text{aq}$, which crystallises in beautiful perfect square-based octahedrons, with the basal pinacoids predominating, like the crystals of potassium ferrocyanide. These crystals remain unaltered in a vacuum over sulphuric acid, but lose water at 100° . The salt begins to decompose above 165° , and, when heated sufficiently, swells up, burns with a sulphur flame, and leaves a residue of potassium chloride and sulphate, discoloured by carbon. Its solution is not precipitated by baryta-water, neutral or basic lead acetate, or silver nitrate. This solution is not altered by boiling with potash, but suffers partial decomposition, when kept for some hours at 140° , and if heated to this temperature with potassium sulphate, it yields a considerable quantity of potassium chloride, so that the chlorine in the salt probably becomes replaced by hydrogen or by the group SO^2K (Rathke, *Ann. Ch. Pharm.* clxi. 149).

Cyanoacetic Acid. The electrolysis of this acid yields results analogous to those of acetic acid itself, the positive cell being found to contain a deliquescent acid substance, which is separable by means of ether, and agrees in physical and other characters with ethylene cyanide, $\text{C}^2\text{H}^2\text{C}^2\text{N}^2$, being solid at ordinary temperatures, melting at $37\text{--}8^\circ$, and being resolved by boiling with potash into ammonia and ethylene-succinic acid. The decomposition may be represented by the equation:

being exactly analogous to the electrolytic decomposition of acetic acid into carbon dioxide and dimethyl or ethane (G. E. Moore, *Silk. Am. J.* [3] iii. 177).

Phenyl-acetic Acid. See TOLUIC ACID.

Thioacetic Acid, $\text{CH}^3 \cdot \text{COSH}$, subjected to electrolysis, yields acetyl bisulphide $(\text{C}^2\text{H}^2\text{O})^2 \text{S}^2$ (Bunge, *Deut. Chem. Ges. Ber.* iii. 576).

Trimethyl-acetic Acid. See VALERIC ACID.

ACETIC BROMIDE, or **ACETYL BROMIDE**, $\text{C}^2\text{H}^3\text{OBr}$.—When this compound is heated for some hours in a tube to $140^\circ\text{--}150^\circ$, with an equivalent quantity of phosphorus pentabromide, bromoacetyl bromide, $\text{C}^2\text{H}^2\text{BrOBr}$ is formed according to the equation:

The bromoacetyl bromide passes over on rectification between $150^\circ\text{--}155^\circ$ (Samoadaky, *Zeitschr. f. Chem* [2] vi. 105).

ACETIC CHLORIDE, or **ACETYL CHLORIDE**, C^2H^3OCl , treated in like manner with phosphorus pentachloride, yields chloroacetyl chloride, C^2H^2ClOCl (Samoadsky).

Trichloroacetyl Chloride, C^2Cl^3O = C^2Cl^2OCl , is formed by heating di- or trichloride of carbon with sulphuric anhydride to 150° :

(Prudhomme, *Compt. rend.* lxx. 1137).

Respecting the conversion of acetic chloride into ethyl alcohol by sodium amalgam, see ETHYL ALCOHOL.

ACETIC OXIDE or **ANHYDRIDE**. $(C^2H^3O)^2O$. *Reaction with Stannic Acid*.

—When two parts of anhydrous acetic acid are heated with one part of stannic (or of metastannic) acid to 150° in a sealed tube, a syrupy liquid is obtained, crystallising on cooling in long needles which, after pressing between blotting-paper and drying over lime *in vacuo*, have the formula, $SnO^2 \left[\begin{smallmatrix} C^2H^3O \\ C^2H^3O \end{smallmatrix} \right] O$.

Washed with anhydrous ether till the washings are free from acid, and dried *in vacuo*, this substance is converted into a body having the formula, $SnO^2 \begin{pmatrix} C^2H^3O \\ C^2H^3O \end{pmatrix} O$.

The first-named crystals, when exposed to air, become amorphous, and are finally transformed into a vitreous mass having the composition $SnO^2 \begin{pmatrix} C^2H^3O \\ H \end{pmatrix} O$ (Lawrence, *Compt. rend.* lxxiv. 1524).

Reaction with Zinc-ethyl.—Acetic oxide treated with zinc ethyl in the nascent state yields methyl-ethyl ketone:

When a mixture of 2 mol. ethyl iodide and 1 mol. acetic oxide is added by drops to zinc-sodium in a cooled vessel, reaction sets in and is complete after 20 or 30 hours. On distilling and purifying the distillate in the usual way, by treatment with potash, combination with sodium bisulphite and decomposition of the resulting crystalline compound by distillation with an alkaline carbonate, methyl-ethyl ketone is obtained, boiling, after dehydration, between 70° and 80° . Other compounds boiling between 100° and 210° , are formed at the same time, probably resulting from the action of the zinc-ethyl on the methyl-ethyl ketone.

Zinc-ethyl, ready formed, acts with great violence on acetic oxide, evolving a large quantity of gas, which carries off with it a considerable portion of the liquid products.

A mixture of *methyl iodide* and acetic oxide acts in like manner on zinc-sodium, yielding common acetone, $(CH^3)^2CO$, together with bodies boiling between 70° and 190° (Saytzeff, *Zeitschr. f. Chem.* [2] vii. 104).

Respecting the action of acetic oxide on carbohydrates, see CELLULOSE, GUM, SUGAR, STARCH, &c.

Acetohypochlorous Oxide, $\begin{matrix} C^2H^3O \\ Cl \end{matrix} O$, or **Chlorine Acetate**, $CH^3.COOCli$.

—When a slow stream of acetylene is passed into a solution of this compound in acetic oxide containing 8 to 10 grams of $C^2H^2ClO^2$ to 35 to 40 grams of $C^2H^3O^2$, the gas is absorbed, with rise of temperature, acetic acid and methyl chloride are formed, and the acetylene either remains unaltered, or forms a compound not yet isolated. But if a very dilute solution of acetohypochlorous oxide be used (containing 15 parts Cl^2O to 100 parts acetic oxide), and cooled to at least -10° , the acetylene is absorbed without perceptible formation of methyl chloride, and water throws down from the saturated solution a somewhat syrupy liquid, having a peculiar aromatic odour and boiling at 120° under a pressure of 2 centimeters. It has the composition $C^2H^2 \begin{pmatrix} (C^2H^3O)^2 \\ (ClO)^2 \end{pmatrix}$ and may be regarded as the acetochlorhydrin of the tetratomic acetylene-alcohol $C^2H^2(OH)^4$. Aqueous potash, at the boiling heat, dissolves it quickly (Prudhomme, *Compt. rend.* lxx. 1137).

Bromacetic Oxide, $C^2H^3Br^2O^2$, or $(C^2H^2BrO)^2O$, the anhydride of monobromacetic acid, is formed by adding monobromacetic bromide, $C^2H^2BrO.Br$, to fused and finely powdered sodium acetate, and distilling. The distillate yields, by rectification, acetic oxide passing over between 137° and 245° , and bromacetic oxide at 245° . The reaction appears to take place by two stages, aceto-bromacetic oxide being first formed, and subsequently splitting up into acetic and dibromacetic oxides, thus:

Bromacetic oxide does not solidify at 0° . When poured into water or exposed to moist air, it is gradually converted into monobromacetic acid. In alcohol it dissolves with formation of ethylic monobromacetate (II. Gal, *Compt. rend.* lxxi. 273, *Chem. Soc. J.* [2] ix. 23).

ACETOBENZIDINE. See BENZIDINE.

ACETOBROMOPHENONE. See ACETOPHENONE.

ACETOCHLORAL. Syn. with CHLORAL.

ACETOCHLORHYDROSE, $\text{C}^4\text{H}^{10}\text{ClO}^3 = \text{C}^4\text{H}^7(\text{C}^2\text{H}^3\text{O})^2\text{ClO}^3$ (A. Colley, *Compt. rend.* lxx. 401).—A compound produced by the action of acetyl chloride on glucose. The action takes place at ordinary temperatures, but it is best to enclose the materials in sealed tubes cooled by a freezing mixture. With 5 mol. acetyl chloride to 1 mol. glucose, a colourless transparent mass is obtained. The reaction is:

On opening the tubes while immersed in the freezing mixture, hydrochloric acid escapes with violence; and on dissolving the residuo in chloroform, agitating with sodium carbonate, drying with calcium chloride, and evaporating off the chloroform, acetochlorhydrose remains as a semifluid, colourless, transparent, scentless, bitter mass, insoluble in water, easily soluble in alcohol, ether, and chloroform, slightly soluble in carbon bisulphide, nearly insoluble in benzene. It turns the plane of polarisation to the right: $[\alpha] = 147^\circ$. It was once obtained, under conditions not specified, as a perfectly dry crystalline mass, the analysis of which led to the formula above given, which is that of the acetochlorhydrin of glucose.

Acetochlorhydrose gives up the whole of its chlorine when treated in alcoholic solution with silver nitrate. Heated with sulphuric acid and alcohol, it gives off the odour of acetic ether. It does not reduce Fehling's solution. When heated with water in sealed tubes, it blackens and decomposes, but when treated in the same manner in shallow vessels exposed to the air, it remains colourless, and glucose is reproduced. It distils partially in a vacuum between 150° and 240° . The distilled product resembles the original substance, but has only half its rotatory power: $[\alpha] = 71^\circ$.

The reaction by which acetochlorhydrose is produced indicates that glucose is a pentatomic alcohol containing 5 hydroxyl-atoms. The sixth oxygen-atom probably binds together two atoms of carbon, as in diethylenic alcohol.

ACETOCINNAMMONNE, $\text{C}^{10}\text{H}^{10}\text{O} = \text{CO} \begin{array}{l} \text{CH}^3 \\ \text{CH}-\text{CH} \end{array} - \text{C}^6\text{H}_5$.—A ketone is

obtained, together with several other products, by the dry distillation of an intimate mixture of acetic oxide and cinnamic acids. It may be separated by repeated fractional distillation of that portion of the crude distillate which boils between 220° and 270° . When recently prepared it is a slightly yellow oily liquid of agreeable odour, turning darker when kept. Sp. gr. 1.008. Boiling point, 240° – 241° (Engler & Leist, *Deut. Chem. Ges. Ber.* vi. 254).

ACETODIBROMOXYLIDIDE. See XYLIDINE.

ACETONAPHTHYLAMIDE. See NAPHTHYLAMIDE.

ACETONE, $\text{C}^3\text{H}^4\text{O}$.—The formation of this body by the action of zinc-sodium on a mixture of acetic oxide and zinc-methyl has already been mentioned (p. 11). It is also formed by oxidation of propylene with aqueous chromic acid (Berthelot, *Compt. rend.* lxxiii. 334), and, according to Schloosmich (*Zeitschr. f. Chem.* v. 336), when aldehyde vapour is passed over red-hot lime.

Acetone heated to 100° – 120° for some days with liquid phosphene, yields a small quantity of liquid, which appears to be dichloracetone (T. Kempff, *J. pr. Chem.* [2] i. 402).

When acetone is treated with phosphorus pentasulphide, a violent reaction takes place, requiring, however, the heat of a water-bath to complete it; and two layers of liquid are obtained, the upper of which yields, by fractional distillation, duple-sulphacetone, $\text{C}^6\text{H}^8\text{S}^2\text{O}$, as a liquid boiling at 183° – 188° (corr.), and having a vapour-density of 5.08 (calc. 5.45). It produces a burning sensation on the skin; gives off vapours which attack the eyes strongly; mixes with alcohol and ether, but not with water; gives a bulky white precipitate with mercuric chloride. The lower

liquid formed in the above reaction consists chiefly of ethereal compounds and a small quantity of duplo-sulphacetone (Wislicenus, *Zeitschr. f. Chem.* [2] v. 324).

Compound of Acetone with Mercuric Oxide.—When solution of mercuric chloride is slowly added to a mixture of acetone with dilute aqueous solution of potassium hydrate, the mercuric oxide first precipitated is dissolved, with production of a clear colourless liquid. This solution gelatinises when heated to ebullition, or on the addition of acid in slight excess. On dialysing the alkaline solution, the diffusate, at the end of two days, contains a large quantity of potassium chloride, some potassium hydrate, and but a very small amount of mercury. If the process of diffusion be continued, the diffusate being replaced by pure water twice each day, until it no longer affords a cloud when treated with solution of silver nitrate, the dialyser will contain a pure colloidal liquid, which, on careful evaporation to dryness, yields a resinoid residue having a composition represented by the formula $2\text{CO}(\text{CH}_3)_2 \cdot 3\text{HgO}$.

Water containing 2 p. c. of this compound retains its liquidity for months; a 5 p. c. solution remains liquid for some days, but produces a firm jelly on being heated to 50° . The liquid colloid hydrate is the *hydrosol* of the new compound; and the gelatinous hydrate, the *hydrogel* (v. 1088). The *alcosol* may be obtained by adding to a 1 p. c. hydrate an equal volume of alcohol, and evaporating the mixture over quicklime until most of the water is removed. This *alcosol*, on being submitted to prolonged ebullition, yields a jelly or *alcogel* corresponding to that produced on heating the hydrate—in the former case alcohol, and in the latter water, being associated with the mercuric ketone-compound. The hydrate, though neutral to test-paper, appears to be a weak acid, probably quadribasic.

Several ketones of the fatty series are capable of uniting with mercuric oxide in presence of alkali, to form compounds analogous to that obtained with acetone, but the hydrates or hydrosols of the mercuric compounds are very difficult to prepare, on account of the insolubility of the higher ketones in water (J. E. Reynolds, *Proc. Roy. Soc.* xix. 431).

Bromacetone. $\text{C}^3\text{H}^5\text{BrO}$.—Monobromacetone is readily formed by diluting acetone with 2–3 vols. of carbon sulphide, and adding a little less than the calculated quantity of bromine. After distilling off the carbon sulphide and excess of acetone, the product is left behind as a dark viscid mass. Freshly-precipitated silver oxide in presence of water converts it into a volatile liquid, having a sweet taste, and reducing alkaline solution of copper salts. This compound, which appears to be the alcohol of pyruvic acid, could not be obtained pure, as it seems to be decomposed by dehydrating bodies. Together with it, a smaller quantity of an acid, $\text{C}^2\text{H}^3\text{O}^2$, is formed, which in the free state forms a syrup having a sour and bitter taste, while the barium salt is a hard, amorphous mass (Emmerling, *Deut. Chem. Ges. Ber.* vi. 22).

Chloracetones.—Monochloracetone was first obtained by Riche, by the electrolysis of a mixture of acetone and hydrochloric acid. Borsche a. Fittig (*Ann. Ch. Pharm.* cxxviii. 111) denied the existence of this compound, because by passing chlorine into well-cooled acetone they obtained dichloracetone directly, without previous formation of the monochlorinated compound; they, therefore, regarded Riche's product as epichlorhydrin, which is isomeric with monochloracetone; this, however, was disproved by Linnemann (*ibid.* cxxiv. 170), who showed that the product in question, when reduced by nascent hydrogen, yields acetone. Kriwaxin (*Zeitschr. f. Chem.* [2] vii. 263), by heating acetone with chlorine, obtained no dichloracetone, but only monochloracetone and products of higher boiling point, apparently a mixture of acetone and monochloracetone. According to Glutz a. Fischer (*J. pr. Chem.* [2] iv. 52), the product obtained by the action of chlorine on perfectly dry acetone is a mixture of mono- and dichloracetone, the former predominating. C. Bischoff, in like manner, obtained a product which yielded by fractional distillation a liquid boiling at 110° – 125° and containing 39 p. c. chlorine: a portion of this boiling at 120° contained 43 p. c. chlorine; now monochloracetone contains 38·4 p. c. and dichloracetone 53·6 p. c. chlorine: hence it appears that the product obtained consisted chiefly of monochloracetone. Lastly, E. Mulder (*Deut. Chem. Ges. Ber.* v. 1007) finds that either mono- or dichloracetone may be obtained at pleasure according to the proportion of chlorine used. To prepare monochloracetone he passes a small quantity of chlorine through acetone, washes the product with a little water, distils it over a mixture of calcium chloride and marble (the latter to saturate the free hydrochloric acid formed); subjects the liquid which passes over between 100° and 140° to fractional distillation, and thereby obtains a liquid which boils at about 119° and contains 39·3 p. c. carbon and 5·9 hydrogen, the formula $\text{C}^3\text{H}^5\text{ClO}$ requiring 38·9 carbon and 5·4 hydrogen.

Monochloracetone, $\text{CH}_3\text{—CO—CH}_2\text{Cl}$, is also easily produced by the action of strong sulphuric acid on epidichlorhydrin, $\text{OH}^2\text{Cl—CCl—CH}_2^2$ (L. Henry, *Deut. Chem. Ges. Ber.* v. 966), and by the action of hypochlorous acid on acetone (Mulder),

Monochloroacetone, heated with potassium acetate and alcohol, is converted into the corresponding acetyl-compound, mono-acetyl-acetone, $\text{CH}_3\text{—CO—CH}^2(\text{OC}^2\text{H}_5\text{O})$, a limpid liquid boiling at 175° and having a refreshing smell and bitter taste. When recently prepared it is neutral, but in contact with moist air or water, in which it is readily soluble, it soon requires an acid reaction. The replacement of the acetyl in this compound by hydrogen would give the alcohol $\text{CH}_3\text{—CO—CH}^2\text{OH}$, corresponding with pyruvic acid; but this transformation has not yet been effected (Henry).

Monochloroacetone is converted by *fuming nitric acid* into a compound $\text{C}^2\text{H}^4\text{Cl}(\text{NO}^2)\text{O}$, which crystallises readily from water-alcohol and ether;—by *alcoholic ammonia* into sal-ammoniac and an oil having the odour of naphthylamine;—by *alcoholic potassium cyanide* into cyanacetone, $\text{C}^2\text{H}^2(\text{CN})\text{O}$;—with the neutral sulphates of the alkali-metals it yields metallic chlorides and acetone-sulphonic acid (Glutz, *J. pr. Chem.* [2] i. 14).

The reactions of monochloroacetone with *hydrocyanic acid* will be described further on.

Dichloroacetone, $\text{C}^2\text{H}^2\text{Cl}_2\text{O}$.—Of this compound there are two modifications, one symmetrical in structure, the other unsymmetrical, viz.:

The symmetrical modification is obtained by oxidising dichlorhydrin, $\text{CH}_2\text{Cl—CHOH—CH}_2\text{Cl}$, with chromic acid mixture. It boils at $170^\circ\text{—}171^\circ$, forms well-crystallised compounds with acid sodium sulphite, potassium iodide, and potassium sulphocyanate; treated in ethereal solution with powdered potassium cyanide, it is converted into a compound having the composition $\text{C}^2\text{H}^2\text{Cl}_2\text{NO}^2$ (Glutz a. Fischer, *J. pr. Chem.* [2] iv. 52; *Chem. Soc. J.* [2] ix. 922).

The unsymmetrical modification is obtained by passing chlorine into acetone till it is saturated, the liquid being heated in the water-bath towards the end of the operation (Fittig;—Glutz a. Fischer).—E. Mulder, (*Deut. Chem. Ges. Ber.* v. 1007), passes chlorine in excess into acetone at ordinary temperatures, washes the product with water, distils it over a mixture of chloride and carbonate of calcium, and, finally, by fractional distillation, obtains a product which boils at 120° and contains 55.5 p.c. chlorine, the formula $\text{C}^2\text{H}^2\text{Cl}_2\text{O}$ requiring 55.9.

Dichloroacetone heated with *potassium hydrate* yields a glucose-like body, $\text{C}^2\text{H}^2\text{O}^3$, similar to that produced by the action of water on sulphacetate of lead, together with a brown substance, which forms with lead acetate the compound $\text{Pb}(\text{C}^2\text{H}^2\text{O}^3)_2$. The formation of these two bodies is represented by the equations:

and:

Similar products are obtained by the action of potassium sulphhydrate on dichloroacetone.

With solid potassium cyanide the unsymmetrical dichloroacetone yields a product isomeric with that which is obtained from the symmetrical modification (Mulder, *Deut. Chem. Ges. Ber.* v. 1007).

Dichloroacetone, heated with excess of water to 200° for six hours, yields a large quantity of lactic acid (Linnemann a. v. Zotta, *Ann. Ch. Pharm.* clix. 247).

Dichlorodibromacetone, $\text{C}^2\text{H}^2\text{Cl}_2\text{Br}_2\text{O}$, is formed, together with the compound $\text{C}^2\text{H}^2\text{BrCl}_2\text{O}$ (not obtained pure), by the action of bromine or dichlorhydrin. With water cooled nearly to 0° it forms, with considerable rise of temperature, a crystalline hydrate, $\text{C}^2\text{H}^2\text{Cl}_2\text{Br}_2\text{O} + 4\text{H}^2\text{O}$, which may be purified by pressure and recrystallisation from water and alcohol; from its alcoholic solution it is separated by water in dazzling white crystalline scales, or sometimes in larger crystals. It gives off its water of crystallisation when left over oil of vitriol, or when fused; in the latter case two layers of liquid are formed at $49^\circ\text{—}50.5^\circ$.

Anhydrous dichlorodibromacetone is a colourless heavy liquid, which does not solidify at 10° , gives off vapours which attack the eyes strongly, and is decomposed by distillation. By exposure to the air it is reconverted into the hydrate. It is decomposed by water, alcohol, and alkalis, with formation of similar products of decomposition. With alcohol at 160° the products are—besides chloride and bromide of ethyl—formic and glycolic acids, together with traces of carbonic acid, acetic acid, and an oily chlorinated body. With barium hydrate, formate and glycolate are obtained, together with larger quantities of carbonate and acetate. Oxalic acid is also formed, especially in strong solutions, together with an amorphous substance which interferes with the crystallisation of the glycolate. With hydriodic acid, dichlorodibromacetone appears to yield dichlorhydrin (Carius, *Deut. Chem. Ges. Ber.* iii. 393; *Zeitschr. f. Chem.* [2] vi. 533).

When dichlorodibromacetone is acted upon by zinc and dilute sulphuric acid, and heated from time to time to a temperature not exceeding 40°, a slow reaction is set up, which lasts for several weeks, the product consisting of acetone and a brominated compound (probably isopropyl bromide), not separable by distillation (Lange, *Deut. Chem. Ges. Ber.* vi. 98).

Cyanogen-derivatives of Acetone. (Urech, *Ann. Ch. Pharm.* clxiv. 255).

1. *Acetone-cyanhydrin*, $C^3H^5NO = C^3H^4O.CNH$.—This compound is formed by direct combination when dry hydrogen cyanide is passed into cooled acetone, and passes over for the most part at 120°, when the product, after remaining for some time, is distilled:

Acetone-cyanhydrin is a very unstable compound, the addition of silver nitrate giving rise to the formation of silver cyanide and the liberation of acetone. By allowing a portion of the acetone which had been saturated with hydrocyanic acid to remain for some months, heating it in a sealed tube to 100°, and allowing the more volatile portions to evaporate spontaneously, a yellow syrup was obtained which yielded ammonia and acetic acid, $C^2H^4O^2$, when boiled with a dilute mineral acid; when, however, the heating in a sealed tube was much prolonged, a brown mass was obtained which no longer yielded acetic acid. The action of alkalis on it gave rise to ammonia, together with a small quantity of a substance crystallising from water in efflorescent prisms.

Acetic acid is more readily produced by the action of nascent hydrocyanic acid on acetone, as when slightly moist potassium is covered with acetone, and hydrochloric acid is added in excess in aqueous solution, or passed into the liquid in the state of gas. On exhausting the resulting brown mass with ether, evaporating the ethereal solution, dissolving the residue in water, and neutralising with zinc carbonate, an abundant crop of zinc acetate is obtained:

When, however, for each molecule of potassium cyanide present, only one molecule of hydrochloric acid is added, the ethereal solution of the product deposits on evaporation a crystalline substance which is not acid, and has the composition $C^3H^4NO^2$.

Diacetone-cyanhydrin, the product thus obtained, is easily soluble in water, alcohol, and ether, and crystallises from these solvents in thick shining anhydrous prisms. It melts between 135° and 162°, and sublimos below its melting point in long, colourless needles. It is decomposed at the ordinary temperature by hydrochloric acid into ammonium chloride, acetone, and acetic acid.

If the products of this reaction be distilled, a distillate is obtained consisting principally of acetone; and when this distillate is treated with quicklime to remove free acid and water, and the acetone separated by distillation, a residue is left containing a body which crystallises in prisms, and contains the elements of calcium chloride with two molecules of monacetonecyanhydrin, $CaCl^2.2C^3H^4NO$.

An attempt to form this substance by the addition of calcium chloride to the ethereal solution of the crude product obtained by the action of hydrochloric acid on acetone and potassium cyanide, led to the formation of a compound of diacetonecyanhydrin and calcium chloride, $CaCl^2.C^3H^4NO^2 + 5H^2O$, which separated from its

etheral solution in large crystals. When dried at 100° it contains $\text{CaCl}_2 \cdot \text{C}^2\text{H}^3\text{NO}^2 + \text{H}^2\text{O}$.

Acetone-cyanhydrin is regarded by Urech as analogous to Völkol's hydrocyanate of benzoyl hydride, $\text{C}^7\text{H}^5\text{O} \cdot \text{CNH}$ (i. 570), and the splitting up of diacetone-cyanhydrin under the influence of hydrochloric acid is analogous to that of amygdalin when subjected to the action of the same reagent.

$\begin{array}{c} \text{CH}^2\text{Cl} \\ | \\ \text{HO}-\text{C}-\text{CN} \\ | \\ \text{CH}^3 \end{array}$

Monochloracetone-cyanhydrin, is formed by gently heating monochlor-

acetone with strong hydrocyanic acid and alcohol for 24 hours, and remains, on evaporation, as a thin oily liquid, which, when heated with hydrochloric acid, yields ammonium chloride and monochloracetic acid, $\text{Cl}(\text{CH}^2\text{Cl})(\text{CO} \cdot \text{OH})(\text{OH} \cdot \text{CH}^3)$, crystallising in prisms, which have a pure sour taste (Bischoff).

Tetrachloro-diacetone-cyanhydrin, $\text{C}^4\text{H}^2\text{Cl}_4\text{NO}^2$.—Bodies having this composition are obtained by the action of potassium cyanide on the two modifications of dichloracetone. The unsymmetrical dichloracetone treated with aqueous potassium cyanide yields a compound crystallisable from water; the symmetrical dichloracetone treated in the same manner yields only a brown tarry liquid, which quickly turns black; but an etheral solution of this dichloracetone treated with pulverised potassium cyanide yields a body crystallisable from alcohol, and isomeric with that which is obtained from the unsymmetrical dichloracetone. The two modifications of tetrachloro-diacetone-cyanhydrin thus obtained are represented by the following formula:—

From symmetrical dichloracetone.

From unsymmetrical dichloracetone.

each being formed by the reaction:

(Glutz a. Fischer, *J. pr. Chem.* [2] iv. 52).

ACETONE-SULPHONIC ACID, $\text{C}^3\text{H}^3\text{SO}^4 = \text{CO} \begin{Bmatrix} \text{CH}^3 \\ \text{CH}^2(\text{SO}^2\text{H}) \end{Bmatrix}$. (Bender, *Zeitschr. f. Chem.* [2] vi. 162; *Deut. Chem. Ges. Ber.* iv. 517).—An acid produced by the action of alkaline sulphites on dichloracetone. When 1 mol. dichloracetone is mixed with a concentrated solution of 2 mol. neutral potassium sulphite, the liquid becomes hot, and the oily layer floating on the top quickly disappears. On evaporating to dryness over the water-bath, and treating the residue with boiling alcohol, potassium acetone-sulphonate, $\text{C}^3\text{H}^3\text{KSO}^4$, dissolves, while neutral potassium sulphate remains behind. The reaction takes place by two stages, thus:

and

The dichloracetone used in this reaction was probably the unsymmetrical modification $\text{CO} \begin{Bmatrix} \text{CH}^3 \\ \text{CHCl}_2 \end{Bmatrix}$, since the symmetrical dichloracetone $\text{CO} \begin{Bmatrix} \text{CH}^2\text{Cl} \\ \text{CH}^2\text{Cl} \end{Bmatrix}$ would rather have yielded acetone-disulphonic acid.

The potassium salt separates from its alcoholic solution on cooling in white laminae, very soluble in water. Decomposed with an equivalent quantity of dilute sulphuric acid, it yields acetone-sulphonic acid, which may be extracted with alcohol and purified by neutralising it with lead carbonate and decomposing the resulting lead salt with hydrogen-sulphide: it then forms a colourless uncrystallisable syrup. The barium salt, $(\text{CH}^3 \cdot \text{CO} \cdot \text{CH}^2\text{SO}^2)^2\text{Ba} + \text{aq.}$, crystallises in colourless glistening scales, which give off part of their water over sulphuric acid, the whole at 100° . The cupric salt, $3(\text{CH}^3 \cdot \text{CO} \cdot \text{CH}^2\text{SO}^2)^2\text{Cu} + \text{aq.}$, forms blue-green scales, very soluble, and having an acid reaction. The lead salt, $(\text{CH}^3 \cdot \text{CO} \cdot \text{CH}^2\text{SO}^2)^2\text{Pb} + \text{aq.}$, crystallises in colourless scales, also very soluble, and having an acid reaction; it melts at 140° and decomposes completely at 170° .

When a dry mixture of potassium acetone-sulphonate and potassium cyanide is heated, a crystalline body sublimes, which is insoluble in alcohol and ether, but soluble in water. This body is a cyanide, $\text{CH}^3-\text{CO}-\text{CH}^2-\text{CN}$, which may be expected to yield an acid, $\text{CH}^3-\text{CO}-\text{CH}^2-\text{COOH}$, homologous with pyruvic acid.

Acetonyl-urea, heated with hydrochloric acid to 150° – 160° , splits up into carbonic anhydride, sal-ammoniac, and α -amido-isobutyric acid—

The α -amido-isobutyric acid thus obtained exhibits the characteristic properties of the glycoicines. Its copper salt, $\text{Cu}(\text{C}^{\circ}\text{H}^{\circ}\text{NO}^{\circ})_2$, forms violet-blue crystals, easily soluble in water. The silver salt, $\text{AgC}^{\circ}\text{H}^{\circ}\text{NO}^{\circ}$, crystallises in silky needles soluble in water.

By evaporating to dryness the product of the action of hydrochloric acid on acetonyl-urea and exhausting the residue with spirit, a hydrochloride of α -amido-isobutyric acid, $\text{C}^{\circ}\text{H}^{\circ}\text{NO}^{\circ}\text{HCl} + \text{H}^{\circ}\text{O}$, is obtained. It crystallises in short, colourless prisms, exhibits a strong acid reaction, is very soluble in water, moderately soluble in alcohol, and insoluble in ether. When its solution is evaporated with platinum chloride, crystalline masses are deposited corresponding with alanine platinochloride. When it is treated with solution of potassium nitrite, acetic acid is formed, nitrogen being set free at the same time.

Synthesis of Acetonyl-urea from the Products of its Decomposition.—When an aqueous solution of sulphate of alaphamidoisobutyric acid is evaporated with potassium cyanate, a residue is obtained, which, by exhaustion with alcohol, evaporation, and treatment with sulphuric acid, yields acetonyluramic acid, or alpha-uramidoisobutyric acid.

This compound is moderately soluble in hot water and alcohol, but insoluble in ether. It melts and gives off water at 160° . Its silver salt, $\text{C}^{\circ}\text{H}^{\circ}\text{AgN}^{\circ}\text{O}^{\circ}$, forms tufts of needles slightly soluble in water.

Acetonyluramic acid, heated for a long time to 130° – 140° , evolves water and yields acetonyl-urea:

ACETOPHENONE. $\text{CO} \begin{Bmatrix} \text{C}^{\circ}\text{H}^{\circ} \\ \text{CH}^{\circ} \end{Bmatrix}$. See PHENYL-METHYL KETONE.

ACETOPIPERIDINE. See PIPERIDINE.

ACETOSACCHAROSE. See SUGAR.

ACETOTOLUIDE.

ACETOTOLUIDINE. } See TOLUIDINE.

ACETYL. *Acetyl Chloride*, $\text{C}^{\circ}\text{H}^{\circ}\text{OCl}$, is one of the products of the action of chlorine on aldehyde (Wurtz, p. 35).

This compound is not decomposed, or but very slightly, by the action of heat alone; on heating it in sealed tubes for a long time to nearly 30° it gave only a trace of hydrochloric acid and a brown substance (Berthelot, *Bull. Soc. Chim.* [2] xvii. 391).

Acetyl chloride heated for several hours with excess of phosphorus pentachloride, is converted into carbon trichloride or hexachlorethane, $\text{C}^{\circ}\text{Cl}^{\circ}$ (Hübner a. Müller, *Zeitschr. f. Chem.* vi. 328).

Bromacetyl bromide, $\text{C}^{\circ}\text{H}^{\circ}\text{BrO.Br}$, treated with zinc-methyl, yields an alcohol—probably $\text{C}^{\circ}\text{H}^{\circ}\text{O}$ —which boils at 110° – 112° , and when oxidised with chromic acid mixture, forms acetic acid and a small quantity of acetone (Shdanow, *Deut. Chem. Ges. Ber.* vi. 479). With zinc-ethyl, the same compound yields a decyl alcohol, boiling at 155° – 157° (Anitow, *ibid.*).

Trichloroacetyl compounds.—The chloride $C^2Cl^4O.Cl$ is easily obtained by the action of phosphorus trichloride on trichloroacetic acid; after rectification it boils regularly at 118° . Phosphorus pentachloride acts in a similar manner, but with formation of oxychloride, which is difficult to separate: hence it is better to use the trichloride. Trichloroacetyl chloride is converted by water into trichloroacetic and hydrochloric acids; by alcohol into ethyl trichloroacetate.

Trichloroacetyl bromide, $C^2Cl^3O.Br$, is obtained in like manner by the action of phosphorus tribromide on trichloroacetic acid, as a liquid boiling at about 143° ; its reactions are similar to those of the chloride.

Trichloroacetyl iodide is more difficult to prepare. Trichloroacetic acid treated with phosphorus tri-iodide yields a small quantity of a liquid boiling at about 180° , and decomposed by water and by alcohol; but its composition has not been satisfactorily made out (H. Gal, *Compt. rend.* lxxvi. 1019).

ACETYLENE. C^2H^2 .—This hydrocarbon is formed by heating isethionic acid with potassium hydrate:

(Berthelot, *Compt. rend.* lxxix. 563).

Acetylene is readily oxidised by aqueous chromic acid, yielding acetic acid if the solution is dilute, formic acid and carbonic acid if it is concentrated (Berthelot). See ACETIC ACID (p. 4).

Acetylene passed together with *phosgene-gas* through a red-hot tube, is partly polymerised to benzene, &c., but does not yield any chlorinated organic compound (Berthelot, *Bull. Soc. Chim.* [2] xiii. 9).

On the reaction of acetylene with *aceto-hypochlorous oxide*, see page 11.

On the constitution of acetylene, see Carstanjon (*J. pr. Chem.* [2] iv. 419; *Chem. Soc. J.* [2] x. 231).

Bromacetylene, C^2HBr , is given off abundantly when dibromethylene, $C^2H^2Br^2$, is heated with alcoholic potash in an open vessel; but if the reaction takes place in a sealed tube, the bromine alone is abstracted and acetylene is produced (Fontaine, *Compt. rend.* lxx. 1361). Bromacetylene is likewise evolved when monobromethylene bromide, $C^2H^2Br.Br^2$, is added by drops to solid sodium ethylate (Alexejeff, *Zeitschr. f. Chem.* vi. 644).

Bromacetylene takes fire at ordinary temperatures in contact with the air, but if it be mixed with a considerable quantity of any indifferent gas, it merely becomes strongly heated on coming in contact with air, and forms white vapours of bromoacetic acid: $C^2HBr + H^2O + O = C^2H^2BrO^2$. This slow oxidation is favoured by sunshine, and does not take place in the dark; it is accompanied by a very perceptible odour of ozone (Fontaine, *Compt. rend.* lxx. 1361). Bromoacetic acid is also formed when an alcoholic solution of bromacetylene is exposed to the air (Glückner, *Ann. Ch. Pharm.* Suppl. vii. 197).

Dibromobromide of Acetylene, $C^2H^2.2HBr$, is formed by the prolonged action of hydrobromic acid on acetylene. It has the same boiling point as the isomeric hydrobromide of bromethylene, $C^2H^2Br.BrHBr$ (Reboul, *Compt. rend.* lxxiv. 941).

CHLORIDES OF ACETYLENE (Berthelot a. Jungfleisch, *Ann. Ch. Phys.* [4] xxvi. 472). When dry acetylene is passed into antimony pentachloride, it is absorbed with considerable evolution of heat. If care has been taken to prevent the temperature from rising too high, the saturated liquid deposits, on cooling, magnificent plates consisting of a compound of acetylene and antimony perchloride, $C^2H^2SbCl^3$. This compound is immediately decomposed by water, and when it is heated by itself, an action takes place, resulting in the formation of antimony trichloride and *acetylene dichloride*:

If, however, a solution of the crystals in antimony pentachloride be heated, a more violent action takes place, giving rise to the formation of antimony trichloride and *acetylene tetrachloride*:

In practice both chlorides are produced at the same time, by heating the crude compound $C^2H^2SbCl^3$ mixed with a certain proportion of antimony pentachloride, distilling, washing with water, and separating the chlorides by fractionation.

Acetylene dichloride, $C^2H^2Cl^2$, is a colourless limpid liquid, having an odour like that of chloroform, and boiling at about 55° . Water acts slowly on it at 180° , with formation of hydrochloric acid and condensed products. With potassium hydrate it forms acetic acid, and when heated to 360° in a sealed tube, it is entirely resolved into carbon and hydrochloric acid.

Acetylene tetrachloride, $C^2H^2Cl^4$, is a colourless liquid, smelling and tasting like chloroform, and boiling at about 147° . Water at 180° slowly decomposes it, with formation of hydrochloric acid. Chlorine converts it into carbon trichloride. Alcoholic potash converts it into glycollic acid: $C^2H^2Cl^4 + 3H^2O = 4HCl + C^2H^2O^2$; but if the action be carefully regulated, the potash simply removes a molecule of HCl , leaving *chloracetylene dichloride*, $C^2HCl_2Cl^2$, a colourless liquid boiling at 88° . This last reaction also takes place when the tetrachloride is merely heated in a sealed tube to 300° for fifteen hours; and if the action be prolonged and the temperature raised to 360° , another molecule of HCl is removed; the product actually obtained consists, however, not of the residual dichloroacetylene C^2Cl^2 , but of its polymeride, *Julin's carbon chloride*, or *hexachlorobenzene*, C^6Cl^6 ; three molecules of acetylene tetrachloride taking part in the reaction: $3C^2H^2Cl^4 = 6HCl + C^6Cl^6$. This corresponds with the formation of benzene by polymerisation of acetylene, and explains the frequent formula of *Julin's chloride* in the destructive distillation of chlorinated organic compounds.

ACHILLEA. The Iva plant (*Achillea moschata*) has been chemically examined by A. v. Planta-Reichenau (*Ann. Ch. Pharm.* clv. 145).

Iva oil.—The herb separated from the root yields, by distillation with steam, a bluish-green volatile oil, having a peculiar, not unpleasant odour, and tasting like peppermint-oil. On distillation it begins to boil at 170° ; the greater part passes over between 180° and 210° ; a very small quantity of yellow liquid between 210° and 230° ; a brown distillate, smelling like wormwood, between 230° and 260° ; and there remains a dark brown viscid, no longer bitter residue, which decomposes when heated above 200° , is not soluble in absolute alcohol, even when heated, but dissolves partially in ether and in turpentine-oil, leaving a carbonaceous residue.

Ivaol, $C^{12}H^{20}O$, or $C^2H^4O^2$.—This name is given to the portion of the distillate which passes over between 170° and 210° . It is a clear, faintly-yellowish liquid, having an extremely fragrant, strongly ethereal odour, which is very persistent, and perceptible a long way off. The liquid has a bitter, heating taste like that of peppermint-oil. Very small quantities dissolved in alcohol impart to that liquid the same powerful odour and agreeably bitter taste.

The fraction of the original oil which distills between 230° and 260° has nearly the composition of *ivaol*. The resin has the composition $C^{14}H^{26}O$.

Ivain, $C^4H^2O^3$.—This is a bitter substance contained in the alcoholic extract of the plant previously exhausted with water, together with stearic acid, which separates on cooling from the residue left after distilling off the alcohol. To prepare *ivain*, the dark green filtered liquid is warmed in the water-bath, with excess of alcoholic solution of neutral lead acetate; the resulting precipitate is separated by filtration; the somewhat concentrated filtrate is freed from lead by sulphuretted hydrogen, and from alcohol by evaporation over the water-bath; the residue is repeatedly treated with acetic acid (which extracts the nitrogenous principles to be hereafter mentioned) till the decanted acid remains colourless; then repeatedly washed with water till this liquid also runs from the tap-funnel colourless and no longer bitter, and the oily unctuous mass, which at first was heavier than water, floats on the top of it; this mass is repeatedly treated with absolute alcohol, and evaporated till the acetic acid is completely removed; and the alcoholic solution is finally treated with animal charcoal.

Ivain is a somewhat dark-coloured mass of the consistence of turpentine, which does not solidify at 17° , dissolves in alcohol, but not in water; the alcoholic solution is extremely bitter. Its composition, determined by analysis, is $C^4H^{10}O$; if this formula be tripled, the compound may be regarded as a hydrate of *ivaol*:

Nitrogenous principles of Iva.—The aqueous extract of the plant contains two nitrogenous bodies, *achillein* and *moschatin*. To prepare them, the aqueous extract is repeatedly treated with absolute alcohol, as long as that liquid becomes coloured and acquires a bitter taste. The great bulk of the aqueous extract consists of a gummy light brown mass, which is insoluble in absolute alcohol, and becomes more pulverulent the more it is freed from *achillein* and *moschatin*. The brown alcoholic solution is completely freed from alcohol by distillation, and distilled water is added to the residue in successive portions and with frequent agitation. The liquid becomes turbid from separation of *moschatin*, which at first redissolves in the aqueous solution of *achillein*, but, on further addition of water, separates in flocks, which must be washed with water. The filtrate contains the *achillein*, also a little *moschatin*, and several acids not yet investigated; these may be removed by digestion for several days in the cold with successive portions of lead-hydrate. The filtrate, freed from lead by sulphuretted hydrogen, is evaporated in the water-bath in small portions, and with brisk stirring; the residue is dissolved in absolute alcohol, to remove traces

of a gummy substance; the solution again evaporated; and the residue redissolved in water to separate the moschatin. The residue obtained after another evaporation is regarded as pure achillein, if samples of the brittle mass dissolve completely in absolute alcohol and in water.

Achillein is a brittle, glassy, brown-red substance, which melts without decomposition at 100° , absorbs moisture very quickly from the air, dissolves readily, with wine-yellow colour, in water, less easily in absolute alcohol, and is insoluble in ether; it has an alkaline reaction, a peculiar odour, and a strongly bitter but not unpleasant taste. When dried at 100° it has the composition $C^{22}H^{28}N^2O^{12}$. It appears to be identical with the achillein obtained from *Achillea millefolium* by Zanon (i. 36), who, however, did not obtain it pure, and gave no analysis of it. When boiled continuously with strong potash-solution it gives off alkaline vapours having a peculiar odour. Chlorine-water decolorises achillein; lannic acid and ferrous sulphate have no action upon it. Ammonia dissolves it, and the solution, if exposed to the air till it no longer smells of ammonia, deposits a flocculent mass less soluble than achillein itself. Achillein is not precipitated by neutral or by basic acetate of lead. When boiled for several days with dilute sulphuric acid, or even with the acids which accompany it in the plant, it yields achilletin, $C^{11}H^{12}NO^4$, which separates as a dark brown powder; also sugar; a volatile product having a powerful aromatic odour; and apparently also ammonia. Achilletin is insoluble in water, very slightly soluble in alcohol; the alcoholic solution has an aromatic odour, but does not taste bitter.

Moschatin, obtained as above, may be purified by dissolving it in absolute alcohol, evaporating to dryness in the water-bath, warming the residue with water, and finally washing it with cold water till the mass can be pulverised under water. It then has the composition $C^{24}H^{26}NO^7$. It melts under water at the heat of the water-bath, and separates again in the pulverulent form on cooling; dissolves more easily in liquids containing achillein. It is somewhat more soluble in absolute alcohol than achillein, and has a more aromatically bitter taste.

The ash of the Iva plant contains, as constituents soluble in water: alkaline carbonates and chlorides, small quantities of sulphuric acid and lime, and traces of magnesia. The portion insoluble in water, but soluble in nitric acid, contains large quantities of carbonic acid and lime, together with phosphoric acid and a little magnesia. The insoluble residue consists of silica and charcoals.

ACIAMIDES. (Anna Wolkow. *Zeitschr. f. Chem.* [2] vi. 577; vii. 422; *Deut. Chem. Ges. Ber.* v. 139; *Chem. Soc. J.* [2] x. 147, 413).—This term is applied to certain bodies which, though formed on the ammonia type, yet possess acid characters, such as the products obtained by the action of benzoyl chloride on sulphotoluenamide, sulphonylenamide, sulphocymenamide, and sulphonaphthalenamide.

The amides, $N(C^6H^4SO^2)H^2$, produced by the action of ammonia on para- and meta-toluenesulphonic acids, are not decomposed by boiling potash-ley like amides in general, but yield crystalline compounds in which one hydrogen-atom of the amide is replaced by potassium. These metallic derivatives are extremely unstable, being decomposed even by carbonic acid, like the metallic derivatives of the alcohols and phenols, their ammoniacal hydrogen not having acquired acid characters under the influence of the acid radicle $C^6H^4SO^2$. But by treating these amides with the chloride of an acid radicle, such as benzoyl chloride, products are obtained having an acid reaction, and dissolving in ammonia, also in alkaline carbonates, with evolution of carbonic anhydride. Their formation may be illustrated by the following example:—

By the action of phosphorus pentachloride, these amides are transformed into chlorinated amides by substitution of Cl for OH, *e. g.*:—

For descriptions of the individual compounds, see Sulphotoluenamide, &c.

ACIDS. On the thermal effects of the combination of acids with bases, see **HEAT.**

ACONIC ACID, $C^3H^4O^4$.—This acid, originally obtained by Kekulé, by the action of alkalis on dibromopyrotartaric acid:

has been further examined by F. Moilly (*Deut. Chem. Ges. Ber.* vi. 242). It is very soluble in water, ether, and alcohol, and crystallises from the alcoholic solution in foliate groups of shining needles, melting at 151° .

From the mode of formation of aconic acid, it might be expected to be bibasic; but the constitution of its salts, $M^+C^3H^3O^4$ and $M^+(C^3H^3O^4)^2$, shows that it is really monobasic, like its homologue, muconic acid; and this conclusion is confirmed by direct titration of the acid with caustic soda.

The aconates are easily prepared by digesting the corresponding carbonates with aqueous aconic acid. They mostly crystallise well, and dissolve very easily in water, excepting the silver salt, which is but sparingly soluble; a solution of sodium aconate is not precipitated by the salts of the earth-metals, or heavy metals. The *sodium salt*, $NaC^3H^3O^4 + 3aq.$, forms shining plates, or, by slow evaporation, well-defined crystals, which effloresce over oil of vitriol. The *silver salt*, $Ag C^3H^3O^4$, crystallises on cooling from a hot solution in small shining laminae. The *barium salt*, $Ba(C^3H^3O^4)^2$, is very soluble in water, is precipitated from the aqueous solution by alcohol, and crystallises from hot alcohol in slender needles. It shrinks together strongly in drying, and gives off about $2\frac{1}{2}$ mol. water at 150° . The *copper salt*, $Cu(C^3H^3O^4)^2 + 4aq.$, crystallises in shining blue prisms, which give off their water with difficulty, acquiring at the same time a dirty green colour. The *zinc salt*, $Zn(C^3H^3O^4)^2 + 8aq.$, crystallises in large measurable crystals with strongly shining faces, melts below 100° in its water of crystallisation, and then swells up strongly in drying. *Methyl aconate*, $CH^3.C^3H^3O^4$, is formed by treating the silver salt with methyl iodide, the action, which begins in the cold, being completed by heating the mixture to 100° in a sealed tube. The resulting methyl aconate is dissolved out by ether, and crystallises from the residue of the ethereal solution in long needles melting at 85° , easily soluble in ether, moderately in alcohol, sparingly in water.

Aconic acid boiled for some hours with baryta-water is resolved into formic and succinic acids, with intermediate formation of a body having the composition of oxyitaconic acid, $C^3H^4O^5$:

This decomposition of aconic acid is similar to that of its homologue, muconic acid, under the same circumstances; the latter, when boiled with baryta-water, being converted into succinic and acetic acids.

The formation of aconic acid from dibromo-pyrotartaric acid, its monobasicity, and its decomposition under the influence of baryta-water may perhaps be represented as follows:

The constitutional formula here assigned to aconic acid represents it, on the one hand, as a monobasic acid; on the other, as an anhydrido analogous to lactide. A similar constitution has been assigned by Dolbrück to muconic acid (*q.v.*)

ACONITE ALKALOIDS.—1. *Aconitine*.—This name appears to have been hitherto applied to several substances differing in their physical properties and physiological action. Schrott (*Schweiz. Pharm. Wochenschrift*, 1865, 205 and 213) dis-

tinguished an acrid and a narcotic principle in aconites, the former existing, with little or none of the latter, in the *Aconitum ferox* of Nepal, whereas all the European aconites contain more or less of the narcotic principle, the acrid principle being, however, greatly predominant in *Aconitum Napellus*. The narcotic principle of aconite has been shown by T. and H. Smith to be identical with narcotine (formerly called *Aconelline* (see 1st Suppl. p. 54). But even the acrid alkaloid, the aconitine, does not appear to be always the same when obtained from different sources. According to Schreiff, from 8 to 10 milligrams of English aconitine (said to have been prepared by Morson from *Aconitum ferox*) killed a rabbit in six minutes, whereas 400 milligrams of a German aconitine had previously been given to the same rabbit without killing it, and with production of different morbid symptoms.

According to Hübschmann (*Arch. Pharm.* cxxxv. 266), Swiss aconitine (prepared by Geiger's process, in the same way as atropine from belladonna root, i. 474) is a white amorphous, somewhat coarse-grained powder, which does not adhere to paper, and has a strongly bitter, but scarcely burning taste. It becomes soft and plastic in boiling water, and hardens to a brittle substance on cooling; dissolves in 2 parts of ether, 2·6 of chloroform, and 4·25 of alcohol, these solvents leaving it on evaporation as an amorphous mass having a vitreous lustre. Cold benzene unites it into resinous drops and slowly dissolves it; on heating the liquid, it dissolves quickly, and does not separate on cooling. English aconitine, on the other hand, is a fine dirty white powder, which adheres very strongly to paper, and has a burning, but not bitter taste. When immersed in boiling water, it remains pulverulent and does not melt. It requires for solution more than 109 parts of boiling ether, which, moreover, leaves a brown substance undissolved: the solution deposits small white crystals. One part of this aconitine dissolves in 230 parts of chloroform and 20 parts of boiling alcohol, from which solution it likewise crystallises. Cold benzene colours it dark and leaves it in the state of powder; on heating the liquid, the aconitine dissolves and separates on cooling, partly in crystals, partly in the state of powder.

The term 'crystallised aconitine' is applied by Duquesnel (*Compt. rend.* lxxiii. 207) to the active principle of *Aconitum Napellus*, prepared as follows:—

Selected roots are pulverised and mixed with $\frac{1}{100}$ th part of tartaric acid, and the whole is exhausted with strong alcohol; the extract obtained is distilled out of contact with air, and at a temperature not exceeding 60°; and the residue is taken up with water to separate fatty and resinous bodies. The aqueous solution of impure aconitine tartrate thus obtained is treated with ether to remove colouring matters, precipitated by an alkaline bicarbonate, and again treated with ether, which dissolves the alkaloid; from this solution the base is obtained in crystals by evaporation, after addition of light petroleum oil, the crystals being colourless, rhombic or hexagonal tables.

Neither the alkaloid nor its salts with mineral acids are affected by a temperature of 100° or lower, either in the dry state or in contact with water; but at 100°, in contact with air and its own peculiar extractive liquor, it partly or wholly disappears. It is almost insoluble in water, but readily soluble in dilute acids, even in carbonic acid solution; it is not volatile at 100°, but at 130° it begins to decompose, and, apparently, to volatilise. It is soluble in ether, alcohol, benzene, and especially in chloroform; insoluble in glycerin and petroleum oils, both light and heavy. It rotates the plane of polarisation to the left, and is amorphous when obtained by precipitation of its salts by alkalis; in this condition it contains water of hydration, which is lost at 100°, without change of appearance; it has a feeble alkaline reaction.

Duquesnel finds in aconitine, prepared as above, 60·21 p.c. carbon, 7·44 hydrogen, 2·61 nitrogen, and 29·74 oxygen; whence he deduces the improbable formula $C^{27}H^{14}NO^{10}$.* He regards it as a glucoside, and considers that this view explains the spontaneous deterioration of various pharmaceutical preparations of aconite on keeping.

From experiments by Gréhaud and Duquesnel (*Compt. rend.* lxxiii. 209; *Chem. Soc. J.* [2] ix. 948), it appears that small doses of aconitine subcutaneously injected are analogous in their physiological effects to curarine, destroying the motor power of nerves.

2. Napelline.—This is an alkaloid obtained by Hübschmann (*N. Repert, Pharm.* vi. 421) from crude aconitine. The crude base is treated with the smallest quantity of ether that will suffice to dissolve out the aconitine; the filtered solution is precipitated with neutral lead acetate; excess of lead is thrown down by hydrogen sulphide; and the filtrate is evaporated to dryness with addition of potassium carbonate. The residue is then exhausted with absolute alcohol, and the alcoholic solution is decolorised with animal charcoal and evaporated to dryness.* Napelline thus obtained is a white electric powder, having a bitter, afterwards burning taste, and an alkaline

* According to v. Planta's analysis, aconitine contains 67·97 C., 8·79 H., 3·42 N. and 19·82 O., leading to the generally received formula $C^{27}H^{14}NO^{10}$ (i. 55).

reaction. It evolves nitrogenous vapours when burnt; neutralises acids completely; dissolves in water more easily than aconitine; and is therefore not precipitated from dilute solution by ammonia. It also dissolves more easily than aconitine in weak spirit, but less easily in ether.

3. *Acolyctine* and *Lycocotonine*.—These alkaloids, first obtained by Hübschmann from the root of wolfsbane (*Aconitum Lycocotum*, 1st Suppl. 55, 793), have been further examined by Schroff (*N. Report. Pharm.* xx. 611, 705), whose description of acolyctine agrees with that given by Hübschmann. Lycocotonine crystallises, according to Schroff, in white prisms and needles, having an intensely bitter taste, soluble in alcohol, chloroform, ether, benzene, amyl alcohol, petroleum spirit, oil of almonds, and oil of turpentine; only sparingly soluble in water (1 part in 800 at 17°); its aqueous solution gives, with bromine-water, a yellow precipitate of microscopic needles, and with potassium-mercuric iodide, a thick precipitate becoming crystalline on standing.

From a large number of physiological experiments made on men, rabbits, and frogs, it appears that the action of acolyctine and of lycocotonine is analogous to that of aconitine, and about one-third as energetic as that of napelline.

On the Alkaloids of Aconite, see also Flückiger, *Arch. Pharm.* [2] cxli. 196; *Jahresb.* 1870, 836.

ACORUS OIL. See OILS, VOLATILE.

ACRIDINE, $C^{12}H^9N$ (Gräbe & Caro, *Ann. Ch. Pharm.* clviii. 265).—A basic substance obtained from crude anthracene. When the semi-solid portion of coal-naphtha, which boils between 300° and 360°, is treated with dilute sulphuric acid, and the acid solution is precipitated with potassium dichromate, a dirty brown precipitate is obtained which dissolves on repeated treatment with boiling water; and the resulting solution, after filtration and cooling, yields orange-yellow crystals of acridine chromate. These, when freed from mother-liquor by washing, and heated with ammonia, yield the free base, which may be purified by converting it into hydrochloride, recrystallising, and again precipitating with ammonia.

Acridine crystallises in small, brownish-yellow, transparent, four-sided rectangular prisms of the rhombic system, often having their edges only narrowly truncated by the vertical prisms ∞P , and terminated by obtuse domes. This combination (fig. 1) is represented by the formula $\infty P \infty, \infty \bar{P} \infty, P \infty, \infty P$.

Fig. 1.

$$\begin{aligned} a &= \infty \bar{P} \infty \\ b &= \infty \bar{P} \infty \\ p &= \infty P \\ q &= \bar{P} \infty \end{aligned}$$

$$\text{Axes } a : b : c = 0.6556 : 1 : 0.3316.$$

Angles.	Calc.	Obs.
$\infty P : \infty P$	$= 113^{\circ}30'$	
$\infty P : \infty \bar{P} \infty$	$=$	$123^{\circ}15'$
$\bar{P} \infty : \bar{P} \infty$	$= 143^{\circ}0'$	$143^{\circ}5'$
$\bar{P} \infty : \infty \bar{P} \infty$	$=$	$108^{\circ}30'$

Acridine melts at 107°, distils without alteration at a temperature above 360°, and sublimes even below its melting point in large broad needles. Its vapour-density is by experiment 6.10, agreeing nearly with that required by the formula $C^{12}H^9N$: $\frac{12 \cdot 12 + 9 \cdot 1 + 14}{2} \times 0.0693 = 5.85$ (Gräbe, *Deut. Chem. Ges. Ber.* v. 15). It is

almost insoluble in cold, and but slightly soluble in boiling water; but dissolves readily in alcohol, ether, carbon bisulphide, and hydrocarbons. The dilute solutions show a beautiful blue colour by reflected light.

Acridine exerts a slight but distinct alkaline reaction on litmus. When inhaled, either in dust or in vapour, it causes sneezing, and, in a large quantity, coughing; the irritating action of the higher fractions of coal naphtha is probably attributable to acridine. It is exceedingly stable, not being altered by potassium hydrate, whether melted in an open vessel or heated to 280° with a small quantity of water, or by concentrated hydrochloric acid at the same temperature. It may be distilled unaltered,

* Krant (Gmelin's *Handbook*, xvii. 177) asks, 'What becomes of the potassium acetate?'

over either ignited zinc or soda-lime. It is equally unaffected by oxidising agents; readily attacked by sodium-amalgam. Potassium dichromate and sulphuric acid convert it into a brownish-red substance, which does not yield any crystalline body. Ethyl iodide simply adds itself on to acridine, but without effecting a substitution.

The salts of acridine crystallise readily, but are not very stable, splitting up partially or wholly when boiled with water; thus the acetate is completely decomposed when its aqueous solution is evaporated, and even the sulphate and hydrochloride are partially decomposed on boiling.

Acridine does not form a carbonate, and may be precipitated in the free state from solutions of its salts by sodium carbonate. There appear to be two series of salts, all of which are yellow. The composition of some of these salts, and that of hydroacridine (*infra*) might lead to the conclusion that the true formula of acridine is $C^{12}H^{10}N^2$, but the vapour-density shows that it is $C^{12}H^{11}N^2$.

The *hydrochloride*, $C^{12}H^{11}N^2.HCl + H^2O$, is formed by direct combination of acridine with hydrochloric acid, the latter being in excess, and crystallises from water on cooling in brownish-yellow prismatic crystals, often several inches long. It must be washed with dilute hydrochloric acid, as it readily gives up hydrochloric acid to water. It effloresces over sulphuric acid, and at the same time its brown-yellow colour becomes pure yellow; the effloresced salt still contains two molecules of water, from which it cannot be freed without loss of hydrochloric acid. It also loses acid by long standing in the exsiccator. It is readily soluble in water, but more easily in hot than in cold; its solubility is decreased by the presence of hydrochloric acid. In alcohol it dissolves but sparingly.

The *platinochloride*, $2(C^{12}H^{11}N^2.HCl).PtCl^4$, is precipitated from a solution of acridine in excess of hydrochloric acid by platinic chloride, as a yellow crystalline precipitate consisting of microscopic needles. It is scarcely soluble in water, and is gradually decomposed by boiling with water. The *aurochloride*, $C^{12}H^{11}N^2.HCl.AuCl^3$, is prepared in a similar manner. The *mercurochloride*, $2(C^{12}H^{11}N^2.HCl).HgCl^2$, is a yellow crystalline precipitate.

Acridine periodide, $2(C^{12}H^{11}N^2.HI).I^2$, is obtained as a brownish-red crystalline precipitate by adding an alcoholic solution of iodine to a solution of acridine hydriodide, and may be purified by repeated recrystallisation from hot alcohol. It forms brownish-red tables, which, by slow crystallisation, may be obtained very large, and then appear almost black. In powder it appears light brownish-red. It is easily soluble in hot alcohol, less so in cold. Water precipitates it from its alcoholic solution as a brown crystalline precipitate; the precipitate is slowly decomposed by boiling with water, iodine being liberated and acridine hydriodide passing into solution. The same decomposition is produced by treating the finely-powdered salt with a solution of sulphurous acid. A compound containing even more iodine appears to exist.

By heating acridine with *ethyl iodide*, two compounds are obtained, which, however, are difficult to purify, and have not yet been accurately examined.

The *nitrate* is readily soluble in water, and crystallises in yellow needles.

The *sulphate*, $2C^{12}H^{11}N^2.H^2SO^4 + H^2O$, precipitated from a boiling solution of acridine in dilute sulphuric acid on cooling (the sulphuric acid not being in great excess), forms golden-yellow needles; by slow crystallisation it is obtained in tolerably large prismatic crystals; they effloresce over sulphuric acid, but still retain one molecule of water of crystallisation, which is not given up till the temperature is raised to 90° or 100° , and then acridine sublimes. This salt is readily soluble in hot water, less so in cold, and very little soluble in alcohol. The *acid sulphate*, $4C^{12}H^{11}N^2.3H^2SO^4$, is precipitated by alcohol from a strong sulphuric acid solution of the base, in the form of yellow needles. It is readily soluble in water, and difficultly in alcohol; by recrystallisation from water it is converted into the neutral salt.

The *acid chromate*, $C^{12}H^{11}N^2.H^2CrO^4$, is the compound employed in obtaining acridine; its preparation has been already described. It is soluble in a large volume of boiling water, but nearly insoluble in cold water. By recrystallisation from water which does not contain an excess of potassium dichromate, a chromous compound is obtained. If the dry salt be heated, the base volatilises unaltered, leaving chromic oxide.

Nitro-acridines. Acridine warmed with nitric acid of sp. gr. about 1.45, is readily attacked, yielding, according to circumstances, mono- or di-substitution products, generally both together. These compounds are readily separated, as tetraniro-acridine does not unite with acids. On diluting with water, the dinitrated compound separates as an orange-red precipitate, while the mononitro-compounds, of which there are two, remain in solution; the last-mentioned bodies may be precipitated by ammonia, and separated by recrystallisation from alcohol.

a-Nitroacridine, $C^{12}H^9(NO^2)N$, which is the less soluble of the two, crystallises from alcohol in golden-yellow plates, resembling chloranil; it melts at 214° and may

be sublimed unaltered in plates. It is insoluble in water, slightly soluble in cold alcohol, rather more so in boiling alcohol, slightly in ether, and with moderate facility in chloroform. It forms salts with acids, which resemble the acridine salts, but in dilute solution they do not exhibit the beautiful blue fluorescence. The sulphate separates from a hot aqueous solution in golden-yellow crystals either acicular or prismatic; it is readily soluble in hot water, less so in cold water. The hydrochloride forms yellow prismatic crystals, easily soluble in water. The hydriodide is similar to the hydrochloride, and, like acridine hydriodide, forms a hyperiodide.

β -Nitroacridine crystallises in hard plates or tables, frequently in warty masses, especially when not quite pure. In hot alcohol it is readily soluble; less so in cold alcohol, and insoluble in water. It melts at 154° . With acids it forms salts which resemble those of the preceding body.

Dinitroacridine, $C^{14}H^7(NO_2)^2N$, obtained as above described, or in greater quantity by heating acridine with a mixture of sulphuric and nitric acids for some hours in the water-bath, and is precipitated on diluting the acid liquid with water. After washing with hot water, and recrystallisation from glacial acetic acid, it is obtained in reddish-yellow tables. In alcohol, ether, and benzene, it dissolves with difficulty, more easily in boiling glacial acetic acid.

Hydroacridine, $C^{14}H^{10}N^2$, is formed by the action of sodium-amalgam on an aqueous or alcoholic solution of acridine, and may be purified from acridine by treatment with acid and solution in alcohol, the latter dissolving the hydroacridine, and leaving a white body, called 'insoluble hydroacridine.' Hydroacridine crystallises in colourless prisms, slightly soluble in cold alcohol, easily in hot alcohol and ether, but insoluble in water. It melts at 169° , and may be sublimed in prismatic crystals; when further heated it distils, but not without decomposition. It is not attacked by dilute acids, dissolves in cold concentrated sulphuric acid, and is precipitated unaltered on the addition of water. If the sulphuric acid solution be heated to 100° and then diluted, no precipitation takes place, but a yellow solution is formed, from which ammonia precipitates acridine. When it is oxidised with dilute solution of potassium dichromate and sulphuric acid, acridine chromate is precipitated, and chromium sulphate remains in solution. Sodium-amalgam converts the boiling alcoholic solution of hydroacridine for the most part into the above-mentioned insoluble hydroacridine. Hydroacridine treated with concentrated hydriodic acid yields a salt of acridine and a second base, which is either fluid or has a low melting point.

Insoluble hydroacridine, $C^{14}H^{12}N^2(?)$ does not dissolve in alcohol, ether, benzene, carbon bisulphide, or chloroform; it is slowly dissolved by boiling nitrobenzene, but is, at the same time, converted into acridine. It dissolves in concentrated sulphuric acid when gently warmed, but is, at the same time, oxidised to acridine. When heated it sublimes, but the sublimate is soluble in alcohol, and consists of a mixture of acridine and hydroacridine.

ACROLEIN. C^3H^4O .—*Acrylic aldehyde*. According to Claus (*Deut. Chem. Ges. Ber.* iii. 401), the product obtained by the action of zinc and sulphuric acid on acrolein consists mainly of allyl alcohol, C^3H^4O (compare Linnemann, *1st Suppl.* 55). By sodium-amalgam, acrolein is almost wholly converted into the polymeric compound, hexacroleic acid, $C^{18}H^{24}O^6$ (iii. 151).

Acrolein absorbs *cyanic acid* with avidity, and on treating the product with hydrochloric acid and leaving it to cool, the trigenic acid of the allyl series, $C^3H^4N^3O^2$, separates in colourless needles, which dissolve, with some difficulty, in water:

(Molms, *Zeitschr. f. Chem.* [2] vii. 27).

When *hydrogen sulphide* is passed into the acid distillate obtained by heating glycerin with potassium sulphate, a pale yellow oil separates, which congealates to a resinous mass on treatment with hydrochloric acid. It gave by analysis 40.4 p. c. carbon, 6.75 hydrogen, and 23.55 sulphur, numbers which do not lead to any simple formula (E. Mulder, *Zeitschr. f. Chem.* v. 59).

The basic product which Claus obtained by distillation of acrolein-ammonia (*1st Suppl.* 56), appears, from further investigation, to have been a mixture of picoline, C^8H^7N (obtained by Beyer, *1st Suppl.* 944), and a base, decomposed by distillation, which is either isomeric with acrolein-ammonia, or intermediate between that compound and picoline (*Ann. Ch. Pharm.* clviii. 222; *Chem. Soc. J.* [2] ix. 537).

ACRYLIC ACID. $C^3H^4O^2 = CH^2=CH-CO^2H$.—This acid is formed: 1. By heating 1 mol. α -iodopropionic acid with 2 mol. potassium ethylate in a flask placed in a water-bath and provided with an upright condenser:

(von Schneider & Erlenmeyer, *Deut. Chem. Ges. Ber.* iii. 339).

2. By heating β -iodopropionic acid with lead-oxide:

On the other hand, acrylic acid is completely converted into β -iodopropionic acid by heating it for three hours to 100° with concentrated hydriodic acid (Wislicous, *Ann. Ch. Pharm.* clxvi).

3. Together with normal propyl alcohol and other products, by heating allyl alcohol with potassium hydrate (Tollens, *Zeitschr. f. Chem.* [2] vi. 457).

4. By oxidising the dibromide of allyl alcohol, $\text{C}^3\text{H}^4\text{Br}^2\text{O}$, with chromic or nitric acid, whereby it is converted into dibromopropionic acid, $\text{C}^3\text{H}^4\text{Br}^2\text{O}_2$, and debrominating this body with zinc-dust (Tollens, *ibid.* vii. 305):

Pure acrylic acid prepared from the lead-salt has a peculiar pungent odour, and boils at 140° – 150° . On cooling it to 15° , half of the liquid solidifies to quadratic tables (Caspary a. Tollens, *Deut. Chem. Ges. Ber.* v. 560).

According to Linnemann (*Ann. Ch. Pharm.* clxii. 95), acrylic acid boils at nearly the same temperature as propionic acid, but is converted into a crystalline mass at $+7^\circ$, and moreover has a tendency to pass into a white amorphous mass, analogous in properties to disacryl. It combines with hydriodic, hydrobromic, and hydrochloric acids, forming substituted propionic acids. The compound with hydriodic acid is identical with the *iodopropionic acid* obtained from glycerin; that with hydrobromic acid is identical with the *isobromopropionic acid* of Richter, obtained with bromine and iodopropionic acid; but the hydrochloric acid compound melts 20° lower than β -chloropropionic acid, Wichelhaus giving the melting point of glycerin chloropropionic acid at 65° ; and Richter, that of the acid from iodopropionic acid and chlorine, at 68° ; while the acrylic acid derivative melts at 40.5° (corrected). The ethylic ether of this acid also boils at a higher temperature than the chloropropionic ether of Wichelhaus.

The *sodium-salt* prepared from acrylic acid, purified by fractional distillation, remains unaltered on exposure to the air. The aqueous solution of *silver acrylate* may be boiled and even evaporated to dryness at 100° without reduction of the silver. There are two basic acrylates of *lead*, which are soluble in water; the normal lead-salt contains water of crystallisation which is not removed by drying over sulphuric acid (Linnemann, *ibid.* 369).

Ethyl acrylate, $\text{C}^3\text{H}^5(\text{C}^2\text{H}^3)\text{O}_2$, is easily prepared by the action of zinc and sulphuric acid on an alcoholic solution of ethylate dibromopropionate: $\text{C}^3\text{H}^5(\text{C}^2\text{H}^3)\text{Br}^2\text{O} + \text{Zn} = \text{ZnBr}^2 + \text{C}^3\text{H}^5(\text{C}^2\text{H}^3)\text{O}_2$. It is a colourless liquid boiling at 100° – 101° , and having an extremely penetrating, but not unpleasant odour (Caspary a. Tollens).

ADAMELLOGRANITE. A rock belonging to the Adamello group in the Tyrol (south of the Ortler). It is regarded by v. Rath as a peculiar species; but according to Baltzer (*Deut. Chem. Ges. Ber.* v. 983), it is a variety of granite.

The mica contained in it gives by analysis (after drying at 100°):

SiO ² .	FeO ² .	Al ² O ³ .	FeO.	MgO.	CaO.	K ² O.	Na ² O.
36.43	16.71	14.40	17.40	6.87	1.66	5.54	0.03 = 99.04

The oxygen ratio is $\text{MO} : \text{M}^2\text{O}^3 : \text{SiO}^2 = 4 : 5.88 : 9.72$, whence it may be inferred that the mica is included in the general formula of the magnesia micas—

and that it exhibits the hitherto unobserved case in which $m = 2$, $n = 1$, so that its formula is—

It is therefore a ferrous magnesia mica, allied to Soltmann's lepidomelane (iii. 574), in which $m = 1$, $n = 1$, and to Scheerer's magnesia mica from the zircon-syenite of Norway ($m = 3$, $n = 1$).

ADAMINE. $4\text{ZnO.As}^2\text{O}^3 + \text{H}_2\text{O}$.—This mineral, first obtained from Chanarcillo, in Chile, and analysed by Friedel (*1st Suppl.* 57), has also been found at Cape Garonne (Département du Var) in small crystals of the form ∞P , rarely with P, agreeing exactly in their angles with those of the Chilean mineral measured by Des Cloizeaux. The finest crystals are rose-red, others incline to green, grey, and

brown tints, and a few are white. Lenticular grains and crystalline aggregates likewise occur. One of these latter (Analysis A) agrees exactly in composition with the formula of adamine; another aggregate (B), containing a considerable quantity of copper, exhibits a transition to olivenite, with which adamine is isomorphous and with which it often occurs intergrown (Pisani, *Compt. rend.* lxx. 1001). Analysis C is by Damour (*ibid.* lxxvii. 1124):

	As ² O ³	ZnO	CuO	CoO	CaO	H ² O
A. 38.50	52.50	—	3.92	—	3.57	= 98.49
B. 39.85	31.85	23.45	0.52	0.87	3.68	= 100.22
C. 39.24	49.11	1.75	5.16	—	4.25	= 99.51

The specimen C also contains traces of ferric oxide.

ADIPIC ACID. $C^6H^{10}O^4$.—The ordinary or a modification of this acid, $(C_6H_7O_2)_2$, which Wislicenus obtained in small quantity by the action of finely divided silver or copper on β -iodopropionic acid (*1st Suppl.* 58), is produced much more abundantly by similar treatment of α -bromopropionic acid. With silver the action takes place at ordinary temperatures, and is attended with considerable evolution of heat; with copper application of heat is necessary. The reaction in either case having been completed at 150° – 160° , the adipic acid may be extracted from the product by water, and purified by neutralising with ammonia, precipitating with basic lead acetate, and decomposing the lead salt with hydrogen sulphide. The filtrate evaporated over the water-bath leaves a strongly acid syrup, which exhibits signs of incipient crystallisation only after standing for some months over oil of vitriol. The solution of the neutral ammonium salt gives off on evaporation a large quantity of ammonia, and is converted into the extremely soluble acid salt; when recently prepared, this solution gives a gummy precipitate with ferric salts, and a flocculent precipitate with lead salts. The lead salt, which soon becomes denser, has the composition $C^6H^4PbO^4$ (Wislicenus, *Deut. Chem. Ges. Ber.* ii. 720).

The same acid is readily formed by treating hydromuconic acid, $C^6H^8O^4$, with water and a large quantity of sodium-amalgam (Lamprecht, *Ann. Ch. Pharm.* clxv. 253).

Adipic acid is also produced, together with acetic and carbonic acids, by oxidation of phorone with chromic acid (Kachler, *ibid.* clxiv. 75):

Bromadipic acids.—*Monobromadipic acid*, $C^6H^9BrO^4$, is obtained by heating 1 mol. adipic acid with 2 atoms bromine to 160° in sealed tubes. It is a solid, dark-coloured body, having an odour of camphor, very soluble in ether, and partially decomposed by water. By boiling with potash it is converted into a dipomallic acid, $C^6H^{10}O^5$.

Dibromadipic acid, $C^6H^8Br_2O^4$, is produced by heating 1 mol. adipic acid with 4 at. bromine, in sealed tubes, to 170° ; if this temperature is exceeded the mass becomes carbonised. It is a yellowish, pulverulent, unstable substance smelling like camphor; dissolves easily, but with decomposition, in water, and after two crystallisations retains only 9.3 (instead of 52.6) pure bromine. When heated with water to 160° for some hours, it is converted into adipotartaric acid, $C^6H^{10}O^6$ (H. Gal and J. Gay-Lussac, *Compt. rend.* lxx. 1175).

The same, or an isomeric acid, is contained in the mother-liquors of bromhydromuconic acid (produced by adding bromine to a hot aqueous solution of hydromuconic acid), and is obtained in larger quantity by adding bromine to a hot saturated solution of bromhydromuconic acid. It has not been isolated from these liquors, but its existence was proved by the action of silver oxide on its aqueous solution whereby it is converted into dioxyadipic acid, $C^6H^{10}O^6$ (Lamprecht).

Isodibromadipic acid is formed by adding bromine to a warm solution of hydromuconic acid in glacial acetic acid. It is readily soluble in alcohol, ether, and hot water, sparingly in cold water, and crystallises in nodular groups of white needles. Between 175° and 190° , it melts and decomposes with ebullition. The *barium salt*, $C^6H^8Br_2BaO^4 + H^2O$, is an indistinct crystalline mass. The acid heated with water and sodium-amalgam is reconverted into hydromuconic acid (Lamprecht).

Tribromadipic acid, $C^6H^7Br_3O^4$, is formed by adding bromine to a solution of hydromuconic acid heated on a water-bath. A colourless oil, smelling like pepper, then separates out, and the watery liquid on standing deposits tribromadipic acid in small white needles, melting at 177° – 180° . Its solution boiled with baryta-water yields the barium salt of trioxadipic acid, $C^6H^8O^7$ (Lamprecht).

Tetrabromadipic acid, $C^6H^6Br_4O^4$, is formed in small quantity when 1 mol. of hydromuconic acid is heated with 3 mols. bromine and some water to 100° for seven hours;

a large quantity of carbon dioxide and the pungent oil above mentioned are formed at the same time. The acid dissolves sparingly in water, easily in alcohol and ether, and is decomposed when its alcoholic solution is boiled, yielding a volatile compound which has an ethereal odour. When heated to 200° – 211° , it melts and blackens (Limpricht).

Oxyadipic acids.—*Monooxyadipic*, or *Adipomalic acid*, $C^{11}H^{10}O^3 = C^{11}H^9(HO)O^3$, is prepared by treating monobromadipic acid with potash, decomposing the resulting potassium-salt with hydrochloric acid, and extracting with alcohol, and remains, on evaporating the alcoholic solution, as a light yellow acid liquid, which, after some time, is partly converted into an indistinctly crystalline mass. The aqueous solution gives with lead acetate a white precipitate, which melts when the liquid is heated, and solidifies on cooling to a somewhat hard brownish mass. This lead salt dissolves in a small quantity of a hot solution of lead acetate, and separates therefrom in nacreous scales having the composition $C^8H^7PbO^3 + 5H^2O$. When decomposed with hydrogen sulphide, it yields a viscid mass exactly like the original acid. The ammonium salt crystallises imperfectly; the potassium salt not at all (Gal a. Gay-Lussac, *loc. cit.*).

Dioxyadipic acid, $C^{11}H^8O^4$, is produced, as above stated, by the action of silver oxide on the aqueous solution of dibromadipic acid, and remains on evaporation as an uncrystallisable syrup soluble in alcohol and ether. The barium salt is formed by boiling a solution of dibromadipic acid with baryta-water. It is very soluble in water, and is precipitated by alcohol as a hygroscopic crystalline powder, $C^{11}H^6BaO^4 + 4H^2O$, which loses half its water at 150° , and begins to decompose at 160° . Its solution is precipitated by lead and silver salts (Limpricht).

An acid isomeric with this, and called adipotartaric acid, is produced by heating pulverulent dibromadipic acid with water to 150° for several hours, and evaporating. It tastes like the fruit-acids, is moderately soluble in alcohol and ether, much more soluble in boiling than in cold water, and always separates from solution in well-defined monoclinic laminae. It has no action on polarised light. Its solution, agitated with potash-ley, yields a crystalline precipitate resembling cream of tartar. With ammonia it forms salts which crystallise with facility (Gal a. Gay-Lussac).

Trioxadipic acid, $C^{11}H^6O^5$.—The barium salt of this acid is formed by boiling tribromadipic acid with baryta-water. It is very soluble in water, and remains on evaporation as an amorphous transparent mass, and is precipitated by alcohol as a light white powder, $4C^{11}H^4BaO^5 + 3H^2O$, which loses one-third of its water at 85° , being reduced to $2C^{11}H^4BaO^5 + H^2O$. Its aqueous solution gives white precipitates with lead and silver salts, reddish-yellow with ferric salts.

The *free acid*, separated from the barium salt by sulphuric acid, is readily soluble in water and in alcohol. By adding alcohol and benzene to its concentrated aqueous solution, and leaving it to evaporate slowly, it is obtained in prisms. Its alcoholic solution turns red on evaporation, without yielding crystals, and the aqueous solution becomes yellowish-brown and colours the skin intensely yellow (Limpricht).

ÆSCULIN, $C^{11}H^{10}O^3$, and **ÆSCULETIN**, $C^{11}H^8O^4$ (Schiff, *Deut. Chem. Ges. Ber.* iii. 366; iv. 472).—Æsculin is converted by acetic anhydride into hexacetylæsculin, $C^{18}H^{16}(C^2H^3O)^6O^3$, and by aniline into trianilæsculin, $C^{18}H^{10}O^4(C^6H^5.N)^3$.—Æsculetin, treated with acetic anhydride, yields well-crystallised triacetylæsculetin, $C^{11}H^6(C^2H^3O)^3O^4$, a compound previously obtained by Nachbaur (*Ann. Ch. Pharm.* cvii. 248). Aniline acts readily on æsculetin, and by heating the two bodies together to 200° trianilæsculetin, $C^{11}H^8O(C^6H^5.N)^3$, is ultimately obtained in the form of a brown amorphous powder soluble with red colour in alcohol.

Paræsculetin (1st Suppl. 59) has the properties of an aldehyde, and acts as a powerful deoxidising agent, reducing alkaline cupric tartrate, indigo, silver-salts, &c., in the cold. It is acted upon by aniline more easily than æsculetin, likewise yielding trianilæsculetin as ultimate product. It is not acted upon by acetic anhydride.

The above reactions may be explained by the following constitutional formulæ:—

In the conversion of paræsculetin into trianilæsculetin, the 3 atoms of aldehydic oxygen are directly replaced by the bivalent imidogen group NC^6H^5 , whereas in the case of æsculetin, the alcoholic groups $C.OH$ must first be converted, under the influence of the high temperature, into the aldehydic groups $CH.O$; hence the greater facility of the transformation in the former case.

By fusion with potash, æsculetin is converted into formic and protocatechuic acids, according to the equation:

The constitution of æsculin may be represented by the formula:

AGARIC. Some agarics contain mannite; others mycose or trehalose (iii. 1068); others again contain both these sugars in very variable proportions; and some contain mannite, trehalose, and another sugar, the nature of which has not yet been fully determined. Botanical analogy affords no guide to the kind of sugar present, for in species closely allied, growing in the same soil and under the same conditions, some contain mannite only and others trehalose only (A. Muntz, *Compt. rend.* lxxvi. 649).

Agaricus fatus contains, according to Taci (*ibid.* 505), 67·20 p. c. water, 0·60 mannite, 0·09 pectic acid, 4·65 fibrin, 1·55 bassorin, 20·09 ligucous matter, 0·68 fat, acids, colouring and odorous matter, and 5·13 ash.

The larch-agaric (*Boletus Laricis*) pulverised, dried, and treated with pure anhydrous ether, yields two substances, viz.: 1. A red-brown amorphous substance, called agaric resin, soluble in alcohol, wood-spirit, chloroform, and acetic acid, insoluble in benzene and carbon bisulphide, and said to have the composition $C^{51}H^{92}O^{10}$.—2. Agaricic acid, which crystallises in tufts of needles, melts at 145° , gives off water and turns brown at a somewhat higher temperature. It dissolves very easily in alcohol, less easily in chloroform, very sparingly in ether and acetic acid, still less in carbon bisulphide and benzene. When the alcoholic solution is distilled, the acid volatilises with the alcohol vapour. Its sodium-salt is precipitated by alcohol in amorphous flocks which, in the course of 24 hours, change to long needles, often united in concentric groups. Metallic salts give, with the dilute solutions, mostly crystalline precipitates (Fleury, *J. Pharm.* [4] x. 202).

AGONIADIN. A non-azotised, crystalline bitter substance, extracted, together with tannic acids, resins, &c., from Agoniada bark (the bark of *Plumeria lanceifolia*), which is used in Brazil as a remedy for intermittent fever. It separates from dilute solutions in stellate groups of needles having a silky lustre; from concentrated solutions in warty groups of crystals. It melts when heated, but does not sublime. It is inodorous, very bitter, nearly insoluble in ether, easily in ether-alcohol, carbon bisulphide, and hot alcohol. Cold water dissolves only traces of it; boiling water dissolves it immediately, and deposits it in white flocks on cooling. It dissolves easily in potash and ammonia. Strong sulphuric acid dissolves it with gold-yellow colour, which after a while passes into greenish. On addition of fuming nitric acid, this solution passes into dark yellow, and deposits yellow crystalline flocks. Dilute sulphuric acid dissolves agoniadin only when warmed; the solution becomes coloured on boiling, and then exhibits the reactions of sugar. Agoniadin is allied in composition to arbutin, but not identical with it. From an analysis by Geuther, it appears to have the composition $C^{10}H^{14}O^6$ (Peckolt, *Arch. Pharm.* [2] cxlii. 34).

ALANINE, or AMIDOLACTIC ACID, $C^3H^7NO^2$, is produced, together with lactic acid, by boiling α -chloropropionic acid with aqueous ammonia. See LACTIC ACID.

ALBITE. See FELSPAR.

ALBUMIN. See PROTEÏDS.

ALCOHOLS. 1. *Simultaneous distillation of Water and certain Alcohols insoluble in Water.*—When a mixture of amylie alcohol and water is submitted to distillation, ebullition begins at 96° , and remains remarkably constant at this point; so long as these temperatures remain constant, the volumes of water and of amylie alcohol condensed during any given time are invariably in a constant ratio, viz. 2 to 3, and the temperature does not begin to rise until either the water or the alcohol has wholly distilled over, leaving a surplus of alcohol or of water (as the case may be) in the retort; if the water was originally more than two-thirds of the volume of the alcohol, the temperature rises to 100° as soon as the whole of the alcohol has distilled over; but if less than the two-thirds of water was originally present, the boiling

point rises to 130° as soon as the whole of the water has distilled over, amylie alcohol only being then left.

Butylic alcohol gives precisely analogous results, the volumetric ratio in this case being 1 of water to 5 of alcohol; the boiling point of the mixture is perfectly constant at 90.5° , i.e. 9.5° below the boiling point of water, and 17.5° below that of butylic alcohol; fourteen experiments gave absolutely the same numbers in each instance.

When a mixture of water, butylic, and amylie alcohols is used, the temperature of ebullition is not constant, but regularly rises; the temperature, however, always lies between 90.5° and 96° , being higher the larger the proportion of amylie alcohol present; the relative volume of water that distils over also continually increases, being, however, always greater than $\frac{1}{2}$ th of the total volume that passes over, and less than $\frac{2}{3}$ ths—i.e. lying between the relative numbers found with butylic alcohol and water, and with amylie alcohol and water (Pierre a. Puchot, *Compt. rend.* lxxiii. 599).

2. *Oxidation of Tertiary Alcohols.*—In the oxidation of these alcohols, as in that of the ketones, the simplest, or one of the simplest of the three alcohol-radicles present remains united to the carbon-atom which binds together the whole group, forming an acid $C^3H^3O^2$, while each of the other two alcohol-radicles is separately oxidised, yielding (if it is a primary radicle) an acid containing the same number of carbon-atoms as itself; formic acid, however, in this, as in similar cases, is not actually eliminated, but is further oxidised to carbonic acid.

Dimethyl-ethyl carbinol yields in this manner, acetic acid and carbon dioxide:

Methyl-diethyl carbinol yields nothing but acetic acid:

Dimethyl-propyl carbinol gives acetic and propionic acids, together with formic or carbonic acid:

Triethyl carbinol gives acetic and propionic acids:

Exceptions to this law of oxidation appear to be furnished by *trimethyl carbinol* and *dimethyl-isopropyl carbinol*, the former of which yields acetone, acetic acid, and, according to former experiments, propionic acid (*1st Suppl.* 66), while the latter yields nothing but acetone. The formation of acetone from trimethyl carbinol may be regarded as an intermediate stage in the oxidation, thus:

In the case of dimethyl-isopropyl carbinol, the oxidation of the simpler alcohol-radicle appears to stop at the first stage—that is to say, at the formation of acetone and the more complex radicle; the isopropyl, being a secondary radicle, is likewise oxidised, not to an acid, but to acetone; hence acetone is the only product:

The formation of propionic acid from trimethyl carbinol, which would be completely at variance with the law above stated, was inferred in the earlier experiments from the composition of a silver salt; but subsequent examination has shown that the supposed propionate of silver was really a mixture of acetate and isobutyrate. The formation of isobutyric acid is not at variance with the above law; it is formed by a molecular change corresponding to that by which Linnemann has found that derivatives of trimethyl carbinol are obtained from isobutyl alcohol (Butlerow, *Zeitschr. f. Chem.* [2] vii. 484).

3. *Formation of Monatomic and Hexatomic Alcohols from Glucose and Milk-sugar.*—When glucose is treated with sodium-amalgam containing 3 p. c. sodium, and the alkaline liquid is neutralised with sulphuric acid, then distilled and treated with potassium carbonate, an oily layer is obtained, consisting of ethylic, isopropylic and hexylic alcohols. The liquid remaining in the retort contains a large quantity of mannite.

Milk-sugar, similarly treated, yields ethylic, isopropylic and hexylic alcohols, the residuo containing dulcitol. Inverted milk-sugar yields the same products, together with mannite (G. Bouchardat, *Compt. rend.* lxxiii. 108).

4. On the formation of Alcohols from the corresponding Fatty Acids, see BUTYL, ETHYL, and PROPYL Alcohols.

5. On a class of bodies intermediate between Alcohols and Aldehydes, see ALDEHYDE-ALCOHOLS.

6. On the Thermal Effects of the combination of Alcohols with Bases, see HEAT.

ALDANE. A term proposed by Riban (*Compt. rend.* lxxv. 98) to designate products formed by the union of two or more molecules of an aldehyde, with elimination of water—e.g. crotonic aldehyde, $C^6H^{10}O^2 = 3$ mol. acetic aldehyde, minus 1 mol. water. The prefixes *di*, *tri*, &c., may be used to denote the number of aldehyde molecules thus condensed—e.g. *diacetaldehyde*, *triacetaldehyde*, *divinylaldehyde*, &c.

ALDEHYDE, $CH^3.CHO$, is formed: α . By oxidation of ethylene with aqueous chromic acid at 120° ; at ordinary temperatures no action takes place (Berthelot, *Compt. rend.* lxxviii. 334).

β . By inverse substitution from chloral, $CCl^3.CHO$, when clippings of zinc are introduced into a solution of that substance slightly acidulated with sulphuric or hydrochloric acid. Considerable quantities of the polymerides of aldehyde, especially paraldehyde, are formed at the same time (Personne, *Compt. rend.* lxxi. 227).

γ . In the electrolysis of sugar-solutions acidulated with sulphuric acid (H. T. Brown, *Chem. Soc. J.* [2] x. 578).

δ . In vinous fermentation. See FERMENTATION.

Aldehyde occurs, together with metalddehyde and paraldehyde, in the 'first runnings' obtained in the manufacture of alcohol from sugar-beet and from potatoes (Krämer a. Pinner, *Deut. Chem. Ges. Ber.* ii. 403; Kekulé, *ibid.* iv. 718). Krämer and Pinner also find acetal and crotonic aldehyde in these runnings (*ibid.* iii. 75). They attribute the formation of the aldehyde to oxidation of the alcohol on the carbon filters. Kekulé, on the other hand, attributes it—at least in the case of alcohol from sugar-beet—to the oxidising action of nitrates which are present in considerable quantity in the liquors. To this Krämer and Pinner reply (*ibid.* iv. 787) that the oxidation of the alcohol to aldehyde cannot be due in all cases to the action of nitrates, since the quantity of those salts in some cases, as in the first runnings from potato-spirit, is too small to account for the quantity of aldehyde produced. Moreover, considerable heating of the carbon-cylinders is observed on passing the spirit through them (compare *1st Suppl.* p. 213).

Aldehyde, mixed with *pyrogallie acid* and hydrochloric acid and gently warmed, produces a red coloration, becoming violet on addition of an alkali. A mixture of aldehyde and *phenol* also gives a red colour when warmed with sulphuric acid (A. Bayer, *Deut. Chem. Ges. Ber.* v. 25).

Aldehyde, heated with *acetamide* in sealed tubes, yields the compound $CH^3CH(NH.C^2H^3O)$, which crystallises in large prisms, melts at 169° , distils with partial decomposition, and gives up the aldehyde when treated with acids (Tawildarow, *Deut. Chem. Ges. Ber.* v. 477).

On the action of *bromine* on aldehyde, see page 36; on the action of *chlorine*, see CROTONIC CHLORAL.

Polymeric modifications of Aldehyde.

Five of these modifications have been described by different chemists, viz.:—1. A liquid modification boiling at 94° , accidentally obtained by Liebig.—2. A modification called *olaldehyde*, melting at $+2^\circ$ and boiling at 94° , which Fehling accidentally obtained by exposing aldehyde to a winter temperature.—3. A liquid modification boiling at 125° , which Weidenbusch obtained by the action of very dilute sulphuric acid or nitric acid on aldehyde, and for which Gerhardt suggested the name *paraldehyde*.—4. Infusible but sublimable *metalddehyde*, discovered by Liebig, and further examined by Fehling and Weidenbusch.—5. *Acetaldehyde*, produced by the action of zinc chloride on glycol or aldehyde, first obtained by Wurtz, further examined by Bauer (i. 109; iv. 349; *1st Suppl.* 76).

Recent investigations have, however, considerably reduced the number of these modifications. The liquid called *acetaldehyde* has been shown by Kekulé to be resolvable by heat into water and crotonic aldehyde; and Wurtz has recently shown that it is not a true polymeride of aldehyde, but a compound intermediate in properties and constitution between aldehyde and alcohol; it will be described in a separate article under the name of *aldol*. The modifications described by Fehling and by Weidenbusch have been shown by Gauthier a. Cartmel (*Ann. Ch. Pharm.* cxii. 16),

and by Lieben (*ibid. Suppl. i. 14*) to be identical with each other and with the modification (paraldehyde) melting at $10-12^{\circ}$ and boiling at 124° , which the former chemists obtained by the action of sulphurous acid, the latter by that of ethyl iodide upon aldehyde; and, finally, it has been shown by Kekulé & Zincke (*Ann. Chem. Pharm.* clxii. 141; *Deut. Chem. Ges. Ber.* iii. 468), that, besides ordinary aldehyde, there are but two distinct modifications, viz.—1. Paraldehyde, fusible and distillable;—2. Metaldehyde, infusible, but sublimable. These chemists find, in accordance with the observations of Gauthier & Cartmell, that carefully purified aldehyde suffers no change either by long keeping or by continued heating or cooling, polymerisation being due in all cases to the presence of some foreign substances which appear to exert a kind of fermentative action. In most cases both modifications are formed together, metaldehyde chiefly in the cold, paraldehyde at ordinary or at higher temperatures.

Paraldehyde. In presence of a very small quantity of hydrochloric acid, chlorocarbonic oxide, or sulphurous anhydride, aldehyde gradually becomes hot, the temperature frequently rising to 38° or 40° . Both zinc chloride and sulphuric acid act in the same way, the addition of a drop of the concentrated acid causing explosive ebullition of the aldehyde; the action of the dilute acid is less energetic. In all these reactions an almost complete transformation into paraldehyde occurs, as is indicated by the change in specific gravity (0.986 at 15°), but the pure substance cannot be directly separated from the product by rectification, as much aldehyde is then regenerated. The best method of separation is to cool the liquid to 0° , when the paraldehyde crystallises out, and may be collected and purified by distillation.

Paraldehyde is a colourless liquid of peculiar odour, resembling that of acetal. It boils at 124° , and crystallises when cooled below 10° , forming large transparent prisms, which melt at 10.5° . Its specific gravity at 15° is 0.998 , and its vapour-density three times that of ordinary aldehyde. It is less soluble in hot than in cold water; 100 parts of the latter dissolving 12 parts at 13° . Distillation with sulphuric acid, hydrochloric acid, zinc chloride, or chlorocarbonic oxide, reconverts it into aldehyde. When subjected to the action of phosphorus pentachloride, it yields ethylidene chloride, as observed by Gauthier (*Zeitschr. f. Chem.* 1865, 32), and with hydrochloric acid it gives the same ethylidene oxychloride that Lieben obtained from ordinary aldehyde (*Ann. Chem. Pharm.* cvi. 336).

The so-called chloracetone, isomeric with vinyl chloride, C^2H^3Cl , which Haritzky obtained some years ago (*Ann. Chem. Pharm.* cxi. 192), by the action of phosgene on aldehyde, appears, from the experiments of Kekulé & Zincke, to be nothing but a mixture of aldehyde and paraldehyde with a small quantity of phosgene, and is completely converted into aldehyde by passing its vapour over heated quicklime.

Metaldehyde. This modification, hitherto obtained only accidentally, has been shown by Kekulé & Zincke to be formed from aldehyde at a low temperature by the same reagents that cause the formation of paraldehyde at a comparatively high temperature. To prepare it in quantity, a few bubbles of hydrochloric acid or sulphurous acid are passed into aldehyde cooled in a freezing mixture, the metaldehyde which crystallises out on standing is removed, and the mother-liquors are submitted to distillation, the distillate being collected in a well cooled receiver; more metaldehyde is then deposited, which is again removed, and the distillation, &c., repeated as above. Calcium chloride effects the same transformation at the ordinary temperature. Metaldehyde crystallises in fine white needles, and that produced by calcium chloride in short, thick transparent prisms belonging to the quadrate system. It is insoluble in water, and but slightly soluble in alcohol, ether, chloroform, or benzene. When heated it sublimates, but ordinary aldehyde is always formed at the same time. Heated to 112° to 115° in a closed tube, it is completely converted into aldehyde, and the same change is produced by distillation with dilute sulphuric acid. With phosphorus pentachloride it forms ethylidene chloride.

As the vapour-density of metaldehyde cannot be determined, on account of its partial conversion by heat into ordinary aldehyde, and as none of its known reactions give any information as to its molecular weight, it is impossible at present to form any definite idea of its constitution. But the formation of ethylidene chloride and the ready conversion into aldehyde render it probable that this modification consists of several (perhaps two) aldehyde molecules united into one by their oxygen-atoms.

As paraldehyde has three times the vapour-density of aldehyde, its molecular formula is $C^3H^4O^3$, and its reaction with phosphorus pentachloride, with hydrochloric acid, sulphuric acid, and generally with all ferment-like bodies, which easily convert it

into aldehyde, suggest that the three aldehyde molecules contained in it are united into a ring through the medium of their oxygen-atoms.

Condensation-products of Aldehyde.

I. Condensation with Separation of Water. (Kekulé, *Ann. Chem. Pharm.* clxii. 92-124.) — The formation of crotonic aldehyde by heating acetic aldehyde with zinc chloride, is mentioned in the First Supplement (p. 513), where crotonic aldehyde is represented by the formula $\text{CH}^2=\text{CH}-\text{CH}^2-\text{CHO}$. Kekulé, however, now takes a somewhat different view of the mode of transformation, leading to the representation of crotonic aldehyde by the formula $\text{CH}^2=\text{CH}-\text{CH}=\text{CHO}$, as shown by the following equation, in which the eliminated atoms are enclosed in brackets:—

The same transformation is effected by the action of hydrochloric acid, other products being however formed at the same time, viz., chlorobutyric aldehyde $\text{C}^4\text{H}^7\text{ClO}$, resulting from the combination of part of the crotonic aldehyde with hydrochloric acid—the same compound being in fact producible by saturating crotonic aldehyde with hydrochloric acid gas; and a chlorinated compound $\text{C}^{10}\text{H}^{16}\text{Cl}^2\text{O}^2$, besides higher condensation-products. The manner in which these several compounds are obtained is as follows:—

When aldehyde is saturated in a cooled vessel with hydrochloric acid, and then left to itself for about two days, two layers of liquid form, the lower of which consists of aqueous hydrochloric acid. On removing the upper layer and distilling immediately, torrents of hydrochloric acid gas escape, and a pungent oil heavier than water passes over, whilst a large portion remains behind as a non-volatile viscid mass. If the upper layer be washed with water previous to distillation, the general course of the action is the same, but the quantity of viscid residuo is less. Still better results are obtained by distilling the washed oil in a stream of hydrogen, and adding marble to neutralise the free acid.

Crotonic aldehyde is easily obtained from all the distillates by rectification; its quantity is, however, relatively small, and smaller as the aldehyde saturated with hydrochloric acid has been left to stand for a longer time. If the crude oils have been washed with water, considerable quantities of tolerably pure crotonic aldehyde may be obtained from this water by distillation.

If the distillation of the oil, after washing with water or with alkali, be performed by means of steam, the viscid residuo deposits needle-shaped crystals of chlorobutyric aldehyde $\text{C}^4\text{H}^7\text{ClO}$; the quantity of which increases on adding alcohol, and leaving the liquid to itself for some days.

If the receivers be occasionally changed during the distillation with steam, the earlier distillates contain chiefly crotonic aldehyde, the latter ones an oil which sinks in water. The oil of the last distillates, deposits, sometimes immediately, sometimes after a few days, laminar crystals of the chlorinated compound $\text{C}^{10}\text{H}^{16}\text{Cl}^2\text{O}^2$; the empirical relation of which to aldehyde may be represented by the equation:

This compound forms broad nacreous rhombic plates or tables, sometimes larger well-developed crystals. It melts at 98° , and volatilises easily with vapour of water.

It is insoluble in water, but slightly soluble in cold alcohol, easily soluble in hot alcohol and in ether.

Higher Condensation-products.—Both the liquid of higher boiling-point which remained after distilling off the crotonic aldehyde as above described, and a product obtained by heating crotonic aldehyde with twice its weight of aldehyde and some zinc chloride to 100° for 96 hours, yielded, by distillation with steam and subsequent rectification, an oily product, boiling at about 172° , and having nearly the composition $C^8H^{10}O$. On exposing small quantities of this oil to the air, crystalline needles were formed, and on boiling it with water and silver oxide, a crystalline, difficultly soluble silver salt was produced, containing an amount of silver closely corresponding with the formula $C^8H^8AgO_2$. This oil was probably the triple condensation-product of aldehyde: $3C^2H^4O - 2H^2O = C^8H^{10}O$. On rectification of the products of still higher boiling-point, an oil was separated, having nearly the composition $C^{12}H^{16}O = 4C^2H^4O - 3H^2O$.

The mode of action of zinc chloride, and of the numerous other salts which exert the above described condensing action on aldehyde, may be explained on the otherwise probable assumption that, in an aqueous solution of zinc chloride, there are present besides the hydrated molecules, a certain number of anhydrous molecules, these latter being always in motion, and constantly changing their condition, the hydrated molecules becoming anhydrous, the anhydrous molecules becoming hydrated, in such a way, however, that a mean condition of equilibrium is always preserved. If then bodies are present from which the elements of water can be withdrawn, a certain, although probably small, proportion of those molecules which are in the act of taking up water, cause the separation of water from these substances, and combine with the water thus separated, so that in course of time a very small quantity of such an agent is capable of performing a large amount of work. It is evident that heat is not absolutely necessary for the production of such reactions, although an increase of temperature has an accelerating influence. In fact, aldehyde mixed with zinc chloride undergoes the same change in a few weeks at summer temperature, and in some months at autumn and winter temperatures, as when heated for several hours to 100° . The action of zinc chloride and similar salts might also be referred to the presence of hydrochloric acid: for an aqueous solution of the former may be supposed to contain free hydrochloric acid and free zinc oxide.

Similar considerations apply to the decomposition of complex compounds with assumption of the elements of water. Thus, that of the glucosides in presence of traces of sulphuric acid may probably be referred to an action of the same nature.

According to Paternò a. Amato, aldehyde is converted into crotonic aldehyde by heating with *ethylidene chloride* (I. Suppl. 513). According to Kekulé, however, (*Deut. Chem. Ges. Ber.* iii. 135), this is the case only when the ethyldiene chloride contains free hydrochloric acid. Pure ethyldiene chloride has no action whatever on aldehyde, but a mere trace of hydrochloric acid is sufficient to produce the condensation. This conclusion is confirmed by the experiments of Krämer a. Pinner (*ibid.* 76 and 390), who find that ethyldiene chloride heated with aldehyde does not undergo the slightest alteration.

Chlorinated Condensation-products.—Krämer a. Pinner (*Ann. Chem. Pharm.* clviii. 37), by passing chlorine into aldehyde, at first cooled by a freezing mixture, but heated to 100° at the close of the reaction, obtained in about 24 hours a semi-solid brown mass, which, when distilled, yielded between 160° and 180° , a liquid from which, by subsequent fractional distillation, trichlorocrotonic aldehyde or crotonic chloral $C^4H^3Cl_3O$ was obtained, boiling at 163° to 165° . The chlorine first takes hydrogen from a portion of the aldehyde, forming hydrochloric acid; this acts on the rest of the aldehyde in the manner above described, forming crotonic aldehyde; and the latter is converted by the excess of chlorine into trichlorocrotonic aldehyde (I. Suppl. p. 513). By adding fragments of marble so as to remove the hydrochloric acid as fast as it is formed, a distillate is obtained exhibiting the properties of ordinary chloral (Pinner, *Deut. Chem. Ges. Ber.* iv. 256).

Wurtz (*Ann. Chem. Phys.* [3] xlix. 58), by passing chlorine into aldehyde obtained acetyl chloride and a body $C^4H^3ClO_2$ containing the elements of acetyl chloride and aldehyde, and producible by their direct combination. Krämer a. Pinner were not able to obtain these substances, but Wurtz (*Compt. rend.*, lxxiii. 528) has recently made further experiments which corroborate his former results.

By passing chlorine through an ice-cold mixture of carbon perchloride and one-tenth of its weight of aldehyde, in sunshine, till the liquid becomes strongly yellow, he obtains a product which, on agitation with mercury and distillation, gives off hydrochloric acid, and yields, after fractionating several times, a liquid boiling below 70° , and another boiling at about 120° . The first is a mixture of acetyl chloride and

carbon perchloride; the second contains the compound $C^4H^2ClO^2$, which, treated with water, yields acetic and hydrochloric acid, and apparently also aldehyde, whence it appears to contain the elements of aldehyde and acetyl chloride condensed: probably thus

either as

II. Condensation with Addition of Hydrogen. (Kokulé, *Ann. Chem. Pharm.* cxlii, 305-320).—When an acidulated dilute aqueous solution of aldehyde is treated with sodium amalgam, butylene-glycol $C^4H^{10}O^2$ is formed in small quantity, according to the equation $2C^2H^4O + H^2 = C^4H^{10}O^2$; the reaction being analogous to that by which benzoic aldehyde C^7H^6O is converted into hydrobenzoin, $C^{10}H^{14}O^2$.

The butylene-glycol thus obtained is different from ordinary butylene-glycol; it boils at $203.5^\circ-204^\circ$, and yields by oxidation with nitric and crotonic aldehyde, acetic acid and oxalic acid, whence it is inferred to have the constitution represented by the formula $CH^2(OH)-CH^2-CH(OH)CH^2$. (See BUTYLENE-COMPOUNDS.)

Substitution-products of Aldehyde.

Dibromaldehyde, $C^2H^2Br^2O$, is produced by the regulated action of bromine on aldehyde. It crystallises in long needles, soluble in water, alcohol, and ether, has a pungent, tear-exciting odour, and reduces silver nitrate. The action of bromine on aldehyde under slightly different circumstances, gives rise to dibromacetic acid (Haarmann, *Deut. Chem. Ges. Ber.* iii, 758).

Monochloraldehyde, C^2H^2ClO (Glinsky, *Zeitschr. f. Chem.* vi, 647).—This compound is produced by the action of hypochlorous acid on vinyl chloride C^2H^3Cl (*I. Suppl.* 76). When this gas is passed into a cooled mixture of hypochlorous acid and mercuric oxide, the latter being added by successive portions when required, and the liquid, after being filtered or mixed with a sufficient quantity of hydrochloric acid to dissolve all the mercuric oxide, is distilled, the first portion of the distillate passes over in oily drops, after which the distillation may be continued as long as the liquid which passes over becomes turbid on addition of potassium cyanide. Both these distillates contain a hydrate of monochloraldehyde, which solidifies when pure; it is most easily obtained from the second distillate. This liquid is saturated with sodium sulphate, and agitated with ether; the ether is distilled off from the ethereal extracts; the residuo is fractionally distilled, the portions going over between 85° and $95^\circ-100^\circ$, being collected apart; and both these distillates are dehydrated by suspending lumps of calcium chloride over them; whereupon, the hydrate of chloraldehyde separates in the solid state. Both this hydrate and the liquid decanted from it exhibit similar phenomena when rectified, the greater part distilling over between 85° and 95° , the smaller portion between 95° and 100° ; the former solidifies on cooling; the latter remains liquid for the most part, as also does the small residuo which boils above 100° .

The hydrate of chloraldehyde has the composition $2C^2H^2ClO.H^2O$. By evaporation of its ethereal solution, it is obtained in groups of flat tabular crystals, which melt at $74^\circ-75^\circ$. When exposed to the air it volatilises and oxidises at the same time. In dilute solution it smells like rotten apples or grapes, but its concentrated solutions have a pungent odour and give off a vapour which attacks the mucous membranes. It has a sweetish-sharp taste, and, when placed on the skin, produces spots which give no pain, and are scarcely visible at first, but afterwards become orange-yellow, and remain till the cuticle peels off. The hydrate reduces ammoniacal silver solution, producing a specular deposit. Sulphuric acid quickly converts it into a thick brown-yellow oil. With potassium cyanide it forms an oil which is converted by acids into chlorolactic acid (See LACTIC ACID). It unites with acid sodium sulphite, forming the compound $2(C^2H^2ClO.NaHSO^3).H^2O$; which separates from the solution in boiling alcohol, as a bulky, white, crystalline powder.

The products of higher boiling-point obtained in the preparation of the hydrate, appear to contain nothing but condensation-products of chloraldehyde. The portion boiling between 95° and 100° , dissolves for the most part in water, and the insoluble portion gives, by analysis, a quantity of chlorine agreeing approximately with the formula $2C^2H^2ClO - H^2O$. The higher the boiling-points of these secondary products the less soluble are they in water; the aqueous solution of the higher-boiling products does not yield any oil with potassium cyanide. They all have a pungent

odour, a sweetish, burning taste, and do not combine with acid sodium sulphite. That these oily secondary products are formed from the solid hydrate of chloraldehyde appears from the fact; that, on distilling the perfectly desiccated hydrate, a portion boiling at 85°–90° and another at 90°–94° were obtained, both of which quickly solidified, but were no longer perfectly soluble in water; insoluble, oily drops remaining, which exhibited the properties above described. It does not appear possible to obtain anhydrous monochloraldehyde by continued distillations; a product thus obtained contained but little more chlorine (41.59 p.c.) than the hydrate (40.57 p.c.).

Sulphaldehyde.—When hydrogen sulphide is passed into an aqueous solution of aldehyde, an oil is formed, which, when treated with acids, yields a solid substance having the composition of aldehyde with the oxygen replaced by sulphur. Hofmann, however, finds that its vapour-density agrees with the triple formula $C^2H^2S^3$; it is very easily formed from paraldehyde (*Zeitschr. f. Chem.* [2] vi. 699).

The oil formed by the action of hydrogen sulphide on aldehyde, was said by Weidenbusch (i. 107) to have the composition $6C^2H^4S_3 \cdot II^2S$, and to give off hydrogen sulphide when treated with acids. According to Pinner, however (*Deut. Chem. Ges. Ber.* iv. 257), these statements are incorrect. The oil is a compound of aldehyde and sulphaldehyde, $C^2H^4O \cdot C^2H^2S$, and when treated with an acid, yields a precipitate of sulphaldehyde $C^2H^2S^2$, and a solution of aldehyde, without any evolution of hydrogen sulphide. By passing sulphydric acid-gas through the strongly acid filtrate, a large quantity of sulphaldehyde may be directly obtained. In like manner, a strongly-acidulated solution of aldehyde yields, with sulphydric acid, not the oil above mentioned, but solid sulphaldehyde.

The oil, $C^2H^4O \cdot C^2H^2S$, solidifies at -8° and liquefies again at -2° . Its vapour-density was found to be between 61.3 and 59.4 ($II=1$). Now, supposing that the oil is resolved by heat into monomolecular aldehyde C^2H^4O and trimolecular sulphaldehyde $C^2H^2S^3$, its vapour-density should be 61.2°, which agrees with the experimental number (Pinner).

ALDEHYDE-ALCOHOLATE. $C^2H^4O \cdot C^2H^4O$.—A compound identical with hydroxyl-ethyl-oxide (See ETHYL OXIDE).

ALDEHYDE-ETHYL-CHLORIDE. $C^2H^4O \cdot C^2H^5Cl$.—Identical with monochloroethyl oxide (See ETHYL OXIDE).

ALDEHYDES. *Reactions with Phenols.*—Acetic aldehyde, mixed with pyrogallol and hydrochloric acid, and gently warmed, produces a red coloration, becoming violet on the addition of an alkali. Bitter almond oil, heated with pyrogallol, produces a colourless body, crystallisable from ether, and having, when dried at 120° , the composition: $C^{20}H^{22}O^7 = 2C^2H^4O + 2C^2H^2O^3 - H^2O$. Heated to 200° , this product loses hydrogen, forming a red body, $C^{20}H^{18}O^7$ soluble in alcohol, while, on treating it with hydrochloric acid, alcohol, and zinc, hydrogen is added, and a crystalline white body, $C^{20}H^{22}O^7$, is formed, soluble in acetone, but insoluble in alcohol and ether. Resorcin behaves with bitter almond oil in a similar manner to pyrogallol; and a phenol dyestuff is produced on adding strong sulphuric acid to a mixture of phenol and bitter almond oil. Aldehyde or chloral with phenol and sulphuric acid; furfural with resorcin, phenol, or pyrogallol and a trace of hydrochloric acid; salicylic and pyrotartaric acids with phenols: all give colouring matters (*A. Bayer, Deut. Chem. Ges. Ber.* v. 25).

Condensation-products of Aldehydes (Aldanes, p. 32).—Many aldehydes when treated with sodium yield condensation-products, with elimination of water. Thus, valeral $C^5H^{10}O$, yields an aldehyde, $C^{10}H^{18}O = 2C^5H^{10}O - H^2O$, which boils at 195° , combines with sodium bisulphite, and is converted by oxidation into an acid, $C^{10}H^{18}O_2$, and by nascent hydrogen into the alcohol $C^{10}H^{22}O$.

Enanthol, similarly treated, is converted into two polymeric modifications: one a liquid, the other a crystalline solid, both of which, on distillation, yield enanthol and condensation-products, with abstraction of water (*Borodin, Deut. Chem. Ges. Ber.* v. 480).

On the Thermal Effects of the Combination of Aldehydes with Bases, see HEAT.

ALDEHYDINE. $C^4H^{11}N$.—This base, discovered by Ador a. Bayer (*1st Suppl.* 82), is regarded by them as a homologue of picoline, C^6H^7N .—It is produced directly from Schiff's tetraldine, which again is formed by the union of 2 mol. crotonic aldehyde with ammonia (*Jahresb. f. Chem.* 1869, 707).

ALDOL. $C^3H^5O^2 = CH^2-CHOH-CH^2-CHO$ (Wurtz, *Compt. rend.* lxxiv. 1361; lxxvi. 1166). A compound polymeric with acetic aldehyde, and regarded by

Wurtz as belonging to a class of bodies intermediate in properties and constitution between the aldehydes and the alcohols. It is formed by the action of hydrochloric acid and water on aldehyde at low temperatures: 1 part of aldehyde is mixed with 1 part of water and 2 parts of hydrochloric acid, and the mixture is left to itself for several days at a temperature of 15° to 20° ; in winter it must be placed in a stove. As soon as it has acquired a tawny colour, and smells but slightly of aldehyde and paraldehyde, it must be neutralised with crystals of sodium carbonate, and agitated several times with ether. The ethereal solution distilled in the water-bath leaves a transparent, slightly-coloured liquid, which becomes syrupy on cooling; and this product, distilled in a vacuum, gives off, first ether, then water, then between 90° and 105° , under a pressure of 2 centimeters, aldol, in the form of a colourless liquid, which remains soluble while hot and even when recently cooled, but when left to itself gradually becomes viscid, giving out, at the same time, a considerable quantity of heat. Thus a quantity of freshly-distilled aldol, perfectly limpid at 11° , gradually rose in an hour to the temperature of 54° , after which it slowly cooled, till, at the end of three hours more, its temperature was 30° : it was then viscid. This viscid aldol probably bears the same relation to mobile aldol that paraldehyde bears to ordinary aldehydes, the polymeric grouping being, however, less stable than that of paraldehyde.

Aldol at 0° is so viscid that it does not run out when the tube containing it is inverted. Its specific gravity is 1.208 at 0° , 1.1094 at 16° , and 1.0819 at 49.6° . It is strongly refractive, its index of refraction being 1.468 for the yellow ray, and 1.455 for the red. It has an aromatic and bitter taste, mixes in all proportions with water and alcohol, dissolves also in ether; when pure, it forms a clear solution with water.

Aldol bears a heat of 100° without sensible alteration, and distils undecomposed at 90° , under a pressure of 2 centimeters; but, when heated above 100° , under the ordinary pressure, it begins to decompose at 135° into water and crotonic aldehyde ($C^4H^6O^2 = H^2O + C^4H^4O$), and at 150° nothing remains in the vessel but a small quantity of viscid liquid. The same decomposition takes place when aldol is heated with glacial acetic acid. The formation of crotonic aldehyde by the action of hydrochloric acid on ordinary aldehyde (p. 34) is probably preceded by that of aldol.

Aldol possesses the reducing powers of the aldehydes; it throws down cuprous oxide from a cupric-potassic solution, and reduces ammoniacal silver nitrate, forming a fine silver speculum.

Nitric acid attacks aldol with great violence, giving rise to acetic aldehyde, oxalic acid, and several other acids not yet examined. Chromic acid likewise exerts a violent oxidising action. The action of silver oxide, on the other hand, is more moderate. When 1 mol. aldol is treated with 2 mol. moist silver oxide, the mixture becomes hot, and metallic silver is deposited. If the liquid be then boiled, filtered and concentrated, a silver salt separates out in long interlaced needles; which, when recomposed with hydrogen sulphide, yields β -oxybutyric acid.

Aldol therefore, as pointed out by Kolbe (*J. pr. Chem.* [2] v. 451), is the aldehyde of β -oxybutyric acid. Its formation from two molecules of acetic aldehyde is represented by this equation:

and its resolution into water and crotonic aldehyde by the equation:

By nascent hydrogen aldol is converted into one of the modifications of butylene-glycol, $C^4H^{10}O^2$. A 4 p. c. aqueous solution of aldol is heated at 0° with sodium-amalgam containing 6 p. c. sodium, the soda formed being continually neutralised with hydrochloric acid. The reaction is very slow, and the liquid must be decanted every evening, as otherwise it might become alkaline during the night, and the experiment would then be lost in consequence of the formation of resinous substances and condensation-products. As soon as the absorption of hydrogen ceases, the liquid is to be shaken several times with ether, which removes condensation-products soluble in water, the ethereal solution separated, and the remaining liquid evaporated at 40° . The residue is treated with alcohol, which leaves the greater part of the sodium chloride undissolved; the alcoholic solution is evaporated, and the residue treated with absolute alcohol, which separates a further quantity of sodium chloride.

The alcohol is then distilled off, and the remaining liquid, which distils between 200° and 220°, yields, by rectification, a thick saccharine liquid, boiling at 201°-203°, identical with the butylone-glycol which Kekulé obtained as a secondary product in the hydrogenation of aldehyde (p. 36). The formation of this glycol from aldol is represented by the equation:

When a current of ammonia gas is passed into an ethereal solution of aldol, a syrupy colourless body is precipitated, which dries in a vacuum to an amorphous transparent, semi-resinous mass, consisting of ammonium-aldol, $\text{C}^4\text{H}^7(\text{NH}^4)\text{O}^2$. This compound is very soluble in water, and has an odour resembling that of aldehyde-ammonia.

When a current of hydrochloric acid gas is passed at 10° to the bottom of a concentrated aqueous solution of aldol, the aldol turns yellow and a thick liquid is deposited, insoluble in water, and probably containing monochloraldol ($\text{CH}^2-\text{CHCl}-\text{CH}^2-\text{CHO}$).

Hydriodic acid produces with aldol a thick, yellow, unstable liquid. Phosphorus pentachloride acts very strongly on aldol, forming phosphorus oxychloride and a chlorinated body, probably having the composition $\text{C}^4\text{H}^7\text{Cl}^2$.

Aldol, heated for several days in the water-bath with 3 times its weight of acetic anhydride, combines with it, and water added to the product throws down an oily body, which, when distilled immediately under reduced pressure, is resolved into two acetates, one boiling under a pressure of 2 centimeters at 160°-100°, the other at 150°-160°. The former, which has the composition:

is a viscid, colourless, sensibly neutral liquid, insoluble in water, soluble in alcohol, decomposed by water at 100°, with formation of acetic acid, and resolved by baryta-water at the same temperature into acetic acid and yellow flocks, probably consisting of aldehyde-resin. The second acetate, which distils *in vacuo* at 150°-160°, has the composition $\text{C}^4\text{H}^6(\text{C}^2\text{H}^3\text{O}^2)^2$, and may be regarded as the diacetate of crotonic aldehyde; it is a thick, yellowish liquid, which stains paper like a fixed oil, but not permanently; is insoluble in water, and gives up acetic acid to that liquid when boiled with it. Saponified with baryta-water, it yields the resinous body above mentioned and 2 molecules of acetic acid.

Anhydride of Aldol, $\text{C}^4\text{H}^{10}\text{O}^2 = (\text{C}^4\text{H}^7\text{O})^2\text{O} = 2\text{C}^4\text{H}^7\text{O}^2 - \text{H}^2\text{O}$.—If the liquid obtained by heating aldehyde with water and hydrochloric acid, as above described, be allowed to stand till it acquires a brown tint and opaline appearance, and be then neutralised and treated with ether as before, the ethereal solution leaves saccharine scales which may be separated from the mother-liquid by means of Bunson's vacuum filter. The product thus obtained is the anhydride of aldol, and is probably related to aldol in the same manner as ether to alcohol. It distils at 137° under a pressure of 2 centimeters, forming a colourless, very viscid liquid, soluble in alcohol and ether, slightly soluble in cold water, more soluble in boiling water, which on cooling deposits it in crystals melting at 155°. It easily reduces ammoniacal silver nitrate and Fehling's cupric-potassic solution.

Aldol also loses water when heated for several hours to 60° in a current of dry air; it then thickens and solidifies on cooling to a colourless, transparent, viscid mass, insoluble in water.

Aldol, by its reducing power and by the readiness with which it unites with acids, exhibits considerable resemblance to the sugars. The aldehydes may, indeed, play an important part in the formation of glucose and similar bodies in the vegetable organism. The simplest of the aldehydes, namely, formic aldehyde, $\text{H}.\text{CHO}$, may possibly be formed in the processes of vegetation by the partial reduction of a molecule of water and a molecule of carbon dioxide: $\text{CO}^2 + \text{H}^2\text{O} - \text{O}^2 = \text{CH}^2\text{O}$; and the condensation of several molecules of formic aldehyde may give rise to carbohydrates in the same manner as aldol is produced by the condensation of two molecules of acetic aldehyde. The condensation of two molecules of formic aldehyde would yield the first aldehyde of glycol, $\text{CH}^2-\text{OH}-\text{CHO}$, which is isomeric with glucose.

Benzoin $\text{C}^8\text{H}^{10}\text{O}^2$, is formed by the condensation of two molecules of benzoic aldehyde, just as aldol by that of two molecules of acetic aldehyde. If the two reactions are similar, the constitution of benzoin may be represented by the formula $\text{C}^6\text{H}^4-\text{CHOH}-\text{C}^6\text{H}^4-\text{CHO}$.

Borodin (*Deut. Chem. Ges. Ber.* v. 480) by treating acetic aldehyde with hydrochloric acid obtained a compound resembling Wurtz's aldol, but yielding by distillation chiefly acetic aldehyde, instead of water and crotonic aldehyde.

ALIZARIN. *Preparation.*—For the preparation of pure madder alizarin, the following process is recommended by Wartha (*Deut. Chem. Ges. Ber.* iii. 545, 673). Stuffs dyed with Turkey red are exhausted at the heat of the water-bath; with hydrochloric acid and alcohol; the solution is precipitated with potash; and the precipitate is decomposed with dilute hydrochloric acid and sublimed. Or the stuffs, after being freed from fatty matter by ligroin (light petroleum oil) may be exhausted with alcohol and hydrochloric acid, and the colouring matter precipitated by water. Pure alizarin may also be obtained by macerating the stuffs for two or three minutes in strong sulphuric acid, precipitating with water, and treating the precipitate with potash.

Madder alizarin sublimes between 130° and 140° ; artificial alizarin between 280° and 300° . For the sublimation of alizarin (and of anthracone), Wartha recommends the use of a wide glass tube exhausted by a mercury or water pump.

The peculiar fiery colour of fabrics dyed with Turkey red is attributed by Wartha to a peculiar fatty acid compound of alizarin, which may be extracted with ligroin and ether.

With reference to Wartha's observations, Bolley (*Dingl. polyt. J.* xcvi. 357) remarks that the methods of separating madder colours from dyed fabrics were described long ago by himself and others.

Isalizarin $C^{14}H^{10}O^4$ (Rochleder, *Deut. Chem. Ges. Ber.* iii. 292; *Zeitschr. f. Chem.* [2] vi. 573).—Madder which has been heated with mineral acids, contains, besides alizarin and purpurin, certain yellow crystallised substances which are, perhaps, present in the root in the form of glucosides. Their quantity is small, many thousand pounds of madder being required to yield a few ounces of them. The material, a waste product of a manufacturing operation, was obtained in the form of yellow, hard, light, easily pulverisable lumps. It dissolves with red colour, in caustic soda; and the solution, treated with hydrochloric acid, deposits dirty-yellow gelatinous flocks, which shrink and lose their gelatinous character when boiled with water, so that they can then be easily washed on a filter. The substance thus obtained dissolves in baryta-water, a nearly black powder remaining behind. The blood-coloured solution, neutralised with hydrochloric acid, yields a yellowish precipitate, which dissolves when boiled with glacial acetic acid, forming a reddish-yellow solution, which, if the quantity of acetic acid used was only just sufficient to dissolve the precipitate, solidifies on cooling to a cake of small crystals, which must be washed on a filter with glacial acetic acid as long as the liquid which runs through exhibits the colour of a saturated solution of potassium dichromate. By this treatment an amorphous resinous body, easily soluble in cold acetic acid, is removed, while only a small quantity of the other constituents passes into solution. The lemon-yellow mass remaining on the filter is separated into its constituents by fractional crystallisation, first from dilute acetic acid, then from hot alcohol, partial solution in alcohol, and partial precipitation of the alcoholic solutions with water.

The compound which is present in largest quantity in the mixture, after removal of the resinous body above mentioned, is isalizarin, a body having the same composition as alizarin, but distinguished from it by the blood-red colour of its solutions in caustic potash and soda, and the red colour of its solution in baryta-water. In the solid state it has a colour nearly intermediate between that of alizarin and that of purpurin. It does not dye calico mordanted with iron or alumina.

The isalizarin is accompanied by small quantities of three other bodies, viz.: α . A body bearing a very close resemblance to isalizarin, and having the composition $C^{14}H^{10}O^4$. β . *Hydrisalizarin* $C^{22}H^{18}O^6$, which has a somewhat lighter yellow colour than isalizarin, dissolves with dark brown colour in a boiling solution of ferric chloride, and separates therefrom partly on cooling, partly on addition of a few drops of hydrochloric acid, in light yellow flocks, which exhibit the same composition. γ . A body, $C^{22}H^{20}O^6$, which, when heated for a long time to 118° – 120° , gives off a molecule of water and assumes a darker colour.

Distinction between Alizarin and Purpurin.—When cloth dyed or printed with madder is boiled for a short time with a strong solution of aluminium sulphate, a liquid is obtained which appears red with a bluish tinge by transmitted light and exhibits a gold-green iridescence by reflected light. This appearance is due to purpurin. A solution of alizarin exhibits slight fluorescence only when a beam of light is thrown into it by a lens. Alizarin separates from the solution in aluminium sulphate in the course of twelve hours; purpurin does not. A solution of aluminium sulphate serves in this manner to detect the presence of purpurin and therefore of madder-colour. Alizarin may be detected, in presence of purpurin, by repeatedly boiling the red colour with potassium carbonate, which dissolves the compound of alumina and purpurin. If the colour does not afterwards appear bleached, the presence of alizarin may be

inferred; in that case also the colour is turned violet by immersion in baryta-water (W. Stein, *Zeitschr. f. Chem.* vi. 479)."

Artificial Alizarin.—The following method of preparing alizarin from anthracene paranaphthalene and their homologues is given by A. Girard (*Bull. Soc. ind. de Mulhouse*, xliii. 54; *Dingl. polyt. J.* cciiv. 490). The material used is that which distils between 290° and 360°; it is purified by distillation and pressure, the portion which passes over between 300° and 335° being collected apart. This mixture is treated with potassium chlorate and hydrochloric acid, whereby it is converted into tetrachlorinated products. These are oxidised either by nitric acid in the water-bath, or by a metallic oxide (red or brown oxide of lead), and sulphuric or acetic acid. In the first case, a mixture of dichloranthraquinone and chloride of chloroxyanthranil are obtained. These substances are treated, in presence of a metallic oxide (zinc oxide, cupric oxide, or litharge), with an alcoholic solution of sodium acetate. The metallic oxide removes the last atom of chlorine from the sodium chloroxyanthranilate, and converts it, like the dichloranthraquinone, into alizarin.

The purification is effected by means of benzene, petroleum, &c., which dissolve out the foreign matters, and by successive precipitation from the alkaline solutions by mineral acids. The foreign matters may also be separated by means of a little alum, when it is necessary to work with neutral potash or soda salts.

The following method has been patented by Dale & Schorlemmer (*Deut. Chem. Ges. Ber.* iii. 838):—1 pt. of anthracene is boiled with 4 to 10 pts. of strong sulphuric acid, then diluted with water, and the solution neutralised with carbonate of calcium, barium, potassium or sodium. The resulting sulphates having been removed by filtration or crystallisation, the solution is heated to 180°–260° with caustic potash or soda, to which a quantity of potassium nitrate or chlorate has been added, about equal in weight to the anthracene—as long as a blue-violet colour is thereby produced. From this product the alizarin is separated in the usual way by precipitation with acid.

On Artificial Alizarin, see also *Deut. Chem. Ges. Ber.* iv. 978; *Chem. Soc. J.* [2] x. 621, 622.

On a secondary colouring matter produced in the manufacture of Alizarin from Anthracene, see ANTHRAPHURPURIN.

Red Colour-printing with Artificial Alizarin.—A. Müller (*Chem. Centralblatt*, 1871, 304) obtains a red, similar in tint and purity to Turkey red, from anthracene-alizarin by a process of direct printing.

The pigment (containing much anthrapurpurin) in a pasty form, and having 25 p.c. of dry material, is dissolved in boiling spirit in the proportion of 1 : 5, and immediately mixed with a concentrated solution of aluminium chloride of which the pure $AlCl_3$ is to the weight of the colouring matter as 1 : 3. The liquid is thickened with a little tragacanth, and for every half litre of this mixture, 30 c. c. of a solution of the best olive-oil in sulphuric acid and a little spirit (15 : 1 : 15) is stirred in. This solution must be as thin as possible, but thick enough to withstand the capillarity of the cloth. The cotton cloth with which this colour is to be used is first impregnated with a solution of aluminium acetate of about 8° B., and after drying and two days' airing, is passed through a soap-bath containing 30 grams of Marseilles soap to the litre of water, then well washed out and dried.

The cloth printed with the above mixture is now exposed to strongly ammoniacal steam at a moderately high pressure, passed through a weak soap-bath, washed in a stream, and passed through the following series of liquids:—1. Cold nitric acid, 3 c. c. to 1 litre water. 2. Washed in stream. 3. Cold nitric acid, 5 c. c. to 1 litre water. 4. Tin salt, $\frac{1}{2}$ gram tin salt to 1 litre water at 30° C. 5. Washed in stream. 6. Liquor of Javelle, 15 c. c. of 8° B. to 1 litre water, cold. 7. Thorough washing. The colour is now thoroughly developed, and behaves to light, air, and soap like ordinary Turkey red. In preparing the aluminium chloride (by addition of barium chloride to aluminium sulphate) it is absolutely necessary to avoid an excess of the barium salt.

Bromalizarin, $C^{14}H^7BrO^4$, is formed by heating alizarin and bromine together with carbon sulphide to 170°; in the dry state the two substances do not act upon each other. By crystallisation from glacial acetic acid, the bromalizarin is obtained in orange-red needles; it dissolves in caustic alkalis with a blue-violet colour, similar to that obtained with alizarin, and giving a similar absorption-spectrum. Bromalizarin dyes a redder violet with iron mordants, and a browner red with alumina mordants than alizarin (Perkin, *Chemical News*, xxvii. 317).

Diacetyl-alizarin, $C^{16}H^{12}O^6 = C^{14}H^7O^4 \begin{Bmatrix} OC^2H^3O \\ OC^2H^3O \end{Bmatrix}$, isomeric with diacetyl-anthraflavic acid, is formed by heating alizarin with acetic anhydride for some hours to 180° in a sealed tube. It separates on cooling as a yellow crystalline substance, which may be purified by heating it with water, drying, and recrystallising two or three times.

from alcohol. It is then obtained as a pale yellow substance, crystallising in flat needles or plates. It melts at 160° , or 68° lower than diacetyl-anthraflavic acid, and is much more soluble than the latter in alcohol and in glacial acetic acid. By heating with alcoholic potash, it is decomposed, with formation of potassium alizarate (Perkin, *Chem. Soc. J.* [2] xi. 21).

When diacetyl-alizarin is added gradually and in small quantities to nitric acid of sp. gr. 1.5, a solution is formed, which, on being slowly added to a large quantity of cold water, deposits a precipitate which dissolves in glacial acetic acid, and crystallises therefrom in needles. This substance dyes alumina mordants a bright orange colour, and iron mordants of a very red purple. The colours are superior to those produced by the nitro-derivative obtained in like manner from anthrapurpurin. It dissolves in alkalis with a purple colour, and the solution gives a spectrum showing a considerable absorption in the orange, which appears to consist of two indistinct bands. It does not appear to be identical with the nitroxyalizarin obtained by Strecker (*Bull. Soc. Chim.* [2] xi. 280), as that substance forms red solutions with alkalis (Perkin, *Chem. Soc. J.* [2] xi. 430).

Methyl-alizarin, $C^{12}H^{10}O^1 = C^{14}H^4(OH)(OCH^3)^2O^2$.—This compound may be prepared by treating artificial alizarin with a mixture of methyl iodide, caustic potash, and a little methyl alcohol in closed tubes, at a moderate temperature, evaporating the contents of the tubes to dryness, and treating the residue successively with water, alcohol, and dilute caustic potash. The second residue, which was found to consist mainly of the potassium compound of methyl-alizarin, $C^{14}H^4(OK)(OCH^3)^2O^2$, is treated with hydrochloric acid, and the insoluble orange-coloured flocks dissolved in boiling alcohol. The alcohol, on cooling, deposits crystalline needles of methyl alizarin.

Methyl-alizarin crystallises in long reddish-yellow needles, which are almost insoluble in boiling water, but readily soluble in oil of vitrol. It volatilises entirely by heat, yielding a sublimate of lustrous yellow scales. It dissolves without decomposition in a boiling solution of caustic potash, but when carefully fused with that alkali, it is converted into alizarin. It differs essentially from alizarin in the appearance of its spectrum, its solution in caustic potash showing no trace of absorption-bands, but only a general obscuration of the green part of the spectrum. The solution in strong sulphuric acid, however, shows an absorption-band between the green and the blue, similar to, but less distinct than that exhibited by a solution of anthraflavic acid. It differs also from alizarin in not being capable of dyeing mordanted cloth, while it resembles anthraflavic acid in its capability of forming crystallisable potassium and sodium compounds (Schunck, *Chemical News*, xxvii. 171).

ALIZARIN-SULPHONIC ACID. Alizarin heated with fuming sulphuric acid forms a sulpho-acid, whose salts are about as soluble as the corresponding sulphates. When fused with potash it yields alizarin.

ALKALIS. On Alkanna-red as a test for Alkalis, see **ALKANNA**.

Respecting the determination of Alkalis in silicates, see **SILICATES**.
On the heat evolved in the electrolysis of Alkaline Bases, see **HEAT**.

ALKALOIDS. Bourgoïn (*Bull. Soc. Chim.* [2] xii. 438) has examined the action of the electric current on the neutral and acid sulphates of atropine, brucine, codeine, quinine, and strychnine, with the following results:—

1. The current decomposes the salts of organic bases in the same manner as inorganic salts—that is to say, the basic element goes to the negative pole, while the remaining constituents of the salt are eliminated at the positive pole.
2. In an acid, and also, though less easily, in a neutral solution, the same colour is produced by the action of the current as by addition of nitric acid, whence it follows that those colours are quite independent of the production of a nitro-compound.
3. The gas evolved at the positive pole does not consist entirely of oxygen, but contains also carbon monoxide and dioxide, sometimes in equal volumes.
4. Besides these gases, various products are formed, chiefly compound ammonias, formed by decomposition of the alkaloids under the influence of oxygen, which produces a gradual combustion, more energetic as the solution is more acid.

Reaction of Alkaloids with Sugar and Sulphuric acid.—*Morphine* is at once coloured a beautiful purple-red, when a small quantity of the mixture of the base (or its salts) with 6 or 8 pts. of sugar is treated with concentrated sulphuric acid. No browning of the sugar is observed. The colour lasts from $\frac{1}{2}$ –1 hour, then gradually becomes blue, violet, dirty blue-green, and lastly, dirty-yellow. This series of colours can be rapidly produced by adding a little water. 0.00001 gram can be clearly indicated by this reaction. Dilute solutions of morphine are to have about as much sugar added as will dissolve in them, and then to be brought in contact with sulphuric acid, when a beautiful rose-red zone will develop itself where the two liquids meet.

Codeine closely resembles morphine, except that the reaction succeeds best when the sulphuric acid is not the most concentrated. Codeine is distinguished from morphine by being readily taken up by chloroform from an alkaline solution.

Aconitine is coloured a beautiful rose-red, soon becoming dirty violet and brown. The aconitine is to be stirred with a drop of sulphuric acid, and then a drop of concentrated sugar-solution brought in contact with it. There is a certain degree of resemblance between the reactions of aconitine and those of morphine and codeine. It is distinguished, however, from them by Dragendorff's process for separating the alkaloids; codeine and aconitine are taken up by benzene from an alkaline solution, but not morphine; aconitine is quite insoluble in water; codeine dissolves easily, especially in hot water.

Delphinine, intimately mixed with a drop of sugar-solution on a porcelain plate, gives also a characteristic reaction, when a small drop of sulphuric acid is dropped into the middle of it. The acid becomes yellow, then yellowish-brown with a dirty-green border, and on addition of a small drop of water, assumes a magnificent green colour, which soon passes into a dirty green, and then into brown.

The behaviour of *narcotine*, *narceine*, *cinchona-bases*, *strychnine*, *brucine*, *atropine*, *colchicine*, *emetine*, and *picrotoxine* is not characteristic (R. Schneider, *Pogg. Ann.* cxlvii. 128).

Reactions with Ceroso-ceric oxide.—This oxide exhibits characteristic colours with several alkaloids, especially with *strychnine*. When strong sulphuric acid is poured upon strychnine, and then a small quantity of ceroso-ceric oxide added, a fine blue colour is produced, similar to that which strychnine exhibits with potassium bichromate, but much more permanent. The blue colour gradually changes to cherry-red, and then remains unaltered for several days. This reaction is capable of detecting 1 pt. of strychnine in a million pts. of liquid. *Brucine*, similarly treated, acquires an orange-colour gradually changing to yellow; *morphine*, olive-brown, finally brown; *narcotine*, brown cherry-red, finally wine-red; *codeine*, olive-green, finally brown; *quinine*, pale-yellow; *cinchonine* and *theine* remain colourless; *veratrine* becomes reddish-brown; *atropine*, dingy yellowish-brown; *solanine*, yellow at first, finally brownish; *emetine*, brown; *colchicine*, first green, then dirty-brown; *aniline*, after a long time, acquires a blue colour extending from the edges inwards; *conine* becomes light-yellow. *Piperine* colours the sulphuric acid blood-red, and is turned dark-brown, almost black, by the cerium oxide (Sommerschein, *Deut. Chem. Ges. Ber.* iii. 632).

Reaction with Cyanides.—According to Flückiger (*Chem. Centr.* 1872, 741), the hydrocyanides of the alkaloids cannot be prepared by double decomposition with metallic cyanides or by the action of hydrocyanic acid on their alcoholic, aqueous, or alkaline solutions, the precipitates so formed consisting only of the pure bases.

Reaction with Picric acid.—According to Hager (*Zeitschr. Ann. Chem.* ix. 110), this acid is a very good precipitant for alkaloids, affording a very delicate test for many of them, and may, perhaps, also serve for separating them one from another. The precipitation takes place even in solutions containing a large excess of sulphuric acid, and is sometimes complete. *Precipitated* are: brucine, strychnine, veratrine, quinine, quindine, cinchonine, most of the opium alkaloids, aconitine (?); *not precipitated*: morphine, atropine (English); pseudo-morphine, caffeine, and all glucosides.

Compounds of Alkaloids with Bile-acids.—The gall of oxen, pigs, and dogs, and the sodium salts of glyco-, hyoglyco-, and tauro-cholic acids, give crystalline precipitates with some alkaloids, amorphous with others; the precipitates usually contain excess of acid, and are decomposed by diffusion, and dissolved by hydrochloric acid, re-appearing on neutralisation; excess of bile or bile-acids also dissolves them. The salts of strychnine, brucine, quinine, cinchonine, veratrine, emetine, and quindine give difficultly soluble compounds, while those of morphine, nicotine, and conine are easily soluble; the strychnine and quinine compounds are about as energetic physiologically as the nitrates and hydrochlorides of these bases respectively (W. F. de l'Arbre, *Chem. Centrbl.* 1872, 231).

ALKANNA. Böttger (*J. pr. Chem.* cvii. 146) recommends alkannin or alkannared as a very delicate test for alkalis, especially for ammonia. Strips of paper dyed red with alcoholic solution of alkannin are instantly turned blue, when moistened, by mere traces of ammonia. The same papers, turned blue by a dilute solution of sodium carbonate, serve for the detection of the smallest traces of free acid. The papers may be preserved unaltered for any length of time in glass vessels.

J. B. Enz (*Jahresb.* 1870, 935) prepares these red papers by exhausting dried alkanna root with about 4 parts of ether at ordinary temperatures, filtering, and dyeing strips of Swedish filter-paper with the splendid ruby-coloured solution.

ALLOPETRE. See PEPTONES.

ALLANIC ACID, $C_4H_5N_3O_5$. (E. Mulder, *Ann. Ch. Pharm.* elix. 353).—An acid produced by the action of nitric acid on allantoin. It is best prepared by gradually

adding powdered allantoin to red fuming nitric acid in a well-cooled porcelain dish till the whole is dissolved. On leaving the solution to stand for some time, till a crystalline crust forms on the surface, and recrystallising this crust from water, allantoic acid is deposited in beautiful stellate groups of needles, consisting of a hydrate $C^4H^4N^4O^5 \cdot H^2O$ isomeric with nitrate of allantoin $C^4H^4N^4O^5 \cdot HNO^3$.

Allantoic acid has an acid reaction, is sparingly soluble in cold water, and decomposes gradually when its aqueous solution is evaporated. The crystals give off their water gradually at ordinary temperatures, more quickly when heated in a test-tube to about 90° , becoming dull at the same time.

Allantoic acid decomposes at 210° – 220° without fusion or evolution of red vapours. It chars when heated on platinum-foil. It does not bleach indigo-solution when mixed with hydrochloric acid, or give off gas with nitric acid containing nitrogen tetroxide. It does not give a precipitate with calcium chloride, even on addition of ammonia. It is precipitated by silver nitrate on addition of ammonia, and by basic lead acetate, but not by the neutral acetate.

Allantoic acid is monobasic. It dissolves readily in ammonia at ordinary temperatures, and the solution on standing deposits well-formed prisms of the ammonium salt $C^4H^4(NH^4)^1N^4O^5$. From the concentrated solution of this salt allantoic acid is precipitated in stellate needles of the hydrate above described. Allantoic acid decomposes potassium carbonate, and the solution, after a while, deposits prisms of potassium allantate. The silver salt is obtained on adding silver nitrate to ammonium allantate, as an amorphous precipitate, which dissolves in warm water, and is deposited on cooling in crystals having the composition $C^4H^4AgN^4O^5 + H^2O$: its ammoniacal solution is decomposed by exposure to light, and deposits metallic silver. It does not detonate, even when heated. The neutral lead salt, $Pb(C^4H^4N^4O^5)^2 \cdot H^2O$, is obtained by gradually adding neutral lead acetate to a saturated solution of allantoic acid, as a warty mass which does not lose weight at 130° . A basic lead salt is obtained by adding basic lead acetate to an excess of allantoic acid; after drying at 100° in a stream of dry air, it has the composition $Pb(C^4H^4N^4O^5)^2 \cdot PbH^2O^2$. Another basic salt, containing $2Pb(C^4H^4N^4O^5)^2 \cdot 5PbH^2O^2$, perhaps a mixture of $Pb(C^4H^4N^4O^5)^2 \cdot 2PbH^2O^2$ and $Pb(C^4H^4N^4O^5)^2 \cdot 3PbH^2O^2$, is obtained by precipitating allantoic acid with excess of basic lead acetate, and drying the precipitate at 100° in a stream of air. The barium salt crystallises with difficulty; the magnesium salt apparently not at all.

Allantoic acid appears not to have the constitution of nitro-allantoin, $C^4H^4(NO^2)N^4O^4$, inasmuch as it is not reduced by hydrogen sulphide in a strongly ammoniacal solution; moreover, it is less easily reduced than allantoin by a strong solution of hydrogen iodide; and its silver salt is not explosive.

ALLANTOIC ACID. $C^4H^4N^4O^5$ (E. Mulder, *Ann. Ch. Pharm.* cliz. 362).—An acid produced by addition of the elements of water to allantoin ($C^4H^4N^4O^3 + H^2O$): it was obtained in an impure state by Schlieper, who called it *hydantoic acid* (iii. 177); that term, however, is now more appropriately applied to the acid $C^4H^4N^4O^3$, formed by hydration of hydantoin (1st Suppl. 702).

A solution of allantoin in aqueous potash which has stood for some days, no longer gives a precipitate with acetic acid even after some time; but if acetic acid be added to acid reaction, then a little alcohol, and the liquid be left in an exsiccator over lime, the potassium salt of allantoic acid, $C^4H^4KN^4O^5$, gradually separates in hard crusts, composed of stellate crystals, which, after recrystallisation, exhibit a neutral reaction. The solution of this salt gives crystalline precipitates with neutral lead acetate and silver nitrate; no precipitate with barium chloride till alcohol is added, whereupon a curdy and very hygroscopic precipitate is formed.

ALLANTOIN. $C^4H^4N^4O^3$ (E. Mulder, *Ann. Ch. Pharm.* cliz. 349).—In preparing this compound by Liebig & Wöhler's method, namely, oxidation of uric acid with lead dioxide (i. 130), the yield is found to be increased by using about one litre of water to every 25 grams of uric acid, instead of the smaller quantity usually recommended. The greatest yield is obtained by effecting the decomposition at the ordinary temperature. 100 grams of uric acid are stirred up with 1 to 2 litres of water, a small quantity of acetic acid is added to start the reaction; the necessary quantity of lead dioxide is gradually introduced; and the mixture is exposed to bright daylight.

For 100 grams of uric acid the dioxide from 1.5 kilogram of red lead is required; both the dioxide and the uric acid are employed in the dried state. The decomposition being ended, the whole is heated and filtered, and the residue is repeatedly exhausted with warm water; the filtrates, to which a small quantity of acetic acid is added, are evaporated and filtered. On cooling, the allantoin separates out, and a further quantity is obtained on concentrating the mother-liquor. 100 grams of uric acid thus treated yield 30–32 grams of pure allantoin.

The formation of allantoin is usually expressed by the equation :

according to which 100 grams of uric acid should yield 92 grams of allantoin, and the loss is supposed to be due to further partial oxidation by the peroxide. Mulder finds, however, that allantoin is *not* perceptibly decomposed by lead dioxide at the ordinary temperature, and only with extreme difficulty on heating. He believes that the formation of dialuric acid precedes that of allantoin, probably according to the equations :

In this case 100 grams of uric acid should yield 46 grams of allantoin. It has, in fact, been shown by Gibbs that dialuric acid may be converted into allantoin by oxidation, viz. by the action of nitrous acid (I. Suppl. 544).

Schliöper (*Ann. Ch. Pharm.* lxxvii. 214) prepares allantoin by oxidising uric acid with potassium ferricyanide, the uric acid being dissolved in potash. The yield is about the same as when lead dioxide is used, and the quantity of the red prussiate required is in accordance with the equation above given for the formation of allantoin from uric acid. The formation of the red body from which Schliöper found it difficult to purify his allantoin, is easily avoided by using less water than he directs, and neutralising with acetic acid. By the further action of potassium ferricyanide on allantoin in presence of potash, Schliöper obtained his lantanuric acid, $\text{C}^4\text{H}^2\text{N}^4\text{O}^3$ (iii. 467). Mulder was not able to obtain this compound (see the next Article).

Allantoin nitrate, $\text{C}^4\text{H}^2\text{N}^4\text{O}^3 \cdot \text{HNO}^3$, isomeric with hydrated allanic acid (p. 44), is obtained by leaving a mixture of 2 grams allantoin and 3 grams ordinary nitric acid to stand for some weeks over lime. It appears to be amorphous, and is decomposed by water and by alcohol, with separation of allantoin. Allantoin combines also with sulphuric acid.

Potassium-allantoin, $\text{C}^4\text{H}^2\text{KN}^4\text{O}^3$, is obtained by adding potassium hydrate to finely powdered allantoin suspended in water, until complete solution is effected. The solution mixed with alcohol and left over lime, deposits the salt, which, after re-crystallisation from aqueous alcohol, forms a silky, glistening, bulky mass, extremely soluble in water, and having an alkaline reaction; the solution mixed with acetic acid yields, after some time, a precipitate of allantoin.

ALLANTOXANIC ACID. $\text{C}^4\text{H}^2\text{N}^4\text{O}^4$ (van Embden, *Ann. Ch. Pharm.* clxvii. 39).—An acid produced by the oxidising action of potassium ferricyanide on allantoin dissolved in caustic potash :

The colour thereby produced disappears quickly at first, more slowly afterwards; potash must be added from time to time or the oxidation will not go on. Ammonia is evolved during the whole of the reaction, and sometimes a crystalline precipitate of potassium ferrocyanide is formed, which may be dissolved up by water. As soon as the colour becomes permanent—which takes place when 1 mol. ferricyanide, $\text{K}^3\text{Fe}^3\text{Cy}^{12}$, has been added for every molecule of allantoin—the liquid must be acidified with acetic acid. It then deposits a crystalline precipitate of *acid potassium allantoxanate*, $\text{C}^4\text{H}^2\text{KN}^4\text{O}^4$, which may be purified by recrystallisation from hot water. The same salt is produced when potassium allantoxanate is oxidised in like manner by potassium ferricyanide.

Acid potassium allantoxanate dissolves in 116 pts. of cold water. By fractional precipitation with neutral lead acetate, it yields neutral *lead allantoxanate*, $\text{C}^4\text{H}^2\text{PbN}^4\text{O}^4$. The silver salt, prepared in a similar manner, has the composition $\text{C}^4\text{H}^2\text{AgN}^4\text{O}^4$. The *neutral barium salt*, $\text{C}^4\text{H}_2\text{BaN}^4\text{O}^4$, is formed by precipitating the acid potassium salt with baryta-water. From the composition of these salts the acid appears to be bibasic.

The *hydrogen salt*, or *free acid*, obtained by decomposing the lead salt with sulphuric or sulphuric acid, is capable of crystallising, but is very unstable, its solution evolving carbon dioxide even at ordinary temperatures.

ALLANTURIC ACID, $\text{C}^4\text{H}^2\text{N}^4\text{O}^5$ (?) (E. Mulder, *Ann. Ch. Pharm.* clix. 359).—This acid, discovered by Pelouze (i. 132), is obtained in small quantity, together with allanic acid, by the action of dilute nitric acid on allantoin. When allantoin is heated on the water-bath with nitric acid of sp. gr. 1.35, it quickly dissolves, and on

evaporating the solution, a sticky substance is left which solidifies on cooling to a hard transparent amorphous mass. This mass recrystallised from water gives stellate crystals of allanic acid, and on leaving the mother-liquor to stand in an exsiccator, a further quantity of allanic acid crystallises out, together with urea nitrate, gas being evolved at the same time. The syrupy residue having been repeatedly washed with cold water till no further deposition of crystals or evolution of gas took place, the solution was fractionally precipitated with basic lead acetate, whereby a series of precipitates was obtained, one of the later of which gave by analysis 10.6 p. c. nitrogen and 10.9 p. c. carbon (nearly equal quantities), and 17.1 p. c. lead. This is nearly the composition of the lead salt of an acid containing $C^2H^{10}N^4O^4$. Its formation may be represented by the equation:

Polouze assigned to this acid the formula $C^2H^{11}N^4O^4$, but his analysis gave less nitrogen than that required by this formula. Gerhardt (*Chimie organique*, i. 528) proposed the formula $C^2H^4N^4O^4$.

Allanturic acid is also formed, but apparently without allanic acid, by evaporation with hydrochloric acid. The lead salt of the resulting acid gave 10.8 p. c. carbon and 10.8 nitrogen. The quantity of allanturic acid obtained by either process is, however, very small.

ALLOPHANE. A specimen of this mineral from Dehn, near Limburg in Nassau, examined by G. vom Rath (*Pogg. Ann.* cxliv. 594), consists of a principal stalactite 8 centimeters long and about 4 thick, to which are attached a number of smaller ones from 5 to 10 mm. long. It is perfectly transparent and colourless; has a strong lustre inclining to fatty; a conchoidal fracture; and is very brittle. The analysis of the mineral dried at 25° and ignited, gave the following results:—

	LPO	AP ² O ³	CaO	H ² O	
Ignited	37.28	59.76	3.05	—	= 100.09.
Dried at 25°	23.53	37.73	1.92	36.86	= 100.04.

reckoning the small quantity of lime as silicate, $2CaO.SiO_2$, those numbers lead to the formula $Al^2O^3.SiO_2$, or Al^2SiO_3 for the anhydrous, and $Al^2SiO_3.5H^2O$ for the hydrated mineral. About half the water is given off at 100°; nearly half the remainder by prolonged heating to 200°–220°; the rest at a red heat, but not quickly, except at the heat of a lamp urged by the blowpipe.

The specific gravity of the mineral in its natural state is 2.079; that of the ignited mineral 2.406.

ALLOXAN boiled with solution of sodium nitrate and a little acetic acid is converted into sodium oxalurate, which, by prolonged boiling, is resolved into oxalic acid and urea.

Barium alloxanate treated in the same manner yields not quite pure barium oxalate.

Alloxantin boiled with sodium nitrate and acetic acid is oxidised to alloxan (Gibbs, *Sill. Am. J.* [2] xlviii. 215).

ALLYL, or **DIALLYL**. $C^3H^5 = C^2H^3.C^2H^3$.—Wagner a. Tollens (*Deut. Chem. Ges. Ber.* vi. 588) obtained this hydrocarbon in attempting to prepare allyl-benzene by heating together 48 pts. of allyl bromide, 56 pts. bromobenzene, 102 pts. benzene, and 23 pts. sodium to 60°. An energetic action took place which had to be moderated by cooling; and by subsequently distilling the product over a naked flame, a liquid was obtained consisting principally of benzene and allyl, but not containing any allyl-benzene. In another experiment the distillation was effected over the water-bath, and the residue was treated with alcohol; the addition of water then caused the separation of an oily substance, which, on distillation in a current of steam, yielded a small portion of a distillate containing diallyl, but no allyl-benzene, and a thick residue smelling of cinnamon, which deposited crystals apparently consisting of diphenyl. Wagner a. Tollens think it probable that this thick oil, which combined with bromine, contained a polymeride of allyl-benzene.

The diallyl formed as above yielded a *tetrabromide*, $C^6H^{10}Br^4$, which, after purification, melted at 62.5°–63.5°. Now this compound is generally said to melt at 37°. To reconcile this difference, diallyl was prepared: α . By the action of sodium on a mixture of allyl bromide and benzene. β . By Oppenheim's method of treating mercuric iodallyl, C^2H^3HgI , with potassium cyanide (p. 51). γ . By the action of finely divided silver on allyl bromide. Diallyl from these several sources was found to boil

at 58°-60°, and its tetrabromide, after purification, melted at 60°-63·5°, agreeing, therefore, with that obtained by the first method.

The boiling point of diallyl appears to indicate that it is analogous in structure rather to di-isopropyl than to normal dipropyl, its constitutional formula being probably

ALLYL ALCOHOL, $\text{C}^3\text{H}^5\text{O}$, or $\text{CH}^2=\text{CH}-\text{CH}^2\text{OH}$, is formed by the action of sodium on dichlorhydrin (Hübner a. Müller, *Zeitschr. f. Chem.* vi. 344):

According to Tollens (*Ann. Ch. Pharm.* clviii. 104), pure allyl alcohol, carefully dehydrated with lime, boils at 96°-97°, a somewhat higher temperature than that previously given by the same chemist (*L. Suppl.* 9). Its specific gravity, determined at different temperatures, is as follows:

Temp.	Sp. gr.	Temp.	Sp. gr.
0°	0·8079	62°	0·81832
13°	0·86045	75·5°	0·80631
25°	0·85074	87·5°	0·79353
47·5°	0·83107	93·5°	0·78882

These numbers give for the expansion of allyl alcohol by heat, the following formula:—

$$V_t = V_0 + 0·000879t + 0·0000026t^2.$$

This gives, for the specific gravity of allyl alcohol at 97° compared with that of water at 0°, the number 0·7846, whence the specific volume is $\frac{58}{0·7846} = 73·92$, which

agrees well with the theoretical value calculated by Kopp, namely 73·8. Hence it may be inferred that the oxygen of allyl alcohol, which is present as hydroxyl, enters with the atomic volume 7·8; whereas the oxygen of the isomeric body acetone, which is present as CO, has the value 12·2*.

The boiling point of allyl alcohol is the same as that of normal propyl alcohol; the boiling points of the chloride, bromide, iodide, formate, acetate, and other ethers of allyl have likewise been found by Tollens to agree with those of the corresponding normal propylic ethers. The agreement between the boiling points of the corresponding allyl and propyl compounds (except diallyl) may therefore be looked upon as general.

Allyl alcohol oxidised with chromic acid mixture gives off an odour of acrolein, and yields, on distillation, formic but no acetic acid (Rinne a. Tollens, *Zeitschr. f. Chem.* [2] vii. 250).

Allyl alcohol unites with *hypochlorous acid*, forming monochlorhydrin, $\text{C}^3\text{H}^4(\text{OH})^2\text{Cl}$; the yield is however but small, as the greater part of the alcohol undergoes oxidation (L. Henry, *Deut. Chem. Ges. Ber.* v. 449).

Allyl alcohol, heated with an equal weight of potassium hydrate to 105° in a flask with inverted condenser, takes up hydrogen and is partly converted into normal propyl alcohol, while ethyl alcohol, formic acid, and acrylic acid are obtained as secondary products. The formation of normal propyl alcohol by this reaction shows that allyl has the constitution $\text{CH}^2=\text{CH}-\text{CH}^2\text{OH}$, as indicated by the equation:

Another allyl alcohol is, however, possible, namely, that represented by the formula $\begin{array}{c} \text{H}^2\text{C} \\ \diagdown \\ \text{H}^2\text{C} \end{array} \text{CHOH}$. This is, perhaps, the isoallyl alcohol which Berthelot obtained by treating allylene with sulphuric acid, and distilling the product with water.

* According to Buff (*Deut. Chem. Ges. Ber.* iv. 647), the above determination of the atomic volume of allyl alcohol is not quite exact.

The *dichloride of allyl alcohol*, $C^3H^4OCl^2$, which Tollens obtained by direct addition of chlorine to allyl alcohol (1st *Suppl.* 91), is likewise produced: a. By addition of hypochlorous acid to allyl chloride (v. Gegerfeldt, *Ann. Ch. Pharm.* cli. 247; *Deut. Chem. Ges. Ber.* vi. 720).

8. Together with the isomeric compound, dichlorhydrin, $CH^2Cl-CHOH-CH^2Cl$, by passing dry hydrochloric acid into a mixture of glycerin and glacial acetic acid. The two isomerides may be separated, though not completely, by fractional distillation, dichlorhydrin boiling at 174° , allyl alcohol dichloride at about 182° . The latter is best prepared by the action of dry chlorine on allyl alcohol dehydrated with lime (Hübner a. Müller, *Ann. Ch. Pharm.* cli. 168). It is a viscid oil, having a faint ethereal odour, and a specific gravity of 1.355 at 17.5° , soluble in alcohol and in a large quantity of water (v. Gegerfeldt).

Both dichlorhydrin and allyl alcohol dichloride, when treated with caustic soda-solution, which abstracts hydrochloric acid, yield one and the same epichlorhydrin, boiling at $118^\circ-119^\circ$. This is easily explained by the following equation, in which the eliminated chlorine and hydrogen atoms are bracketed:—

This transformation, therefore, does not enable us to decide which of the two isomerides is represented by the symmetrical, and which by the unsymmetrical formula; but the formation of allyl-alcohol dichloride by direct addition of chlorine to the alcohol leads to the conclusion that it has the constitution $CH^2Cl-CHCl-CH^2OH$, which is further corroborated by its analogy to the dibromide.

Allyl-alcohol dibromide, $C^3H^4Br^2O$, oxidised with chromic or nitric acid, is converted into dibromopropionic acid $C^3H^3Br^2O^2$, which, when treated with zinc-dust, is converted into acrylic acid $C^3H^3O^2$. This reaction leads to the conclusion that dibromide of allyl alcohol contains the group CH^2OH , and is represented by the formula $CH^2Br-CHBr-CH^2OH$, which is, moreover, in accordance with its formation from allyl alcohol by direct addition of bromine:—

(Tollens, *Zeitschr. f. Chem.* [2] vii. 305.)

Allyl-alcohol dicyanide, $C^3H^4(CN)^2O = C^3H^4(CN)^2OH$, is obtained by passing cyanogen gas for some time into allyl alcohol, washing with salt water, drying with calcium chloride, and fractional distillation. It is a colourless liquid boiling at $150^\circ-151^\circ$, and having a not unpleasant odour, resembling that of pure ethyl cyanide (Tollens, *Deut. Chem. Ges. Ber.* v. 621).

Di-isallyl alcohol, $C^6H^{10}O^2$ (Hübner a. Müller, *Ann. Ch. Pharm.* cli. 384).—When dry epichlorhydrin is added drop by drop to sodium immersed in anhydrous ether, the ether distilled off at the end of the reaction, the residuo treated with water to remove the excess of sodium, the whole then evaporated to dryness, the residue digested in absolute alcohol, and the alcoholic solution evaporated, a syrupy liquid is left which distils with partial decomposition at $218^\circ-225^\circ$. It has the composition $C^6H^{10}O^2$, and appears to be a polymeride formed from two molecules of isallyl-

alcohol, $\begin{array}{c} H^2C \\ | \\ H^2C \end{array} \begin{array}{c} \diagup \\ \diagdown \end{array} \begin{array}{c} H^2C \\ | \\ CHOH \end{array}$ (p. 47) arranged in a ring. The action of the sodium on the epichlorhydrin first forms the compound $C^3H^5NaO^2$, and on treating this compound

with water, the sodium is replaced by hydrogen, so that the final result may be represented by the equation:

ALLYL ETHERS. The *bromide*, $\text{C}^3\text{H}^5\text{Br}$, or $\text{CH}^2=\text{CH}-\text{CH}^2\text{Br}$, is formed, together with dibromhydrin, by the action of phosphorus bromide on slightly warmed syrupy glycerin (L. Henry, *Zeitschr. f. Chem.* [2] vi. 575). It is also produced from the iodide by the action of cupric bromide in alcoholic solution, a precipitate of cuprous iodide being formed at the same time, and bromine set free:

Part of the liberated bromine, however, unites with the allyl bromide, so that the latter is not obtained pure (Oppenheim, *Deut. Chem. Ges. Ber.* iii. 442).

Allyl bromide heated in a sealed tube at 100° for a few minutes with highly concentrated hydrobromic acid is almost wholly converted into a mixture of two isomeric bodies $\text{C}^3\text{H}^5\text{Br}^2$, separable by fractional distillation. One of these is propylene (methyl-ethylene) bromide $\text{CH}^3-\text{CHBr}-\text{CH}^2\text{Br}$, which, when treated with excess of potash, yields only allylene; the other, which boils at a higher temperature ($160^\circ-163^\circ$ at 719 mm., uncorrected), is trimethylene bromide, $\text{CH}^2\text{Br}-\text{CH}^2-\text{CH}^2\text{Br}$, which with alcoholic potash forms allyl-ethyl oxide. With barium hydrate this bromide yields trimethylene glycol $\text{CH}^2\text{OH}-\text{CH}^2-\text{CH}^2\text{OH}$, a thick, sweet-tasting liquid, boiling between 208° and 218° ; it is the alcohol corresponding to ethylene-lactic and malonic acids (Geromont, *Ann. Ch. Pharm.* clviii. 369).

Diallyl tetrabromide, $\text{C}^6\text{H}^{10}\text{Br}^4$, heated with solid caustic potash, yields a product containing *dibromodiallyl*, $\text{C}^4\text{H}^6\text{Br}^2$. This, when heated with an alcoholic potash solution, is converted into *diallylene*, C^4H^6 , an isomeric of benzene. It is a very refractive liquid, boiling at about 85° . It burns with a luminous and smoky flame, and combines explosively with bromine. With an aqueous solution of silver nitrate, it gives a white, amorphous precipitate insoluble in ammonia and exploding when heated below 100° (Henry, *Deut. Chem. Ges. Ber.* v. 449).

Allyl trichloride, $\text{C}^3\text{H}^5\text{Cl}^3$, is very slowly acted on by chlorine. On dissolving iodine in it, and passing dry chlorine into the heated solution in sunshine, a small quantity of white crystals gradually separates, consisting of perchlorethane, C^2Cl^6 . The action of chlorine on trichlorallyl consists therefore in a destruction of the molecule (Oppenheim, *Deut. Chem. Ges. Ber.* iv. 669).

Allyl cyanide, $\text{C}^3\text{H}^5\text{CN} = \text{C}^3\text{H}^5\text{C}^2\text{N}$.—Rinne a. Tollens (*Zeitschr. f. Chem.* [2] vii. 251) prepare this compound by heating allyl iodide with potassium cyanide to 110° for two days, washing the product, again heating with potassium cyanide, and fractionating after treatment with a few drops of nitric acid. It has a not disagreeable alliaceous odour, boils at $116^\circ-118^\circ$, and is converted by aqueous or alcoholic potash into crotonic acid melting at $71^\circ-72^\circ$. The allyl cyanide thus prepared is therefore identical with that which Will and Körner obtained by decomposition of myronic acid (1st *Suppl.* 525).

A mixture of allyl chloride with a solution of potassium cyanide in allyl alcohol heated to 100° in a sealed tube, yields a small quantity of the compound $\text{C}^4\text{H}^7\text{CN} \cdot 3\text{C}^2\text{H}^5\text{O}$ analogous to the ethyl-compound $\text{C}^2\text{H}^5\text{CN} \cdot \text{C}^2\text{H}^5\text{O}$, which Gautier obtained (*Bull. Soc. Chim.* [2] ix. 2), together with propionitril, by heating a mixture of potassium ethyl-sulphate and potassium cyanide. This allyl-compound boils at $95^\circ-96^\circ$; it has an extremely pungent odour when first prepared, but after purification by repeated washing with dilute hydrochloric acid and with water, it smells more like mustard. Heated to 130° with hydrochloric acid, it yields a thick oil, together with sal-ammoniac.

A compound of allyl cyanide with *ethyl alcohol*, $\text{C}^3\text{H}^5\text{CN} \cdot 3\text{C}^2\text{H}^5\text{O}$, is produced by digesting a mixture of allyl iodide and alcohol with excess of potassium cyanide, and may be separated by fractional distillation. It is a liquid having an agreeable odour like that of allyl cyanide; boils at $173^\circ-174^\circ$. It is decomposed by digestion with potash, yielding crotonic acid, ammonia, and alcohol, but no ethylamine (Rinne, *Deut. Chem. Ges. Ber.* vi. 389).

Allyl-ethyl-oxide, $\text{C}^5\text{H}^9\text{OC}^2\text{H}^5$, agitated in a cooled vessel with cold dilute hypochlorous acid, forms oxethyl-chlorhydrin, or $(\text{C}^2\text{H}^5)^m\text{Cl}(\text{OH})(\text{OC}^2\text{H}^5)^n$, a thick colourless liquid boiling at $183^\circ-185^\circ$ (Henry, *loc. cit.*).

2nd *Suppl.*

E

Allyl-methyl oxide, $C^3H^5OCH^3$, obtained by the action of sodium methylate on allyl bromide, is a liquid boiling at 46° . Its dibromide, $CH^3OC^3H^5Br^2$, boils at 185° , and yields by distillation over solid caustic soda, *methyl-monobromallyl oxide*, boiling at 115° – 116° , together with some *methyl-propargyl oxide*, $CH^3OC^3H^3$.

Allyl-phenyl oxide, $C^6H^5OC^3H^5$, is produced by the action of sodium phenylate upon allyl bromide. It is a colourless, strongly refracting liquid, boiling at 192° – 195° , and having the same density as water. It combines with bromine, but products containing brominated phenyl are formed at the same time (Henry).

Bromallyl and Chlorallyl Alcohols and Ethers (Henry, *Deut. Chem. Ges. Ber.* v. 186, 449).

Monobromallyl acetate, $C^3H^5Br.C^2H^3O^2$, is produced by the action of dibromoglycide or epidibromhydrin, $C^3H^5Br^2$ (which may be regarded as bromallyl bromide, $C^3H^5Br.Br$), upon potassium acetate. It is a mobile liquid, boiling at 163° – 164° , and having a pleasant, refreshing odour; it is not acted upon by the chlorides of phosphorus. By distillation with caustic soda it yields *monobromallyl alcohol*, $CH^3.CBr.CH^2.OH$, a mobile liquid boiling at 155° , and having also an agreeable odour. By the action of phosphorus pentachloride the alcohol is converted into *monochlorallyl chloride*, $(C^3H^5Br)Cl$, a heavy liquid boiling at 120° , and most probably identical with Reboul's chlorhydrobromoglycide.

By heating the alcohol with an alcoholic potash-solution, a distillate is obtained showing the reactions of the propargyl-compounds, and containing most probably *propargyl-alcohol*, C^3H^5OH , which, however, could not be isolated.

Dibromoglycide treated with silver nitrate, yields *monobromallyl nitrate*, $C^3H^5Br.NO^3$, a liquid having an agreeable odour and sweetish pungent taste: $C^3H^5Br.Br + AgNO^3 = AgBr + C^3H^5Br.NO^3$.

By the action of potassium acetate upon dichloroglycide, a mixture of several products is obtained, among them being a small quantity of monochlorallyl acetate; and when dichloroglycide is heated with potassium sulphocyanate, pure monochlorallyl sulphocyanate is produced.

Monochlorallyl sulphocyanate, $(C^3H^5Cl)SCN$, produced by the action of potassium sulphocyanate on dichloroglycide (chlorallyl chloride), is a colourless liquid boiling at 185° , and having a very pungent smell, like that of mustard-oil. It combines quickly with ammonia, yielding *monochlorothiosinamine*, $CS \begin{Bmatrix} NH^3 \\ NH.C^3H^5Cl \end{Bmatrix}$, in colourless crystals, melting at 90° – 91° . *Monobromallyl sulphocyanate* boils at 200° and yields a thiosinamine melting at 110° – 111° .

Monobromallyl-ethyl oxide, $C^3H^5BrOC^2H^5$, is obtained by distilling ethyl-dibromhydrin, $C^3H^5Br^2OC^2H^5$, with caustic soda. It is a colourless liquid having a pleasant smell, and boiling at 130° – 135° . It is easily transformed into propargylether, $C^3H^5OC^3H^3$, by heating it with an alcoholic potash-solution.

Monochlorallyl-ethyl oxide, $C^3H^5ClOC^2H^5$, is formed by the action of alkalis upon ethyl-dichlorhydrin; it boils at 120° .

The formation of these substituted allyl compounds is analogous to that of monochlorpropylene from propylene dichloride. They contain, therefore, the chlorine or bromine combined with the middle carbon atom of the allyl group. This is further proved by the fact, that by the action of sulphuric acid upon pure epidichlorhydrin, monochloracetone is formed, whilst, as Oppenheim has shown, acetone is obtained by acting with sulphuric acid upon monochloro-propylene.

ALLYLENE. C^3H^4 .—On the constitution of this hydrocarbon, see Carstanjen, (*J. pr. Chem.* [2] iv. 419; *Chem. Soc. J.* [2] x. 231). Allylene is converted into propionic acid by the action of aqueous chromic acid, in the same manner as acetylene into acetic acid (p. 4). The reaction appears, however, to take place by two stages, the allylene being first converted into allylene oxide, C^3H^4O , and this, by addition of H^2O , into propionic acid.

Allylene oxide, which is also produced by the action of chromic anhydride on isonally alcohol (prepared by treating allylene with sulphuric acid, &c.), is a mobile neutral liquid, having a pungent odour and boiling at 62° – 63° . It is extremely stable, not being acted on by baryta-water at 150° , or when heated in a sealed tube with syrupy potassium hydrate to 220° or even to 300° . It reduces silver nitrate.

Hydrobromides.—Allylene unites directly and rapidly in the cold, with a concentrated aqueous solution of hydrobromic acid employed in great excess. With an acid marking 66° Baumé, and at 0° , the process is complete in five or six hours. The oily body obtained is *dihydromide of allylene*, $C^3H^4.H^2Br^2$, with a small quantity of the monohydromide. On rectification, a liquid is obtained, having a density of 1.875 at 10° , and boiling at 114° – 115° . This body is isomeric with propylene

bromide, $C^3H^5Br^2$, but has a much less fragrant odour, and appears to be identical with Linnemann's methylbromacetol, or *dimethyl-dibromomethane* $C(CH^3)^2Br^2$. The dihydrobromide, submitted to the action of alcoholic potash, loses one molecule of hydrobromic acid, and is reduced to *monohydrobromide*, $C^3H^4.HBr$, which has a density of 1.39 at 9° , and boils at 48° – 49° . Allylene hydrobromide, though isomeric with bromopropylene, is quite a distinct body, having a lower boiling point, and being much more readily acted upon by a concentrated solution of hydrobromic acid (Reboul, *Compt. rend.* lxxiv. 669).

The monohydrobromide is also formed by the action of alcoholic potash on bromopropylene hydriodide, $C^3H^4Br.HI$. It unites with hydriodic acid, forming *allylene hydrobromide*, $C^3H^4.HBr.HI$, which boils at 147° – 148° , and is identical with the hydriodide of bromopropylene. The combination of hydriodic acid with allylene hydrobromide takes place, however, much more energetically than that of the same acid with bromopropylene. Probably the hydriodic acid in the latter case first transforms the bromopropylene into allylene hydrobromide, and then unites with the latter. Allylene dihydrobromide, $C^3H^4.2HBr$, is identical with bromopropylene hydrobromide, $C^3H^4Br.HBr$, both these bodies, when treated with potash, yielding allylene monohydrobromide (Reboul, *Compt. rend.* lxxiv. 669, 944).

Hydrochlorides.—Allylene also unites directly in the cold with concentrated hydrochloric acid, but much less rapidly than with hydrobromic acid. The oily product is a mixture of mono- and di-hydrochloride of allylene, in which the latter largely predominates. On rectification the dihydrochloride is found to boil at 69° – 70° , and is probably identical with Friedel's methylchloracetol, or *dimethyl-dichloromethane*, $C(CH^3)^2Cl^2$ (Reboul).

ALLYLIN. $C^3H^5O^2 = (C^3H^5)^{'''} \left\{ \begin{array}{l} (OH)^2 \\ OC^3H^3 \end{array} \right.$ (Tollens, *Deut. Chem. Ges. Ber.* v. 68),

—Obtained from the syrupy liquid which remains after the rectification of crude allyl alcohol, prepared by distilling glycerin with oxalic acid. It is a viscid liquid boiling at 225° – 240° , soluble in water, partly decomposed by distillation, with formation of allyl alcohol. Bromine dropped into its aqueous solution unites with it, forming allylin dibromide, $C^3H^5O^2Br^2$, which separates as an oil.

Allylin is distinguished from glycerin-ether, $(C^3H^5)^2O^2$ —likewise a by-product in the preparation of allyl alcohol, and regarded by Linnemann and v. Zotta (*Ann. Ch. Pharm. Suppl.* viii. 252) as identical with it—both by its composition and by its reactions, glycerin-ether not being decomposed by distillation, and not combining with bromine.

ALLYLMERCURIC COMPOUNDS. *Mercuric iodallylide*, C^3H^5HgI , is best obtained by shaking mercury with a mixture of equal volumes of allyl iodide and alcohol. It crystallises from carbon bisulphide and acetone in white scales, which soon turn yellow. It is not acted upon either by phosphorus tribromide or by acetyl chloride or benzoyl chloride. On adding it to a solution of zinc-ethyl in ether, an energetic reaction sets in, the products being mercury, zinc iodide, mercuric ethide, and diallyl:

A solution of potassium cyanide acts on mercuric iodallylide quickly in the cold, according to the equation:

Besides these products, two mercury-allyl compounds are probably formed, one of which is liquid, and explodes when the distillation of the diallyl is not stopped in time.

The mercury compounds of allyl attack the skin, but the action becomes perceptible only after 6–8 hours, when painful blisters appear (Oppenheim, *Deut. Chem. Ges. Ber.* iv. 670).

Mercuric iodallylide heated to 100° in a sealed tube with aqueous potassium iodide, yields metallic mercury, potassio-mercuric iodide, and diallyl:

When a mixture of mercuric iodallylide and allyl iodide is heated with iron turnings to 100° for three days, the greater part of the mercuric iodallylide remains unaltered, and only a small quantity of a substance smelling like diallyl is produced. If the same mixture is heated for a day with granulated zinc, a gas is formed which burns with a bright flame. When moist silver oxide is added to mercuric iodallylide under alcohol, and the mixture is shaken, silver iodide is formed, together with an alkaline solution (doubtless containing the base C^3H^5HgOH), which, when evaporated over

sulphuric acid, yields crystals soluble in water, together with a large quantity of oil; but the reaction is slow and incomplete. The alkaline solution neutralised with acids yields crystalline salts. The chloride C^3H^5HgCl is sparingly soluble and is precipitated on adding hydrochloric acid to the alkaline solution (Krasowsky, *Zeitschr. f. Chem.* vi. 527).

ALLYL-PHENOL. See PHENOL.

ALLYL-PHENYL-FORMIC ACID. See FORMIC ACID.

ALLYL-SULPHONIC ACID, $C^3H^5.H.SO^2$.—When neutral potassium sulphite, dissolved in a small quantity of water, is boiled with its own weight of allyl iodide till the latter disappears, the liquid, on evaporation on the water-bath, leaves a crystalline residue; and on exhausting with boiling alcohol and cooling, a white salt is obtained, which, after washing with alcohol, has the composition of a mixture of potassium iodide and allyl-sulphite, $6KI.7K(C^3H^5)SO^2$. On addition of ether to the alcoholic mother-liquor, a salt of similar appearance is precipitated, which has the composition $2KI.3K(C^3H^5)SO^2$. On addition of lead acetate to the aqueous solution of these salts, lead iodide is precipitated; the filtrate decomposed by hydrogen sulphide, evaporated, extracted with alcohol, and precipitated with ether, yields a salt not quite free from iodine; but a pure salt having the composition $K(C^3H^5)SO^2$ is obtained by decomposing the double iodised compound with warm sulphuric acid, evaporation of most of the excess of acid, extraction with alcohol after neutralisation with potassium carbonate, and precipitation with ether; the product thus obtained is white, indistinctly crystalline, and readily soluble in water.

Barium allylsulphonate is a hygroscopic white mass, soluble in water and alcohol, but not in ether; the *lead salt* crystallises from alcohol in golden crystalline plates (A. v. Rad. *Ann. Ch. Pharm.* clxi. 218).

ALLYL-URETHANES. See SULPHOCARBONIC ETHERS.

ALOES. The two varieties of this drug—namely, Barbadoes aloes, or Liver aloes, *Aloë hepatica*, and Cape or Natal aloes, *Aloë lucida* (1st *Suppl.* 99), contain different crystalline principles, which may be distinguished as barbaloin and nataloin.

Barbaloin, $C^{12}H^{10}O^7$, which is the variety discovered by T. and H. Smith, and examined some years ago by Stenhouse (i. 148), may be prepared by dissolving Barbadoes aloes in boiling water slightly acidulated with hydrochloric acid, and evaporating the filtered liquid to a syrupy consistence; in a few days a lemon-yellow mass of barbaloin results, which may be purified by draining, pressure and recrystallisation. By the action of cold fuming nitric acid it is converted into a mixture of aloetic, chrysammic, oxalic and picric acids, the two former of which are but very slightly soluble in cold water. By prolonged boiling with nitric acid, the aloetic acid is finally converted into chrysammic acid, which may, in fact, be more conveniently prepared in this manner from aloin than from crude aloes (Tilden, *Pharm. J. Trans.* [3] ii. 845; *Chem. Soc. J.* [2] x. 488). Barbaloin fused with caustic potash, yields, in addition to orcin and picroxybenzoic acid (1st *Suppl.* 10), a small quantity of alorcinic acid (*infra*).

Chloraloin, $C^{12}H^{10}Cl^2O^7$, analogous to the bromaloin discovered by Stenhouse, is obtained by gradually adding aloin dissolved in hydrochloric acid to a mixture of potassium chlorate and fuming hydrochloric acid. After each addition of the aloin, a red coloration is produced, which, however, quickly disappears, the solution assuming a clear orange colour, and depositing in a few minutes a copious crop of yellow granules, the quantity of which increases by standing for a few hours. It may then be filtered off, washed with a little water, and crystallised from warm rectified spirit. The tufts of bright yellow prisms which separate in a few hours are collected and dried by exposure to dry air. They bear, without change of colour or general appearance, a temperature of 120° , and even much higher. They give, by analysis, numbers agreeing nearly with the formula $C^{12}H^{10}Cl^2O^7.3H^2O$, the proportion of chlorine being, however, a little too high, probably owing to the presence of a small quantity of a more highly chlorinated compound.

Chloraloin is more soluble in water than bromaloin, and more stable than the original aloin. Thus, although very soluble in aqueous ammonia, it crystallises out but little altered when the ammonia is evaporated, and it may be dissolved in ordinary nitric acid (sp. gr. 1.37) without change of colour. Boiled with nitric acid and silver nitrate, it yields oxalic and picric acids only, without a trace of aloetic or chrysammic acid. In most of the reactions of aloin and of its chloro- and bromo-derivatives, there is a marked resemblance to those of the orcins (Tilden, *Chem. Soc. J.* [3] x. 204).

Nataloin. $C^{24}H^{32}O^{13}$ [$= 2C^{12}H^{16}O^7 + H^2O$].—Natal aloes, moistened with spirit and examined by the microscope, exhibits crystals of a compound which is but slightly soluble in alcohol, so that, on treating the aloes with its own weight of that solvent at 49° , the crystalline principle, nataloin, is readily obtained in a crude state. When purified by crystallisation from hot spirit, it forms thin, bright yellow scales, sparingly soluble in water, benzol, carbon disulphide, chloroform, and ether. It contains no water of crystallisation, melts between 212° and 222° , dissolves in concentrated sulphuric acid, and the addition of a crystal of potassium nitrate to this solution produces a characteristic bright green coloration, rapidly passing through red to blue. Heated with nitric acid it is decomposed, yielding oxalic acid without a trace of picric or chrysammic acid (Flückiger, *Arch. Pharm.* [2] cxlix. 11). According to Tilden, on the contrary (*Chem. Soc. J.* [2] x. 153) it yields picric as well as oxalic acid. The non-production of chrysammic acid shows, however, that this kind of aloin differs essentially from barbaloin.

Another modification of aloin is obtained from crude Zanzibar aloes by slight washing with dilute spirit. When purified by crystallisation from spirit, it forms tufts of needles. It is much more soluble than nataloin, and contains water of crystallisation, $C^{24}H^{32}O^{13} + 5H^2O$, which it loses when dried over sulphuric acid, leaving anhydrous Zanzibar aloin, $C^{24}H^{32}O^{13}$, isomeric with nataloin. It does not appear to form a substitution-product with bromine; neither does it give with nitric acid the deep red colour exhibited by barbaloin (Flückiger, *loc. cit.*).

Lign Aloes, Oil of. See OILS, VOLATILE.

ALOES-RED. On the detection of this colour, see COLOURING MATTERS.

ALORCINIC ACID. $C^{21}H^{16}O^8$ (Weselsky, *Deut. Chem. Ges. Ber.* v. 168; *Ann. Ch. Pharm.* clxvii. 65).—This acid, isomeric with melilotic, hydroparacoumaric, phenyl-licetic, xylic, oxymesitylenic, phloretic, and tropic acids, is obtained, in comparatively small quantity, together with orcin and paraoxybenzoic acid, by the action of melting potash upon aloes, and separates in crystalline masses from the mother-liquors of the paraoxybenzoic acid. It dissolves with difficulty in cold water, but readily in boiling water, in alcohol, and in ether, and crystallises from the boiling aqueous solution on cooling, in bulky concentric groups of long needles. It has a sour, somewhat astringent taste. The air-dried acid melts at 97° ; that which has been dried over sulphuric acid melts at 115° . By distillation it yields an oil which soon solidifies to a crystalline mass of the anhydride $C^{21}H^{16}O^3$, which melts at 138° , sublimes when heated between two watch-glasses, in light-shining laminae resembling benzoic acid, dissolves slowly in water, and is gradually reconverted into the acid—much more quickly, however, in a solution of alkaline carbonate.

The aqueous solution of alorcinic acid is not coloured by ferric chloride, but, if rendered alkaline, it acquires a characteristic cherry-red colour on exposure to the air. With hypochlorites the aqueous acid produces a splendid purple-red colour, which, however, is destroyed by excess of hypochlorite. A neutralised solution of the acid reduces silver nitrate on gentle heating, and separates cuprous oxide on heating from a solution of potassio-cupric tartrate. The acid in dilute solution is not precipitated by neutral lead acetate, but with the basic acetate it forms a white precipitate which gradually turns red.

Alorcinic acid easily decomposes metallic carbonates. Its barium salt, $Ba(C^{21}H^{16}O^3)^2 + 6H^2O$, crystallises in groups of small needles, moderately soluble in water, soluble also in alcohol, insoluble in ether; at 100° it becomes rose-coloured and begins to decompose. The calcium salt, $Ca(C^{21}H^{16}O^3)^2$, is more soluble than the barium salt, and crystallises in anhydrous needles. The copper salt, $Cu(C^{21}H^{16}O^3)^2 + 4H^2O$, is obtained by decomposing the barium salt with cupric sulphate. The green filtrate, if concentrated and stirred, deposits the salt in emerald-green crystals, but if left at rest it is apt to dry up to a green varnish. The crystals are nearly insoluble in water, but dissolve with moderate facility in ether-alcohol. The alorcinates of the alkali-metals are difficult to purify, on account of the sensibility of the acid to the action of oxygen in presence of strong bases.

Alorcinic acid is resolved by fusion with potash into acetic acid and orcin:

Hence it is nearly related to everninic acid, $C^{17}H^{12}O^4$, which likewise yields orcin when fused with potash:

It is probable also that alorcinic acid is one of the first products of the decomposition of aloes by potash, and that the orcin thereby obtained results from the further decomposition of this acid.

Acetyl-alorcinic acid, $C^{11}H^{12}O^4 = C^9H^9(C^2H^3O)O^2$, is produced by the action of acetyl chloride on alorcinic acid, the action commencing in the cold, and being completed, with strong evolution of hydrochloric acid, on application of heat. After the excess of acetyl chloride has been expelled by heating over the water-bath, there remains a thickish residue, which soon solidifies in the crystalline state, is nearly insoluble in boiling water, but may easily be recrystallised from dilute alcohol.

Acetyl-alorcinic acid crystallises in colourless needles easily soluble in ether. It begins to melt at 125° , but decomposes partially at the same time. By distillation it is resolved into acetic acid and alorcinic anhydride.

ALUMINITE. This mineral occurs in many localities near Halle, in white, or more rarely yellowish, crystalline nodules of various shape and size (up to that of the fist), also in strings and plates attached together, between strata and in clefts of the so-called Magdeburg sand. Where this carbonaceous and somewhat pyriteferous sand comes to the surface, and therefore in contact with the air, there is formed, by the mutual action of the atmospheric gases, the finely divided iron pyrites, and the fine particles of lignite and clay (kaolin particles and mica), a hydrated basic aluminium sulphate, namely aluminite. In these sands, which may be called 'aluminite sands,' the aluminite occurs so abundantly, where the conditions are favourable to its formation, that its nodules almost displace the sand (Lasepyres, *Jahrbuch f. Mineralogie*, 1872, 951.)

ALUMINIUM. The reactions of this metal with certain metallic solutions have been examined by A. Cossa (*Il nuovo Cimento* [2] iii. 75, 228; *Zeitschr. f. Chem.* [2] vi. 380, 443).

Copper salts.—A solution of cupric nitrate or sulphate is not acted on by aluminium at first, but in about two days, slowly growing crystals are deposited on the plate, consisting partly of dendrites, but mostly of well-defined octohedrons. From the solution of the nitrate there separates, besides metallic copper, a basic salt in the form of a green insoluble powder. From cupric chloride the copper is immediately precipitated, and likewise from the acetate, though the deposition goes on more slowly. The reduction also takes place immediately when a small quantity of a very dilute solution of an alkaline chloride is added to the sulphate or nitrate, and if a sufficient quantity of aluminium is present the precipitation is complete.

Lead salts.—From solutions of the nitrate or acetate aluminium slowly precipitates the lead in crystals, and immediately from a solution of the chloride. An alkaline solution of lead chromate is immediately decomposed by aluminium, with formation of metallic lead and chromic oxide.

Mercury salts.—From solutions of mercuric chloride, cyanide or nitrate, aluminium first throws down metallic mercury, which then unites with the aluminium, forming an amalgam, which decomposes water at ordinary temperatures, and oxidises in the air with great rise of temperature.

From an alcoholic solution of mercuric chloride the precipitation of the mercury is much quicker than from an aqueous solution, and is attended with considerable rise of temperature. Mercury is also thrown down by aluminium from a solution of mercuric iodide in potassium iodide. Aluminium foil acts very strongly on vapour of mercuric chloride, mercury being set free and aluminium deposited on the colder parts of the tube: the reaction is attended with so much heat that the excess of aluminium melts into globules.

Silver salts.—From slightly acid or from neutral solutions of silver nitrate, aluminium throws down the silver in the form of dendrites. Whether the solution be concentrated or dilute, the precipitation of the silver does not begin till about six hours after the immersion of the aluminium. From an ammoniacal solution of silver chloride the silver is immediately precipitated as a crystalline powder; aluminium also throws down the silver from an ammoniacal solution of silver chromate.

When aluminium is brought in contact with fused silver chloride, great heat is evolved, and silver is separated in melted globules.

Thallium salts.—A plate of aluminium immersed in a slightly acid solution of thallium sulphate, becomes coated in ten days with regular octohedrons of thallium alum. From a solution of thallium chloride at 90° , metallic thallium is precipitated.

Zinc salts.—From an alkaline zinc-solution, aluminium easily separates the metal.

Aluminium Amalgam may be formed either by bringing aluminium in contact with mercury containing a small quantity of sodium (iii. 886), or by Joule's method of

electrolysing the solution of an aluminium salt, with mercury for the negative pole (*Chem. Gaz.* 1850, 339); but the best method is to heat the two metals together in a gas which does not act on either of them. A piece of aluminium foil is placed at the bottom of a thick-walled test-tube, and well-dried mercury is poured upon it, the tube having been previously drawn out in the middle to prevent the aluminium from rising to the surface of the mercury. The air is then expelled from the tube by a stream of dry carbonic anhydride, and the tube is heated without interrupting the current of gas, till the aluminium is completely dissolved.

Aluminium-amalgam decomposes in contact with air or with water more quickly than sodium-amalgam. When a few drops of an amalgam containing but a small proportion of aluminium are left in contact with moist air, gelatinous opalescent excrescences of pure aluminium hydrate are seen to form on their surface, exhibiting, both in their form and mode of growth, considerable resemblance to the so-called Pharaoh's serpents. The aluminium hydrate thus obtained is perfectly soluble in alkalis and acids. When, on the other hand, the amalgam containing a small proportion of aluminium is brought in contact with a large quantity of water, transparent iridescent laminæ, also having a crystalline aspect and consisting of the hydrate $\text{Al}^3\text{H}^4\text{O}^7$, form in the course of two days. These laminæ give up all their water when heated, retaining their crystalline aspect, but becoming much less easily soluble in alkalis and acids (Cossa, *loc. cit.*).

On compounds of Aluminium with Zirconium, see ZIRCONIUM.

An impure chloride of aluminium, containing calcium and sodium salts, and known commercially as 'chlor-alum,' is now much used as a disinfectant.

ALUMS. See SULPHATES.

AMARIC ACID. $\text{C}^{12}\text{H}^{12}\text{O}^7$, or $\text{C}^{12}\text{H}^{10}\text{O}^4, \text{H}^2\text{O}$.—An acid formed, together with deoxybenzoin, when benzamarone is heated for a long time with alcoholic potash, unaltered benzamarone being first deposited; then, on addition of water, deoxybenzoin; and finally after evaporation, potassium amarate, in the form of an oil which solidifies on cooling in white scales insoluble in the excess of potash. From the solution of this salt amaric acid is thrown down by all acids, even acetic, in the form of a white, curdy, crystalline precipitate, $\text{C}^{12}\text{H}^{12}\text{O}^7$, insoluble in cold water, but soluble in boiling alcohol, ether and acetic acid. It loses 1 mol. water at 125° , and melts at 140° , losing a further $1\frac{1}{2}$ mol. of water, and then solidifies in the crystalline form. After being once heated to 140° it melts at 155° , is no longer soluble in 15 parts of 90 per cent. alcohol, dissolves in ammonia at 110° – 120° , also in potash-solution, forming potassium amarate. Potassium amarate, $\text{C}^{12}\text{H}^{12}\text{K}^2\text{O}^6 + 2\text{H}^2\text{O}$, separates from boiling ether, either in luncelle, or as an oil gradually solidifying in warty groups. The barium, lead, and silver salts are curdy, loose, amorphous precipitates, which gradually become heavy and crystalline. The silver salt, $\text{C}^{12}\text{H}^{12}\text{Ag}^2\text{O}^6$, is white and almost insoluble in water and alcohol. The barium salt crystallises well from alcohol. All the salts are bitter (Zinin, *Zeitschr. f. Chem.* [2] vii. 538).

AMBYLONITE. See PHOSPHATES OF ALUMINIUM.

AMBYLSTEGITE. A rhombic mineral from a spheroidal mass, found near Lake Taach. It has the axial ratio $0.971 : 1 : 0.570$, and exhibits the faces, $P, 2P_2, \bar{P}_2, \bar{P}_3, \infty P, \infty \bar{P}_2, \frac{1}{2}P_\infty, \infty P_\infty, \infty \bar{P}_\infty$. Cleavage not determined; fracture conchoidal; lustre adamantine vitreous; colour brown to reddish brown streak grey, inclining to green; hardness nearly equal to that of quartz; not decomposable by hydrochloric acid; difficult to fuse before the blowpipe. The powder, freed by the magnet from intimately admixed magnetic iron ore, has a sp. gr. of 3.454 at 20° . The mineral is also accompanied by oligoclase and mica, less frequently with iron-glance and augite. Its analysis leads to the formula $16\text{RSiO}^3.\text{Al}^2\text{O}^3$ [where $R = 1\text{Mg} + 1\text{Fe}$], which is that of an aluminous augite:

	SiO^2	Al^2O^3	MgO	CaO	FeO
Found	49.8	5.05	17.7	0.15	25.6 = 98.30
Calculated	48.99	5.25	16.35	—	29.41 = 100

(G. vom Rath, *Pogg. Ann.* cxxxviii. 529). V. von Lang, on the other hand (*ibid.* cxxxix. 319), regards the mineral as identical with hypersthene.

AMEROSITE. A resin from Charleston, South Carolina. It is yellowish-brown externally, clove-brown internally; semi-transparent. Melts at 238° , giving off succinic acid and a yellow oil. Burns with a yellowish-white light, with a fragrant odour, and without leaving any ash (C. U. Shepard, *Sul. Am. J.* [2] i. 273).

AMETHENIC ACID. $\text{C}^7\text{H}^{14}\text{O}^2$.—An oily acid, isomeric with ananthylic acid, obtained, together with carbonic and acetic acids and a neutral oil, by the

oxidising action of a mixture of potassium dichromate and dilute sulphuric acid on diamylene. It may be separated from the neutral oil by solution in caustic soda, and precipitation with a mineral acid. It is partially decomposed by distillation, and therefore does not exhibit a constant boiling point, but volatilises with steam without decomposition.

Amethenic acid differs from cenanthylic acid by exhibiting only very feeble acid properties, its salts being decomposed even by carbonic acid. The potassium, ammonium, calcium, and magnesium salts are crystalline and readily soluble in water; the sodium, barium, strontium, and copper salts are amorphous gum-like masses; also very soluble; the mercury, cadmium, zinc, lead and silver salts are white amorphous precipitates.

By subjecting this acid to the further action of chromic acid solution, it is completely oxidised to carbonic and acetic acids, together with a small quantity of a crystalline acid different from succinic acid. When amethenic acid is boiled for several days with concentrated nitric acid, nitrous fumes are evolved, and it is converted into a reddish-yellow oil, which appears to be a nitro-product. On heating amethenic acid with phosphorus pentachloride, hydrochloric acid is evolved, and a colourless, very unstable, oily chloride is formed, which soon turns brown, and evolves hydrochloric acid (W. v. Schneider, *Ann. Ch. Pharm.* clvii. 185).

AMIDODICYANIC ACID. See CYANIC ACID.

AMINES. *Diagnosis of Primary, Secondary, and Tertiary Amines* (Hofmann, *Deut. Chem. Ges. Ber.* iii. 762).—Primary amines are alone capable of yielding isocyanides when treated with chloroform and potash-ley (1st Suppl. 528). This reaction being extremely delicate, and the odour of the isocyanides being quite unmistakable, though it varies to some extent with different radicles, the presence of a primary amine may be easily distinguished. It is only necessary to dissolve a few centigrams of the base in alcohol, and mix the solution with alcoholic potash or soda in a test-tube, and having added a few drops of chloroform, to warm gently. If a primary amine is present, a violent reaction occurs, and vapours of isocyanide, recognisable by their simultaneous effect upon the nose and the tongue, are at once evolved. If in this experiment the characteristic odour of an isocyanide is not perceived, the question remains whether the base under examination is a secondary or tertiary amine. In this case advantage may be taken of the formation of isosulphocyanates. Both *primary* and *secondary* amines, when treated with alcoholic carbon bisulphide, yield isosulphocyanates analogous to mustard-oil, the peculiar odour of which is easily recognisable. The experiment is made by dissolving a few centigrams of the base in alcohol, mixing the solution with about an equal volume of carbon bisulphide, and evaporating a part of the alcohol. The residual liquid is then heated with an alcoholic solution of mercuric chloride. If a primary or secondary amino is present, the irritating odour of the isosulphocyanate is at once perceived. This reaction, however, is not quite general. The first reaction described above is common to all primary amines, whether belonging to the fatty or to the aromatic series; but in the case of the secondary bases, the formation of sulphocyanates takes place only with amines of the fatty series, or with mixed amines. To distinguish between secondary and tertiary aromatic amines, which do not yield sulphocyanate, recourse must be had to the method of treatment with alcoholic iodides; this, however, is very troublesome, inasmuch as considerable quantities of substance must be used, mixed products are frequently obtained, and a weight-analysis must be made after purification; a further disadvantage is, that the whole operation must be repeated for each hydrogen-atom.

The following mode of discrimination, depending on the reaction of amines with aldehydes, is given by Schiff (*Ann. Ch. Pharm.* clix. 158):—

The reaction of aldehydes on primary and secondary amines may be expressed by the following general equations, in which R denotes a monatomic alcohol-radicle:—

These reactions in many instances occur at the ordinary temperature, or at temperatures but little elevated, so perfectly that the water actually separated differs from the theoretical amount by only an inappreciable quantity. The aldehyde most convenient for quantitative estimation based on this principle, an account of its easy purification, high molecular weight, slight volatility, and comparative unalterability, is *cenanthic aldehyde*. A recent estimation of its specific gravity gives the number 0.8257 at 13°, whence its molecular volume is calculated as 139.

139 vols. of cenanthic aldehyde represent, according to the above equations, two

atoms of hydrogen in the form of water, or 0.7 c.c. represents 0.01 gram of hydrogen: hence if the molecular weight of a base (or a multiple thereof) in centigrams be weighed out, every 0.7 c.c. of *œnanthol* employed for perfect action will represent *one* atom of typical hydrogen; or if 69.5 c.c. of *œnanthol* are dissolved in benzene to 100 c.c. then each c.c. of the mixture used will represent *one* centigram of typical hydrogen.

The mode of analysis is as follows: 2 to 4 grams of the base are weighed in a small test-tube, and dissolved in 2 to 3 times their bulk of benzene; a few grams of fused calcium chloride in lumps the size of peas are added, and lastly the *œnanthol* solution is dropped in from a burette divided into $\frac{1}{50}$ c.c.; each drop produces a thick turbidity from separation of water, which is readily taken up by the calcium chloride on gentle agitation; as soon as no more turbidity is produced, the titration is finished.

By this means satisfactory results have been obtained in the titration of aniline, diaminiline, aniline, toluidine, ethylamine, naphthylamine, and toluylendiamine. For example, with *aniline* boiling constantly at 185° to 186°, but containing a small quantity of toluidine,

2.312 grams required	3.4 c.c. <i>œnanthol</i> :	calculated	3.45 c.c.
2.240 "	3.25 "	"	3.34 "

Hence 1 molecule = 93 grams represents 1.95 grams of typical hydrogen, instead of 2 as required by theory.

The same reaction may be employed in the approximate analysis of mixtures of bases; by this means it is shown that distillation alone will not suffice for the separation of diethylaniline and ethylaniline, several per cent. of the latter base being retained; this may, however, be separated by addition of *œnanthol*, as the heptene-diethyl-diphenylamine produced does not volatilise at the boiling point of diethylaniline; similarly ethyl-aniline, though of constant boiling point, always retains a little diethylaniline.

It is necessary that fused calcium chloride be used, the ordinary spongy substance absorbing some of the base, and preventing the complete action of the *œnanthol*; it is best not to add the calcium chloride at first, but to begin by adding a little *œnanthol*, which sets free some water; the calcium chloride is then dropped in, and becomes covered with an aqueous layer, after which the operation proceeds readily; if the calcium chloride be directly added to the dry benzene solution, its surface becomes moistened by the benzene, and the absorption of water proceeds much less quickly. A certain amount of turbidity is always produced on adding *œnanthol* to benzene, even though the latter already contains *œnanthol*; this appearance is in practice distinguishable from the turbidity caused by the evolution of water.

The behaviour of triamines with *œnanthol* has been studied only in the case of rosaniline (see 1st Suppl. p. 908).

Synthesis of Aromatic Monamines by Intramolecular Atomic Interchange (A. W. Hofmann, *Proc. Roy. Soc.* xxi. 47; *Deutsch. Chem. Ges. Ber.* v. 704).—When trimethyl-phenyl-ammonium iodide, $C^6H^3.N(CH^3)^3I$ (prepared from pure dimethylaniline and methyl iodide), is heated in a sealed tube to 200°, no change takes place, but if it be heated for a day to 200°–230° or higher, changes ensue represented by the following equations:—

that is to say, there is formed: first, the hydriodide of the tertiary base, dimethylated methylaniline or dimethyl-toluidine; then the hydriodide of the secondary base, monomethylated dimethylaniline or methyl-xylydine; and, finally, the hydriodide of the primary base, trimethyl-aniline or cumidine. The essential character of the reaction is therefore an intramolecular change in the position of the methyl groups. According to the duration of the process there are incorporated in the benzene-nucleus: first, the methyl group of the alcoholic iodide, and then successively the two methyl groups situated in the ammonia residue or lateral chain. Thus the action of heat on the quaternary ammonium compound affords the means of rising from the benzene series to the toluene, xylene, and cumene series, or generally (for the reaction may probably be utilised in many other cases) of passing from a less carbonated to a more carbonated series of compounds.

1. The products formed at 220°–230° yielded when decomposed by alkalis an oily mixture of bases boiling between 200° and 230°. The lowest boiling fraction finally obtained boiled at 186°, gave a platinochloride agreeing in composition with that of dimethyl-toluidine, and when treated with methyl iodide produced a quaternary iodide

having the composition $C^6H^4(CH^3)_2.N(CH^3)_2I$, which is that of the iodide of trimethyl-tolylammonium.

2. The higher-boiling portions were not completely separable by fractional distillation. Portions collected at the temperatures $200^\circ-203^\circ$, $203^\circ-208^\circ$, $208^\circ-212^\circ$, $212^\circ-220^\circ$, were treated with methyl iodide, whereby crystalline solid products were obtained, which all had the composition of trimethyltolylammonium iodide, and yielded the corresponding platinum salt. These iodides were mixed together, decomposed by silver hydrate, and the resulting hydrates decomposed by distillation. A tertiary base was thus produced, boiling constantly at 205° , and having the same composition as the dimethyl-toluidine boiling at 186° . Hence two isomeric dimethylised toluidines are formed by the action of heat on trimethylphenylammonium iodide.

To decide whether either of these corresponds with the dimethylised toluidine obtained by methylising solid toluidine, some of this latter was prepared from pure solid toluidine by the action of methyl iodide, and was found to boil at $207^\circ-208^\circ$. This was converted into trimethyltolylammonium iodide, which was decomposed by silver hydrate and distillation, furnishing a pure dimethyl-toluidine boiling constantly at 210° . This base resembled in smell the former one boiling at 205° , but differed from the one boiling at 186° . It is thus not improbable that three dimethyl-toluidines have been obtained; but until the dimethylised bases corresponding with the other two toluidines have been investigated, it cannot be said with certainty that the bases boiling at 205° and 210° are really isomeric. All three dimethylised toluidines remained liquid when cooled to -10° .

The above-mentioned fractions between 203° and 220° yielded, on treatment with methyl iodide in excess, not only the crystalline trimethyltolylammonium iodide, but also a small quantity of a base which only combined with methyl iodide with great difficulty. This base boiled at 196° , and gave numbers agreeing with the formula of

dimethyl-xylidine, $\left. \begin{matrix} C^6H^3(CH^3)_2 \\ CH^3 \\ CH^3 \end{matrix} \right\} N$. At 100° it did not combine at all with methyl iodide, but at 150° a small portion became converted into a quaternary iodide, which furnished the platinum salt of trimethyl-xylylammonium.

The formation of dimethylated toluidines and monomethyl-xylidines is due to intramolecular atomic interchange, thus:

The formation of dimethyl-xylidine is due to a secondary reaction, two molecules of trimethylphenylammonium iodide splitting up into the hydriodides of dimethyl-xylidine and monomethyl toluidine:

For comparison, dimethyl-xylidine was prepared by the action of methyl iodide on xyldine from commercial aniline oil. This xyldine, boiled at 216° , and the dimethyl-xyldine obtained from it at 203° , or 7° higher than that from trimethylphenylammonium iodide; it readily united with methyl iodide to form a quaternary iodide.

3. When the isomeric transformation of trimethylphenylammonium iodide was effected at a temperature of about 335° (melting point of lead), a further action was noticed, and also the production of several bye-products by secondary reactions. On distilling with water the acid product of the action, a considerable quantity of hydrocarbons, partly solid, partly fluid, was obtained. When the residue was distilled with caustic soda, a mixture of bases distilled, the principal portion of which boiled at $217^\circ-230^\circ$, and furnished a crystalline hydrochloride, from which was isolated a base boiling constantly at $225^\circ-227^\circ$. This was a cumidine, $\left. \begin{matrix} C^6H^2(CH^3)_2 \\ H_2 \end{matrix} \right\} N$, which was shown to be a primary base by methylation. The dimethyl-cumidine thereby produced boiled at $213^\circ-214^\circ$, and absolutely refused to combine with methyl iodide to form a trimethylcumylammonium iodide. The dimethyl-cumidine and dimethyl-xyldine obtained in the manufacture of dimethyl-aniline, on the other hand, readily unite with methyl iodide, forming quaternary compounds. The cumidine thus obtained from aniline did not yield a trace of colour by the action of corrosive sublimate; but when a mixture of this cumidine and pure aniline was similarly treated, a beautiful carmine-red colouring matter resulted.

Another example of the atomic interchange above described is afforded by the con-

version of aniline into toluidine. When pure aniline hydrochloride is heated to 230°-250° for several hours with methyl alcohol, a yellow transparent honey-like mass is formed, consisting chiefly of methylaniline hydrochloride:

On heating the contents of the tube to 350° for a day, a crystalline hydrochloride is formed by the transformation

in short, *methylaniline becomes converted into toluidine.*

After recrystallisation from water, this toluidine melts at 45°; when, however, the hydriodide of methylaniline is similarly treated, solid toluidine is not formed, but one of the liquid modifications.

The bye-products of the action of heat (about 330°) on trimethyl-phenylammonium contain, amongst other substances, a crystalline primary amine of constitution $\text{C}^6(\text{CH}^3)^3.\text{NH}^2$, and a beautifully crystallised hydrocarbon melting at 136° and boiling at 230°-240°, which gives numbers agreeing with the formula $\text{C}^6(\text{CH}^3)^6 = \text{hexmethyl-benzene}$ (Hofmann, *Proc. Roy. Soc. xxi. 54*; *Deut. Chem. Ges. Ber. v. 720*).

AMMELINE. $\text{C}^6\text{H}^5\text{N}^3\text{O}$. See CYANURAMIC ACIDS (ii. 287).—Triethyl-ammeline, $(\text{C}^2\text{H}^5(\text{C}^6\text{H}^5)^3\text{N}^3\text{O})$, is formed by the action of hydrochloric acid on triethyl-melamine either by prolonged contact in the cold, or by boiling for a short time:

(See 1st Suppl. 808, where ammeline is erroneously printed *ammelide*.)

AMMONIA. *Detection.*—A very delicate test for ammonia is afforded by an aqueous solution of *phenol*. On adding to a liquid containing the smallest quantity of ammonia, or an ammoniacal salt, a few drops of this solution and then a small quantity of a filtered solution of chloride of lime, the liquid becomes green, especially when warmed (Böttger, *N. Reprint. Pharm. xxi. 50*).

Guyot (*Zeitschr. anal. Chem. ix. 253*) recommends, as a test for ammonia, an acid solution of *mercuric nitrate* to which potassium bromide is added till the precipitate formed at first is redissolved, and then caustic potash till a permanent orange-yellow precipitate begins to form. With this solution the smallest traces of ammonia produce a white precipitate which remains floating in the liquid for a while, but soon settles to the bottom. Lime and baryta produce in the same liquid only a faint yellowish white turbidity.

Paper stained with alkanina-red is also a very delicate test for ammonia (p. 43).

Estimation.—W. Knop (*Zeitschr. anal. Chem. ix. 225*) employs for the estimation of ammonia, especially when several determinations are required to be made in a short time, a solution of *barium* or *sodium hypobromite*. The form of apparatus used in the estimation varies accordingly as the nitrogen-compound under examination is volatile or not. For volatile compounds, the reaction-vessel, A, consists of a wide-necked glass flask, which has a capacity of 250 cub. cent., and can be closed by a perforated caoutchouc stopper. Through this stopper passes a glass tube 12 cent. long and 1.5 cent. in diameter, drawn out to a point at the top, and provided with a stop-cock below the point. Into this flask another vessel, B, can be passed with its mouth downwards by means of a looped string. The mouth of this second vessel is cut off in a slanting direction, and is closed by a circular or oval glass plate fitted closely to it by means of tallow-grease.

To perform the analysis, 20 or 40 cub. cent. of the liquid under examination are introduced into the vessel B, which is then filled up to the mouth with water in case it is not already quite filled by the solution; and the glass plate, previously greased, is pressed upon the oblique edge, so as to rest upon it eccentrically. The vessel B is then introduced, with its mouth downwards, into A, into which 50 cub. cent. of the brominated liquid, and a sufficient quantity of water, have previously been poured. The quantity of liquid in the vessel A must be such that the spaces between its surface and the caoutchouc stopper shall not exceed 15 cub. cent. The stop-cock is then opened and the vessel A is immersed in a cylinder of water, the water reaching above the stop-cock, and the whole is left at rest for a few minutes, so that the air in the glass tube may take the temperature of the water. This tube is then connected with a graduated glass tube standing over mercury (the azometer); the glass plate which closes the inner vessel is made to drop off by shaking the apparatus; and after the first violent evolution of gas has slackened, the vessel A, with closed stop-cock, is inverted, so that all the gas may escape out of B. Connection having again been made with the azometer, the vessel A, after agitation for a while, is once more immersed in the water, and the quantity of gas collected in the azometer is read

off. Correction for temperature is indispensable; that for variation of barometric pressure is in many cases quite unnecessary. By working with three such apparatus at once, two ammonia determinations may easily be made in a quarter of an hour. The same method may be used for the determination of the nitrogen in urea.

For the estimation of ammonia and non-volatile nitrogen compounds, glass vessels are used, divided by a vertical partition into two cells, one containing the compound to be examined, the other the brominated solution.

The solution of barium hypobromite for this process is prepared by introducing 600 grams of barium hydrate into 2 litres of water, adding 100 cub. cent. of bromine, agitating, and then immediately pouring in a previously prepared and cooled solution of 300 grams of barium hydrate in a litre of hot water. The bromine disappears immediately, and a golden-yellow solution is formed. In making an experiment, it is advisable to add to the cell containing the brominated solution a few grams of barium hydrate.

The solution of sodium hypobromite is prepared by mixing a previously cooled solution of 100 grams of sodium hydrate in 250 cub. cent. of water with 25 cub. cent. of bromine. Of this solution, 50 cub. cent. diluted with 200 cub. cent. water are sufficient to liberate 130 to 150 cub. cent. gas from a solution of sal-ammoniac. If the quantity of gas evolved in the analysis does not exceed 15 to 20 cub. cent., this quantity of solution will therefore suffice for six or seven determinations in succession. The error arising from absorption of the nitrogen gas is very small.

Solution of Metals in Liquid Ammonia.—According to Seeley (*Chem. News*, xxiii, 160) the alkali-metals dissolve in anhydrous liquid ammonia, without definite chemical action, just as salt dissolves in water, and are left behind with their original appearance and character when the liquid is evaporated. An iron retort, filled with anhydrous chloride of calcium saturated with ammonia at 0°, had a stout glass tube connected with its turned-down neck by means of a screw coupling. This glass tube served to contain the metal or other substance to be acted on by the ammonia. When sodium was subjected to the condensing ammonia, it increased in bulk, became dark-coloured and pasty, and finally formed a homogeneous mobile liquid, of a lively blue colour, both by reflected and transmitted light. On reversing the process by cooling the ammonia-generator, the ammonia gradually evaporates out of the liquid, and the changes observed during the condensation reappear in the reverse order, till at last the sodium is restored to its original bright metallic state. If the evaporation be conducted slowly, the metal is left in crystals. Potassium and lithium behave like sodium. The blue solution of sodium acts as a very powerful reducing agent on metallic salts. The blue liquids obtained in like manner by Weyl (v. 329) and regarded by him as definite alloys of ammonium, were, in all probability, solutions of the several metals in liquid ammonia.

Action of various Metallic Salts on Ammonia-salts.—The action of sal-ammoniac at high temperatures on various metallic oxides and salts was examined by H. Rose (*Pogg. Ann.* lxxiii, 582), who found that, for the most part, chlorides of the respective metals were formed, some of which, e.g. the chlorides of ammonium, iron, &c., were readily volatilised; also that basic oxides of the formula M^xO , such as CoO , NiO , MnO , FeO , and oxides of the formulae $(M^x)^yO$, such as Cu^2O , decompose ammonium chloride, when heated in an aqueous solution, with evolution of ammonia gas and formation of fixed metallic chlorides, whereas not one of the sesquioxides has this power.

Rose also found that borax is not changed when ignited with ammonium chloride; that sodium phosphate is converted into sodium chloride and a little phosphorus chloride, whilst calcium phosphate is not affected; and that alkaline chromates leave chromic oxide and alkaline chlorides.

Bolley observed (*Ann. Ch. Pharm.* lxxviii, 122) that free ammonia is evolved on mixing solutions of borax and ammonium chloride in the proportions of 1 mol. of the former to one of the latter; the solution, when slowly evaporated, deposited crystals requiring five or six parts of water for their solution, and exhibiting the composition $Na^2O \cdot 4B^2O^3 + 10aq.$ or $2NaBO_2 \cdot 3B^2O^3 + 10aq.$ The solution of this salt had no action, either upon litmus or upon turmeric paper, and on the addition of *dilute* sulphuric or nitric acid, gave a white precipitate of boric acid. Bolley also found that an excess of sal-ammoniac converts borax entirely into sodium chloride and boric acid.

Woodcock (*Chem. Soc. J.* [2] ix, 786) finds that various other salts containing fixed bases, when brought together, in the dry state, or in aqueous solution, with ammonium chloride, likewise decompose the latter, with formation of fixed metallic chlorides and evolution of gaseous ammonia.

When 4 mol. sodium metaborate (prepared by igniting borax with sodium nitrate, till the whole of the latter was decomposed) and 2 mol. sal-ammoniac were heated

together in a retort, ammonia was abundantly evolved, and the whole decomposed rapidly and completely, leaving a residuo of baborate and chloride of sodium: thus—

When 2 mol. borax and 2 mol. sal-ammoniac are heated together, Bolley's tetraborate is produced:

Normal and acid borates may be advantageously employed, instead of lime, for liberating ammonia from its salts, the reaction being complete, and not attended with frothing.

Trisodic and hydrosodic phosphate readily decompose ammonium salts, but in the case of the latter, the decomposition is not complete. 3.345 grams of common sodium phosphate distilled from an aqueous solution with .5 gram of ammonium chloride, yielded ammonia corresponding only to 75.69 per cent. of the ammonium chloride employed. This experiment, viewed in connection with the known fact that a solution of microcosmic salt is capable of yielding ammonia when boiled in aqueous solutions, probably giving rise to the formation of dihydro-sodic phosphate, appears to show that the tendency to form acid salts, which is so pronounced in the borates, as to yield (according to Bolley) boric acid by the continuous action of sal-ammoniac upon a solution of borax, does not hold good in the case of phosphates.

The *normal chromates of the alkali-metals*, as well as other soluble and insoluble metallic chromates, evolve ammonia when distilled in aqueous solution with ammonium salts, metallic chlorides being formed, and an acid chromate or bichromate being left, according to the equation:

The quantity of ammonia evolved is, however, always less than the theoretical quantity, probably in consequence of the formation of ammonio-potassic chromate,

The action upon ammonium chloride just described is not confined to normal alkaline chromates, inasmuch as insoluble chromates, such as barium or lead chromate, likewise eliminate ammonia when boiled with sal-ammoniac, with formation of acid chromates; ignited lead chromate appears to eliminate ammonia more quickly than the precipitated chromate.

Ammonia is also given off when normal sodium succinate is heated with sal-ammoniac in aqueous solution: thus—

Normal potassium tartrate and citrate act in the same manner.

On the action of Ammonia on Phosphorus, see PHOSPHORUS.

Quantities of Ammonia evolved from various Animal Fluids under the influence of Potash and of Potassium Permanganate (Wanklyn, *Chem. Soc. J.* [2] x. 646).—When an animal fluid is mixed with excess of potash, and the mixture, after being evaporated down, is kept for some time at a temperature of 160°, a certain quantity of ammonia is evolved, and a further quantity may be obtained by boiling the residue with an alkaline solution of potassium permanganate. For certain animal fluids the quantity of ammonia yielded by a given weight or volume is characteristic; so likewise are the relative quantities of ammonia evolved by the action of caustic potash and of the permanganate. These reactions afford two criteria which may be of some importance in practical biology, especially in enquiries connected with medical jurisprudence.

Of all the animal fluids, urine is the only one that yields a large proportion of ammonia to caustic potash. On the other hand, this liquid is distinguished by the smallness of its yield of ammonia to potassium permanganate.

Milk yields about half as much ammonia to potash as to permanganate.

Blood yields about one-fifth as much ammonia to potash as to permanganate.

White of egg, moist, just as it occurs naturally, gives about one-fourth as much ammonia to potash as to the permanganate.

Gelatin gives no ammonia (or only the least trace) to potash, but a good quantity to permanganate.

It is remarkable, also, that if the preliminary heating to 160° with caustic potash be omitted, and the boiling with permanganate be at once proceeded with, only that

quantity of ammonia is obtained which would have been yielded to permanganate if the entire process had been gone through.

The experiments, which may be performed on very small quantities of liquid, are conducted as follows:—5 cub. cent. of the animal fluid are mixed with water in a 500 cub. cent. flask, and diluted up to the 500 cub. cent. mark, thereby forming a dilute solution, whereof 1 cub. cent. contains $\frac{1}{100}$ cub. cent. of the animal fluid; 5 or 10 cub. cent. of this dilute liquid are usually taken for one experiment, and a small retort fitted to a small Liebig's condenser is used. The retort is heated in an oil-bath, and the ammonia measured by Nessler's test.

The quantities of ammonia evolved from various liquids thus treated are given in the following table:—

Name of fluid	Ammonia by potash at 150° C.	Ammonia by permanganate of potassium
Urine (human)	0.90 gram.	0.05 gram.
Milk of cow.	0.13 "	0.28 "
Blood of sheep	0.46 "	2.20 "
Liquid white of egg (hen)	0.32 "	1.30 "
Dry solid gelatin (100 grams)	0. "	10. "

On the compounds of Ammonia with Ammonium Nitrate, see NITRATES.

On the composition of Ammonium Amalgam, see R. Routledge (*Chem. News*, xxvi. 210; *Chem. Soc. J.* [2] xi. 135).

AMYL ALCOHOLS. On *Normal Amyl Alcohol*, or *Normal Butyl Carbinol*, $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$, see 1st *Suppl.* pp. 106, 1137, and *Chem. Soc. J.* [2] ix. 1033.

Isoamyl Alcohol, or *Isobutyl Carbinol*, $\text{CH}_3\text{CH}(\text{CH}_3)_2\text{CH}_2\text{OH}$.—This alcohol, prepared by fractional distillation of beet fusel-oil, and carefully purified by means of the ordinary dehydrating agents, was found by Pierre a. Puchot (*Bull. Soc. Chim.* [2] ix. 1033) to exhibit the following physical properties:—*

Boiling point, 130–130.1° under normal pressure. Index of refraction for the middle orange ray = 1.411. Rotation of a polarised ray (what colour?) in a tube 20 cm. long = 8.5° to 8.9° to the left. Sp. gr. determined directly at 0°, at other temperatures by calculation from the rate of expansion:

Temperature	0°	25°	50°	75°	100°	125°
Sp. gr.	0.826	0.808	0.780	0.768	0.746	0.720.

In a recent communication (*Compt. rend.* lxxvi. 1332) the same chemists give the following determinations of the densities, boiling points, and rotatory powers of several amyl compounds:—

	Density at 0°.	Boiling point.	Rotation in a tube 20 cm. long.
Amyl Alcohol (anhydrous)	0.8255	130°	—8.5°
" " with 6 p.c. water	—	—	—11°
" Valerate	0.874	190°	+40°
" Butyrate	0.8769	170.3°	+8.5°
Butyl Valerate	0.8884	173.4°	+3°
Propyl "	0.8862	157°	+0°
Ethyl "	0.886	135.5°	+12.5°
Methyl "	0.9005	117.5°	+8.5°
Valeric Acid	0.947	178°	+5°
" Aldehyde (pure)	0.8200	92.5°	+6°
" " (crude)	—	—	+18°

They state that, in the course of their experiments, they have never met with optically inactive amyl alcohol; but they say nothing about the means which they adopted for obtaining it. Some of the discrepancies between their own determinations of the optical rotatory power of amyl-compounds and those made by other

* These determinations agree nearly with those of other chemists, excepting as regards the optical rotatory power (see l. 203 and 1st *Suppl.* 107). Nevertheless, Messrs. Pierre a. Puchot appear to think that their own investigations are the first which have afforded satisfactory evidence of the existence of fermentation amyl alcohol, and of the corresponding propyl and butyl alcohol, as distinct chemical species. Moreover, they designate these alcohols as 'Normal Alcohols' (!)

observers are exactly such as might be expected to arise if the amyl compounds on which they experimented were mixtures of active and inactive compounds. Thus Pedler found that active valeric acid turns the plane of polarisation 43° to the right in a tube 50 cm. long, which is equivalent to a rotation of $17\cdot2^\circ$ in a tube 20 cm. long; and Erlonmeyer a. Hell (*Ann. Ch. Pharm.* clx. 257) found a somewhat higher value: namely, $48\cdot7^\circ$ for 50 cm., or $19\cdot5^\circ$ for 20 cm., whereas Pierre a. Puchot find only 5° . On the other hand, the rotation which the latter assign to amyl alcohol, namely, $8\cdot5^\circ$ for 20 cm., is rather higher than that given by Pedler, who obtained a rotation of 17° for 50 cm., or $6\cdot8^\circ$ for 20 cm.

The most remarkable result of Pierre a. Puchot's experiments is, that amyl alcohol containing 6 p.c. water has a rotatory power (-11°) greater than that of the anhydrous alcohol ($-8\cdot5^\circ$).

The numbers in the preceding table show also that isomeric compounds exhibit, in some instances at least, different optical rotatory powers: e.g. amyl butyrate ($8\cdot5^\circ$) and butyl valerate (3°); also valeric aldehyde (6°) and amyl valerate (40°). In the latter case, however, the two compounds are polymeric, not merely isomeric.

According to Popoff (*Dent. Chem. Ges. Ber.* vi. 560), commercial amyl alcohol yields by fractional distillation a portion having a stronger rotatory power than the original liquid.

AMYL HYDRIDE, *Pentane* or *Quintane*, C^5H^{12} .—This hydrocarbon admits of three modifications, viz. :—

- (1) $CH^3-CH^2-CH^2-CH^2-CH^3$
- (2) $\begin{array}{c} H^3C \\ H^3C \end{array} \begin{array}{c} \diagup \\ \diagdown \end{array} CH-CH^2-CH^3$
- (3) $C(CH^3)_4$.

The first, or normal pentane, is contained in the light oils from Cannel and Boghead tar, and in large quantities in Pennsylvanian petroleum; it may be separated by fractional distillation, and boils at $37^\circ-39^\circ$. On passing chlorine into its vapour at the boiling heat, two *pentyl* or *amyl chlorides*, $C^5H^{11}Cl$, are obtained, one boiling at $95^\circ-100^\circ$, the other, which is the chief product, at $100^\circ-102^\circ$. These chlorides, decomposed with potassium acetate, yield *pentene* or *amylene*, C^5H^{10} , boiling at $39^\circ-40^\circ$, and two *acetic ethers* boiling between 135° and 140° ; and these ethers, decomposed by potash, yield normal primary *amyl alcohol*, boiling at $134^\circ-137^\circ$, and converted by oxidation into normal valeric acid, together with a secondary amyl alcohol: viz.

methyl-propyl carbinol $\left. \begin{array}{c} CH^3 \\ C^5H^7 \end{array} \right\} CH\cdot OH$, which yields by oxidation methyl-propyl ketone (Schlorlemmer, *Phil. Trans.* 1872, 111; *Chem. Soc. J.* [2] x. 1085).

The second modification, or isopentane, is obtained by dehydration of ordinary amyl alcohol; or by heating ordinary amyl iodide with water and zinc (1st *Suppl.* 115).

The third modification, or tetramethyl-methane, $C(CH^3)_4$, has lately been obtained by Lwow (*Zeitschr. f. Chem.* [2] vi. 520) by the action of zinc-methyl on tertiary butyl iodide (trimethyl-carbinyl iodide):

The zinc-methyl must be added to the tertiary iodide by drops. The action goes on without application of heat, and the escaping gas must be washed with dilute hydrochloric acid and received in strong, well-cooled alcohol. On diluting the saturated alcoholic solution with water, the gas is given off and may be condensed to a liquid in a well-cooled receiver. To remove adhering hydrocarbons it is treated first with bromine, then with sodium at 100° in a sealed tube. The quantity of the pure product obtained is nearly that required by theory. It might, perhaps, also be prepared by the action of zinc-methyl on dichloropropane, $CH^3-CCl^2-CH^3$.

Tetramethyl-methane is a colourless mobile liquid, which boils constantly at $9\cdot5^\circ$ and solidifies at -20° to crystals resembling sublimed sal-ammoniac. It is remarkable that other highly-methylated compounds (as trimethyl-carbinol, methyl oxalate, durenne, &c.) are likewise crystalline.

AMYLENE, C^5H^{10} .—This hydrocarbon, like the other olefines, might be represented as a molecule in which each carbon-atom is linked to its neighbours by only one unit of affinity, and consequently two units of affinity are unsaturated (see 1st *Suppl.* pp. 117, 718). It is, however, more in accordance with the known relations of these bodies to represent them, in the free state, as saturated molecules having two of their carbon-atoms linked together by two units of affinity, and to suppose that, when they come in contact with chlorine, bromine, &c., this double linking is broken up, the molecule then becoming bivalent, and capable of taking up Cl^2 , Br^2 , O , &c. On this view, the olefines will exhibit isomeric modifications, accordingly as the double

linking of the carbon-atoms takes place in the middle or towards the end of the chain. Amylene, for example, is susceptible of the four following modifications:—

The first of these is the amyleno corresponding to normal amylic alcohol, and probably identical with Wurtz's ethyl-allyl. The second is ordinary amyleno obtained from the amylic alcohol of fermentation. The fourth is obtained from tertiary amyl alcohol or dimethyl-ethyl carbinol, $\text{C}(\text{CH}_3)_2(\text{C}^2\text{H}_5)\text{OH}$, by the action of very strong alcoholic potash. It boils at 35° , unites with bromine, and with hydriodic acid when heated with the fuming acid to 100° , forming dimethyl-carbinyl iodide, $\text{C}(\text{CH}_3)_2(\text{C}^2\text{H}_5)\text{I}$, which is converted into tertiary amyl alcohol by treatment with silver oxide and water (Ermolaïen, *Zeitschr. f. Chem.* [2] vii. 275). The third is not positively known, but is perhaps identical with an amyleno boiling at 25° , which Flavitzky, has lately obtained by treating ordinary amyl iodide with concentrated alcoholic potash (*Ann. Ch. Pharm.* elxix. 205.)

Conversion of Amylene into an Amyl Alcohol by Sulphuric Acid.—According to Berthelot (*Ann. Ch. Pharm.* cxx. 71), small quantities of amyleno hydrate (secondary amyl alcohol) are formed by the action of sulphuric acid upon amyleno. Erlenmeyer (*Zeitschr. f. Chem.* 1865, 362) contradicts this statement, asserting that nothing but diamyleno is produced by this reaction. Flavitzky, however (*Ann. Ch. Pharm.* clxv. 157), found that when a stream of carbon dioxide charged with amyleno vapour was passed into a mixture of 2 parts sulphuric acid and one of water in an apparatus arranged so as to carry on the process continuously, part of the amyleno was converted into diamyleno, while the rest dissolved, forming a solution from which, on addition of water, an alcohol was separated. This alcohol boiled between 100° and 108° , and more than half of it at 102.4° . No amyleno hydrate was separated from it even by repeated fractional distillation. By oxidation with chromic acid mixture, it yielded common acetone, but no methyl-isopropyl ketone, which is the normal product of the oxidation of amyleno-hydrate. From the boiling point of the alcohol, it probably contained dimethyl-ethyl carbinol (tertiary amyl alcohol), which might be formed if the amyleno contained isomeric modifications.

Diamylene, C^4H^{10} .—This hydrocarbon is most easily prepared by shaking together one volume of pure amyleno with two volumes of strong sulphuric acid and one volume of water in stoppered cylinders immersed in ice-cold water. From the product, which boils at 150° – 170° , pure diamylene may be isolated by fractional distillation. It boils at 150° – 153° under a pressure of 721 mm., and has a specific gravity of 0.8416 at 0° , and 0.8248 at 20° .

A solution of potassium dichromate in dilute sulphuric acid acts slowly on diamylene in the cold, more quickly on heating; the products consisting—besides carbonic and acetic acids—of a neutral and of an acid oil, which may be separated by means of caustic soda.

The acid liquid which volatilises with the steam, consists of amethenic acid, a weak acid isomeric with cinnanthylic acid (p. 56).

The neutral oil may be separated by fractional distillation into fractions boiling between 140° and 210° , and a residue which decomposes on further heating. The chief fraction, which boils between 180° – 190° , has the composition of diamylene oxide, $\text{C}^4\text{H}^{10}\text{O}$. It is a light, mobile, colourless liquid, having a penetrating smell, like that of camphor. It easily reduces an ammoniacal silver solution, but does not combine with sodium bisulphite. It is the first product of the action of chromic acid upon diamylene, and yields by further oxidation, carbonic, acetic, and amethenic acids.

Phosphorus pentabromide does not act on the neutral oil in the cold; on heating, a quiet reaction sets in, hydrobromic acid and the compound $\text{C}^4\text{H}^{10}\text{Br}$ being formed. Probably diamylene dibromide, $\text{C}^4\text{H}^{10}\text{Br}_2$, is first formed, a compound which easily decomposes even at ordinary temperatures (W. v. Schneider, *Ann. Ch. Pharm.* clvii. 185).

Diamylene unites with bromine as readily as amyleno does, and must therefore be supposed to have two of its carbon-atoms linked together by two units of affinity. The same view of its constitution affords an insight into the mode of its further condensation to triamyleno and tetramyleno, and of the formation of rutyleno, C^6H^{14} .

and terebene, $C^{10}H^{16}$, by abstraction of 2 and 4 atoms hydrogen respectively from diamylene. The transition from amylene to diamylene and terebene may be represented by the following formulae:—

In terebene we see the closed ring of the benzene molecule; consequently, a further abstraction of H° will give the molecule $C^{10}H^{14}$, homologous with benzene—in fact, isopropyl-methyl-benzene, which is one of the modifications of cymene; and this transformation has actually been effected. (See CYMENE and TEREBENE.)

The condensation of diamylene to triamylene and tetramylene may be represented as follows:—

Respecting v. Schneider's views of the constitution of diamylene, see *Ann. Ch. Pharm.* clvii. 185; *Chem. Soc. J.* [2] ix. 217.

AMYL-ISETHIONIC, or OXYAMYL-SULPHONIC ACID. $C^5H^9SO^4$ = $C^5H^9(OH)SO^3H$. (F. A. Falk, *J. pr. Chem.* [2] ii. 272).—This acid is formed by the action of amylene-chlorhydrin on sodium sulphite:

The two bodies are enclosed in a glass tube together with a little water, and heated to 120° ; the undecomposed amylene-chlorhydrin is then removed by distillation; the aqueous solution is mixed with the requisite quantity of sulphuric acid; the sodium sulphate precipitated by alcohol; the alcohol evaporated; and the residue freed, first from chlorine by silver sulphate, then from silver by hydrogen sulphide; lastly, the solution is saturated with baryta, and the barium salt decomposed by copper sulphate. The cupric salt thus formed is the most easily crystallisable of all the amyl-isethionates; its solution, decomposed by hydrogen sulphide, yields amyl-isethionic acid, which, however, cannot be obtained in the pure state, as the solution is decomposed by evaporation.

The metallic amylisethionates are more stable, their solutions not being decomposed by boiling. At higher temperatures, however, they decompose the copper salt a little above 100° . They are all very soluble and difficult to crystallise.

The sodium salt $C^5H^9(OH)SO^3Na$ forms thin, white, very deliquescent laminae. The ammonium salt dries up over sulphuric acid to an amorphous mass. The calcium salt $[C^5H^9(OH)SO^3]_2Ca$ crystallises in thin, soft, very soluble laminae; so likewise does the barium salt $[C^5H^9(OH)SO^3]_2Ba$, which decomposes at 130° with formation of barium sulphate. The copper salt $(C^5H^9(OH)SO^3)_2Cu + 2H_2O$ dissolves easily in water and in alcohol, and crystallises in thin, soft, pale blue laminae. The lead salt crystallises with difficulty; the silver salt is very decomposable.

According to E. Schwarz (*Deut. Chem. Ges. Ber.* iii. 691), amylisethionic acid, or an isomeric acid, is produced by the action of sulphuric anhydride on amyl alcohol.

2nd Sup.

F

The anhydride is pressed into a glass tube 3 or 4 inches long and 2 lines wide, and this tube is introduced into a wider one containing cooled amyl alcohol. As soon as all the anhydride is dissolved, the solution is diluted with water, boiled for some hours, saturated with barium carbonate, filtered, concentrated, mixed with alcohol, again filtered, then left over oil of vitriol, and the hygroscopic crystalline mass which remains is purified by recrystallisation from dilute alcohol. The barium salt thus obtained forms distinct crystals easily soluble in water and in alcohol, and swelling up strongly when heated. The aqueous solution does not deposit barium sulphate when boiled.

AMYL-PHOSPHOPLATINOUS ETHER. See PHOSPHOPLATINOUS COMPOUNDS under PLATINUM.

AMYL-PROPARGYLIC ETHERS. See PROPARGYLIC ETHERS.

ANALYSIS. Application of Sulphuretted Hydrogen reactions to Analysis in the dry way (J. Landauer, *Deut. Chem. Ges. Ber.* v. 406).

Characteristic reactions may be obtained by heating the borax bead in which a metallic salt is dissolved, with sodium thiosulphate; but this method has the disadvantage of not being applicable to volatile metals like arsenic and mercury, besides that the production of liver of sulphur causes uncertainty by colouring the bead. Instead, therefore, of proceeding in this way, it is better to heat the substance with the thiosulphate in a test-tube. If the water of crystallisation of the reagent has not been previously expelled, the tube must be held horizontally to prevent the water running back and breaking it.

The annexed table shows that nearly all metallic compounds may be thus identified by means of the sulphide-reactions, aided by those with the ordinary borax bead.

Metallic oxide	With $\text{Na}_2\text{S}_2\text{O}_3$	Cold borax bead	
		In oxidising flame	In reducing flame
Antimony oxide	Red	Colourless	Grey to colourless.
Arsenious acid	Yellow		
Lead oxide	Black	Colourless	Grey to colourless.
Chromium oxide	Green	Yellowish-green . .	Emerald green.
Iron oxide	Black	Yellow	Bottle green.
Gold oxide	Black	Reduced without being dissolved.	Reduced without being dissolved.
Cadmium oxide	Yellow	Colourless	Grey to colourless.
Cobaltous oxide	Black	Blue	Blue.
Cuprous oxide	Black	Blue	Brownish-red (turbid).
Manganese oxide	Bright green . .	Violet	Colourless.
Molybdic acid	Brown	Colourless	Brown.
Nickel oxide	Black	Reddish-brown . . .	Grey to colourless.
Platinum oxide	Black	Reduced without being dissolved.	Reduced without being dissolved.
Mercury oxide	Black		
Silver oxide	Black	Colourless	Grey to colourless.
Uranium oxide	Black	Yellow	Bottle-green.
Bismuth oxide	Black	Colourless	Grey to colourless.
Zinc oxide	White	Colourless	Grey to colourless.
Tin oxide	Brown	Colourless	Colourless.

New Method of Quantitative Inorganic Analysis.—H. Carmichael (*Zeitschr. anal. Chem.* x. 82; *Zeitschr. f. Chem.* [2] vi. 481) points out that the ordinary methods of quantitative analysis are affected by several sources of error, arising not so much from the nature of the processes employed, or from impurity in the reagents, as from the manipulations required, especially the decantation of liquids from one vessel to another,—the separation of a precipitate from the filter, the burning of the filter, and the estimation of the ash being also not unimportant sources of inaccuracy. From an examination of a large number of published analyses, he infers that when 100 parts of a substance are taken for analysis, the sum of the constituents actually found varies from 100.67 to 99.17, or by about 1.5 per cent, while analyses in which it varies from 102 to 97 per cent, are by no means uncommon. Moreover, it is for the most part impossible to say whether the excess or deficiency should be distributed amongst several of the constituents or falls on one only.

To avoid the sources of error above mentioned, Carmichael has devised the following apparatus:—

The apparatus represented in Fig. 2—one-fourth of its actual size—consists of a glass tube twice bent at right angles, and having at one end a funnel-shaped enlargement, the bottom of which is pierced with a number of small holes. The other arm fits into the T-shaped tube BCD, which is closed air-tight at B with a caoutchouc ring. This tube is fixed into the glass plate EF, and is likewise closed air-tight with a caoutchouc ring. The plate EF is covered with a so-called caoutchouc 'cap.' Between B and C is attached a side-tube, bent at right angles at D, so that the spring-clamp which closes the small caoutchouc bag at D may be easily handled.

The 'cap' and the ring B are thinly coated with grease. The edges of the beaker glasses may be easily ground on a plate of sandstone. When the whole is exactly fitted, the cover EF closes so completely that the beaker may be kept air-tight for 24 hours.

FIG. 2.

FIG. 3.

The filter-bulb A (Fig. 3), on the action of which the process mainly depends, is blown at the lower end of a tube 2 mm. in internal diameter; it is then flattened at the bottom, left to cool a little, and while the glass is kept in a scarcely soft state, pierced through the flattened surface with a fine white-hot steel wire. The holes must be close together, and must have a diameter not exceeding 0.7 mm. The width of the edges *a b* (Fig. 3) must be regulated according to the thickness of the paper with which the bulb is to be covered. For ordinary paper it must be 3 mm.; but it is better to use thin Swedish paper, and for this a width of 2 mm. is sufficient. The sieve thus formed is ground. The tube itself is bent in such a manner that the arm B is a little longer than A. The height *bc* must be small, so that the air which rises at the end of the filtration may drive all the liquid before it. For ordinary use, a diameter of 2.5 centimeters is sufficient. The number of holes required is in general about fifty; a smaller number will, however, suffice if they are connected together by narrow gutters etched out with hydrofluoric acid.

The apparatus is connected by means of a thick-walled caoutchouc tube with an exhausting apparatus, the exhaustion being made either with the lips or by a Sprengel pump, or an aspirator, according to circumstances.

To use the apparatus, the air is pumped out, whilst the end A is immersed in water; the rapid stream of water then washes out all impurities, and serves at the same time to rinse out the beaker. A disc of filter-paper of the same diameter as A is then pressed against the lower surface, and remains adhering to it, even when air is blown in again, and does not tear even under full atmospheric pressure. The vessel is now again exhausted, the disc of filter-paper having been previously immersed in the solution, but never to the bottom. When the solution has been filtered, the precipitate is washed a little; the apparatus, with the adhering precipitate, is removed; the remainder is washed into a tared crucible into which the bulb is also dipped, in order to wash it thoroughly. The air is then allowed to pass through the precipitate for some time, whereby the substance is almost completely dried, while gelatinous

precipitates become fissured and shrink together. The spring-clamp is then opened, so as to admit air into the beaker, and the filter-tube is removed both from the crucible and from the cover F E. When the operation has been properly performed, the disc of paper remains upon the precipitate. The upper surface of the bulb appears clean, and only a small ring of the substance remains adhering to the lower edge; this portion may likewise be removed by holding a small piece of filter-paper against the bulb with one hand, while with the other the tube is turned round, and the paper, with the small quantity of the precipitate adhering to it, is brought into the crucible.

The crucible is then covered and heated in an air-bath to 105° . At this temperature the precipitates dry very quickly, and there is no fear of subsequent spitting. The crucible is afterwards heated without its cover till the paper is burnt, and then raised to a red heat.

* In most cases a bulb of the size above mentioned is sufficient; for gelatinous precipitates, however, like alumina and ferric hydrate, a bulb 3.5 centimeters in diameter is better. A small platinum dish, weighing about 28 grams, may also be advantageously substituted for the crucible.

One of the principal advantages ascribed to this method of analysis is the avoidance of loss in the washing and burning of a filter, and of error in estimating the weight of the ash; for as a filter 12 centimeters in diameter yields about 0.0005 gram of ash, the ash of the little discs of paper used in the preceding process cannot weigh more than 0.00002 grams, a quantity altogether inappreciable. Another advantage claimed for this process is the small quantity of substance required for the analysis, 2 milligrams being in fact sufficient, whereby a great saving of time is effected.

The same method may of course be applied to qualitative analysis (Carmichael).

Filtration under pressure may also be effected by means of the diminution of pressure which takes place on the cooling of a close space filled with steam. A cylinder of tin-plate which can be closed air-tight is connected by a glass tube having a glass stop-cock, with a bottle closed by a caoutchouc stopper, through which the neck of the funnel also passes. The cylinder is filled with steam by heating water contained in it, then closed, and brought into connection with the bottle which carries the funnel by opening the glass cock. As the cylinder cools, a partial vacuum is produced in the bottle, and the pressure of the external air forces the liquid through the filter (J. Oster, *Zeitschr. anal. Chem.* xi. 290).

To obviate the tearing of filters which sometimes takes place in filtering under pressure, C. Tiehborne (*Pharm. J. Trans.* 1871, 881) makes use of parchment-paper filters. These stand the pressure either with or without the help of a platinum cone. The only objection to them—namely, that they do not fit so close to the surface of the funnel as filters of ordinary paper do, and consequently permit the passage of air—may be obviated by first placing an ordinary filter in the funnel and the parchment-paper filter within it. For this purpose it is best to use paper converted into parchment-paper on one side only, the unaltered side being placed in contact with the ordinary filter.

To prepare such paper, pieces of Swedish filtering paper are carefully laid on a mixture of 2 parts pure strong sulphuric acid and 1 part distilled water, the mixture, if possible, being used ice-cold, and never while yet warm; care must be taken that every part of the surface comes in contact with the liquid. The paper must afterwards be quickly and thoroughly warmed.

Earthenware Filters.—These are made of very porous earthenware, compact enough, however, to prevent the most finely divided precipitates from running through. They are washed, before use, with hydrochloric acid and water, then dried—and if required for filtering under pressure—they are supported within a glass funnel by means of a piece of sheet caoutchouc passing over the edge of the latter (O. E. Munroe, *Dent. Ges. Chem. Ber.* iv. 279).

Washing of Gelatinous Precipitates.—To accelerate this process, which is long and tedious even with the air of a filter-pump, T. M. Chatard (*Zeitschr. anal. Chem.* xi. 299) mixes the liquids in which such precipitates are formed with a slight excess of the precipitant, and evaporates the whole to dryness, stirring the gelatinous mass with a glass rod till it forms a perfectly dry powder, which may then be easily washed on a filter. Examples given by Chatard of the analysis of potassium dichromate and ammonio-ferric sulphate, in which the precipitated chromic and ferric hydrates were thus treated, exhibit close agreement with the calculated results. Nevertheless, Fresenius thinks that the method cannot be applicable in all cases, inasmuch as the precipitates during evaporation to dryness may very easily enclose foreign matters, which will afterwards be very difficult to remove by washing; in fact, Chatard himself admits that such is the case with carbonate of cobalt.

Calculation of Indirect Analyses.—Let $x + m$ and $y + p$ be two compounds: x and y being the two constituents to be determined; m and p the quantities of the common

constituent whose sum = b , is known; a the sum of the weights of the two compounds: also let K denote the atomic weight of x , N that of y , C that of m and p ; then

$$x = \frac{K}{C} \cdot \frac{b(N+C) - aC}{N-K}$$

$$y = a - b - x.$$

The percentage of x contained in a is:

$$\frac{100K}{aC} \cdot \frac{b(N+C) - aC}{N-K} = \frac{100K}{C(N-K)} \cdot \frac{b(N+C) - aC}{a}$$

This shows at once that $x = 0$ when

$$b(N+C) - aC = 0, \text{ or when}$$

$$\frac{b}{a} = \frac{C}{N+C}$$

If, therefore, in a substance regarded as a mixture of the chlorides of sodium and potassium, the quantity of chlorine found by experiment is to the total weight of the substance as 35.5 : 58.5, it follows that no potassium chloride can be present. The fraction $\frac{100K}{C(N-K)}$ is for the most part of considerable magnitude (in the determination of potassium and sodium chlorides, for example, it is 6.84). Errors in the estimation of a and b have a greater influence on the result in proportion as $N-K$ is smaller; if $N = K$, the method is inapplicable (Casselmann, *Zeitschr. anal. Chem.* ix. 66); compare i. 224.

Oxidation with Nitric Acid and Potassium Chlorate.—F. H. Storer (*Sill. Am. J.* [2] xlviii. 190) recommends this mixture as preferable in most cases to all other oxidising agents commonly used in analysis. Chromic oxide, even after ignition, is easily and completely oxidised to chromic acid, by treating it with nitric acid to which potassium chlorate is gradually added; chrome-iron ore treated in the same manner does not dissolve completely, but the residue, tested by fusion with sodium-carbonate and nitro, is found to be quite free from chromium; metallic arsenic and arsenious acid are easily converted into arsenic acid; cinnabar is oxidised without separation of sulphur; the sulphur in potassium sulphocyanate, vulcanised caoutchouc, anthracite, bituminous coal, and pyrite, is completely oxidised and dissolved; and organic substances in general are so completely oxidised and decomposed, that this method of oxidation may perhaps afford an easy method of determining the carbon by passing the resulting carbon dioxide into baryta-water.

The oxidation in all cases is performed in a porcelain basin on the water-bath, and loss by spitting is prevented by placing in the basin an inverted funnel having its neck bent downwards.

Oxidation with Nitric Acid in Organic Analysis (i. 247).—For the oxidation of the elements of organic bodies other than carbon, hydrogen, and oxygen, Carus (*Deut. Chem. Ges. Ber.* iv. 697) now uses hydrogen nitrate of sp. gr. 1.5, which is easily prepared from the pure red commercial acid of sp. gr. 1.57 by gently heating in an open flask. The quantity used should be from one and a half times to twice that which is actually required for the oxidation according to the equation:

but the proportion of this quantity to the capacity of the tube should not exceed 4 grams to 50 cubic centimeters. The quantity of nitric acid required is in general very small, since, for example, 0.24 grams of mercaptan, which is one of those bodies which require the largest amount of oxygen, may be oxidised by 3.3, or at most 4.4 grams of nitric acid. The duration of the oxidation need never exceed an hour and a half, reckoning the first half hour for attaining the requisite temperature.

The temperature required for complete oxidation is very different for different bodies. Easily oxidisable substances are decomposed at temperatures between 150° and 200°, compounds of the aromatic class at 250°–260°, while for derivatives of the sulphonic acids a temperature of 260° to 300° is required. Hard black wood-charcoal disappears very quickly at 250°–260°, traces of organic matter, however, remaining in the solution; at 300° it is easily and completely oxidised to carbon dioxide. English graphite disappears in two hours at 300°–330°, and is completely oxidised to carbon dioxide.

The oxidation is performed in sealed combustion-tubes 0.45 to 0.6 met. long and 0.013 met. wide. When it is complete the tube is opened, and cold water is slowly added to the greenish blue liquid, whereupon a considerable evolution of nitric oxide takes place.

The rest of the analysis is very simple. In the estimation of sulphur, the small quantity of nitric acid used renders the contamination of the barium sulphate with barium nitrate very small and easily removable. In the estimation of chlorine, bromine, and iodine, silver nitrate is immediately added to the contents of the tube, as in the mode of operating formerly described. Iodide of silver melts with the excess of nitrate into a yellow mass, and must be heated for two or three hours under the dilute liquid to separate the nitrate. The small quantity of nitric acid used precludes the formation of iodate.

Use of Bromine in Analysis.—P. Waage (*Zeitschr. anal. Chem.* x. 206) recommends the use of bromine as an oxidising agent in preference to nitric acid, chlorine, or a mixture of potassium chlorate and hydrochloric acid, for the following reasons:—The action of nitric acid is but feeble when the acid is used in a dilute state, and even when concentrated it oxidises sulphur but slowly. Most solutions used in analysis are rarely quite free from hydrochloric acid (chlorides), and the use of platinum vessels has, therefore, to be carefully avoided. Nitric acid, lastly, acts upon filter-paper, the nitrocellulose preventing the complete precipitation of certain metallic oxides. Potassium chlorate necessitates the employment of concentrated hydrochloric acid, and any undecomposed chlorate, especially in dilute solution, can only be removed by introducing into the solutions a large excess of free hydrochloric acid. Chlorine-water is a comparatively weak oxidising agent, as it contains only about one-half per cent. of chlorine; and the use of gaseous chlorine involves each time the generation of chlorine and the preparation of a chlorine apparatus. Waage recommends, therefore, the more frequent use of bromine, both in qualitative and quantitative analysis, either in the form of pure bromine, or dissolved in water, or in concentrated hydrochloric acid. Bromine water, obtained by shaking up bromine with cold water, contains from 2 to 3 per cent. of bromine; concentrated hydrochloric acid takes up about 13 per cent. Either of these three oxidising agents may be employed, according to the intensity of the oxidising power to be exerted. Excess of bromine can be very easily removed by heat. Bromine, moreover, is without action upon platinum vessels, either in alkaline or acid solutions, free nitric acid excepted, and does not act upon filter-paper when used in the form of bromine-water or dissolved in hydrochloric acid—a great desideratum, whenever precipitates have to be partly oxidised on the filter itself.

Bromine is a useful and powerful solvent for sulphur, magnetic pyrites, copper pyrites, arsenical pyrites, nickel glance, as well as for precipitated sulphides, for determining either the sulphur or the metals. Sulphur shaken up with bromine and water in the proportion of about 15 parts bromine to 1 part of sulphur is speedily converted into hydrobromic and sulphuric acids. The whole of the bromine is added at once, in order to avoid loss of sulphur in the shape of sulphur bromide. The pyrites need not be powdered very finely; the action of bromine being very violent, it is advisable to add first a little water to the pieces of pyrites, and then the bromine in small quantities at a time, and with repeated shaking.

Bromine-water may conveniently be used for removing sulphuretted hydrogen from solutions. Precipitated metallic sulphides must, for the most part, be removed from the filter by a fine jet of water from a wash-bottle, and the last traces treated on the filter by pouring a little bromine gas or bromine water into the funnel and covering it up with a watch-glass. The sulphides are rapidly oxidised and absorbed by the filter, and can then be washed out.

Bromine does not oxidise in ammoniacal solutions, but liberates nitrogen; ammonia may therefore be used with advantage for removing excess of bromine. The peroxides of nickel, cobalt, and manganese, e.g., are not precipitated by bromine from solutions containing ammoniacal salts. Ferrous, stannous, and mercurous salts, on the contrary, are readily oxidised by bromine in an acid solution in the presence of ammoniacal salts.

Commercial bromine cannot always be obtained pure, and should be redistilled, if necessary, without the intervention of caoutchouc.

Sources of Error in Volumetric Analysis.—Errors may arise in volumetric determinations from the contraction which takes place on mixing saline solutions with water, and from the fact that vessels do not deliver in a given time corresponding volumes of water and saline solution, but rather less of the latter, the exact amount depending to some extent upon the specific gravity of the solution. The first-named source of error may be obviated: first, by using as weak solutions as possible; secondly, by mixing the saline liquids thoroughly with the water before making quite up to the required bulk. The error caused by the adhesion of a saline liquid to the delivering vessel may be obviated by graduating it in terms of the particular solution to be employed (Tutlock, *Chem. News*, xxiii. 13).

Volumetric Estimation of Sulphuric Acid, Baryta, Chlorine, Bromine, and Iodine.—(Bohlig, *Arch. Pharm.* [2] cxlv. 118).—This method is based upon alkalimetric

principles. Alkaline sulphates are known to be partially decomposed, in contact with barium carbonate, into alkaline carbonates and barium sulphate. The decomposition is complete in presence of free carbonic anhydride; acid carbonates of the alkali-metals are left in solution, together with some acid barium carbonate, which can be removed by boiling. The solution is filtered, and the alkaline carbonate determined by means of a standard acid solution, and the amount of sulphuric acid or alkaline sulphate calculated from the amount of normal acid required.

Neutral chlorides, bromides, and iodides, more especially of the alkali-metals, are most readily decomposed by pure silver oxide into insoluble silver salts, leaving the alkali-metal in solution as hydrate (ammonia salts always excepted), which can then be determined as usual by standard acid.

Solutions containing sulphates of the heavy metals, of the earths or alkaline earths (lime), and free from acids whose presence would influence the method, viz., phosphoric, arsenic, oxalic, &c., are treated with a solution of potassium carbonate so as to precipitate the bases and leave about double or treble the amount of alkaline carbonate in solution. From 1 to $1\frac{1}{2}$ gram of substance is operated upon in a flask. The solution is made up to 500 c.c., well shaken, and the precipitate allowed to subside. 50 c.c. are then filtered into a porcelain dish and heated to boiling, and standard acid (HCl) added to neutralisation. Another 100 c.c. are filtered, in like manner, into a strong quarter-litre flask, and diluted with about 100 c.c. of hot water; the requisite quantity of normal acid is then run in at once from a burette; the solution diluted to 250 c.c.; and about a gram of dry barium carbonate (free from alkali) added. The flask is next closed and the liquid well agitated. The decomposition of the alkaline sulphate is completed in a few minutes. The flask should be opened now and then to allow the carbonic anhydride to escape. Finally, about $\frac{1}{2}$ gram of pulverised barium hydrate is added, the whole well shaken, and a portion of the rapidly clearing liquid tested qualitatively for barium and sulphuric acid. The result should be negative. 50 c.c. corresponding to 20 c.c. of the original solution are then filtered into a porcelain dish and standardised with normal acid (hydrochloric or sulphuric), and the quantity of sulphuric acid (sulphate) calculated as usual. The source of carbonic anhydride is thus placed in the liquid itself, provided the quantity of potassium carbonate be not too small. Molecular quantities of $K_2SO_4 + 2K_2CO_3 + 2HCl + BaCO_3$, when mixed with sufficient water, change into $BaSO_4 + 2KHCO_3 + 2KCl$, and it is therefore more than sufficient to add twice the quantity of potassium carbonate compared with the alkaline sulphate operated upon. Barium hydrate is added with the view of removing any carbonic anhydride left in the liquid after boiling, which would otherwise dissolve some of the excess of barium carbonate contained in the precipitate. Any barium hydrate not required to remove carbonic anhydride is acted upon by the hydro-potassic carbonate, but does not influence the final result.

Phosphoric and oxalic acids may be removed by means of calcium chloride, chromic acid by deoxidising agents, such as alcohol and hydrochloric acid. Böhlig recommends this method for estimating sulphuric acid volumetrically in ashes, crude soda, Stassfurt salts, &c.

Solutions containing baryta are estimated in like manner by precipitation as carbonate, and decomposition with potassium sulphate in a solution containing free carbonic acid. Chlorine is determined volumetrically in solutions by first precipitating any metallic chloride with potassium carbonate added in moderate excess. The filtrate is made up to 250 c.c. and the excess of potassium carbonate determined in 50 c.c. by means of a normal solution of hydrochloric acid. 125 c.c. of the solution are next treated with excess of silver oxide and made up to 250 c.c., well shaken (in the dark) and filtered. 100 c.c. of the filtrate are standardised with normal hydrochloric acid solution. The difference between the quantity of acid required in the last experiment and that of the former experiment, multiplied by 5, gives the amount of chlorine contained in the original solution. A portion of the filtrate should be tested for chlorine by means of mercurous nitrate.

The filtrate is obtained perfectly clear only in presence of potassium or sodium carbonate, and by employing argentic oxide free from argentous oxide. A few drops of pure potassium permanganate added to the argentic oxide suspended in water, prevent the formation of argentous oxide. The oxide to be employed for each experiment is filtered when required, and thoroughly washed.

Bromine and iodine are determined in like manner. The method has not, however, been yet applied to the estimation of mixtures of the halogen salts; but it has been observed that potassium iodide, when boiled with potassium permanganate, is completely oxidised into iodate. This facilitates the detection of small quantities of chlorine and bromine in presence of much iodide. The greater part of the iodate may be separated also by precipitation with barium nitrate before determining chlorine. The standard acid solutions employed contain not more than one-third of the acid.

valent of hydrochloric or sulphuric acid per litre. The strength may be determined by means of pure potassium carbonate or ignited potassium sulphate.

An apparatus for the quantitative analysis and synthesis of gases and vapours, chiefly for lecture experiments, is described by E. Mulder (*Zeitschr. f. Chem.* [2] vii. 2).

An apparatus for gas-analysis, similar in principle to that of Frankland and Ward, but of simpler construction, is described by J. Parry (*Chem. News*, xxiv. 282).

ANETHOL. C^6H^4O .—This compound is the methylic ether of anol or allyl-phenol $C^6H^4\left\{\begin{smallmatrix} OH \\ C^6H^3 \end{smallmatrix}\right.$ (1st Suppl. 175). It has a specific gravity of 0.9877, and its index of refraction is 1.5430 for the line A, and 1.6129 for H (Gladstone, *Chem. Soc. J.* [2] viii. 147). Treated with phosphorus pentachloride, it yields phosphorus trichloride and chloranethyloxy, C^6H^4OClO :

Chloranethol is a light yellow liquid, which solidifies at low temperatures, melts at 6°, boils at 258°, and has a sp. gr. of 1.1254 at 0°. The chlorine-atom is very intimately combined. By heating with alcoholic potash, HCl is removed, and a body is formed which boils at about 240°, and probably has the composition C^6H^4O . Chloranethol is oxidised by silver acetate at 260°, with formation of anisic acid.

Sodium amalgam scarcely acts either upon anethol or upon its addition-product with hydrogen chloride, only a small quantity of a substance being formed, which boils at 220°–224°, and appears to contain the compound C^6H^4O .

With 1 mol. bromine, anethol forms an addition-product, anethol dibromide, $C^6H^4OBr_2$, which crystallises in small needles, insoluble in water, soluble in ether and in chloroform, melting at 65° (Ladenburg, *Ann. Ch. Pharm. Suppl.* viii. 87).

ANGELINE. An alkaloid contained, according to Peckolt (*Vierteljahrsschrift pr. Pharm.* xviii. 444), in *Ferreira spectabilis* (known in Brazil, where it is indigenous, as *Angelin-pedra*), in a reddish resinous mass deposited between the bark and the wood. This mass, which in some trees amounts to 20 or 30 pounds, has the following composition:—

Chestnut-brown resin	3.64
Extractive matter	5.45
Angeline	86.84
Angelinic acid (cryst. organic acid)	1.28
Acid potassium tartrate and chloride	0.05
Red colouring matter	0.42
Gum with inorganic salts and traces of sugar	0.15
Moisture	2.17

100.00

The angeline is extracted in the form of hydrochloride. Genth (*J. pr. Chem.* cxi. 116) regards it as impure ratanhine.

ANHYDRIDES. On the reaction of various anhydrides with phosphorus trichloride, see that compound, under PHOSPHORUS.

ANHYDRITE. $CaSO^4$.—This mineral often occurs associated with gypsum and rock-salt, in such a manner as to indicate that it is not a primary formation, but has been produced by dehydration of gypsum. That it can be produced in this manner, especially in presence of sodium chloride, has been shown by the experiments of Hoppe-Seyler and of G. Rose, both of whom find that crystallised gypsum, or selenite, heated to 130° in a saturated solution of sodium chloride, is converted into a white opaque mass made up of microscopic crystals of anhydrite. Rose also finds that crystals of selenite heated for a short time with solution of sodium chloride in a platinum dish are converted on the edges into fibrous anhydrite. Powdered gypsum similarly treated is converted into small prismatic crystals of anhydrite; and a saturated solution of gypsum mixed with an equal volume of concentrated salt solution, when evaporated, yields microscopic crystals of anhydrite. Pseudomorphs of anhydrite in the form of gypsum are found at Sulz on the Neckar (G. Rose, *Jahrbuch Mineralogie*, 1871, 932).

W. Scherer (*Zeitschr. f. Chem.* v. 324) obtained crystals of anhydrite of sp. gr. 2.022 by evaporating a solution of burnt gypsum in very strong sulphuric acid. 100°

sulphuric acid of sp. gr. 1.82 dissolve at ordinary temperatures 1.992 parts of artificial and 1.958 of natural anhydrite.

Anhydrite from the Schäferotz mine, near Werfen, where it occurs in a bed two feet thick, accompanied by gypsum, has a specific gravity of 2.978, and contains 40.96 p.c. CaO , 58.44 SO_2 , and 0.42 Fe_2O_3 (Zepharovich, *Jahrbuch d. geolog. Reichsanstalt*, ii. 978).

Anhydrite nodules (A) coated with gypsum (B), varying in size from that of a hazel-nut to that of a walnut, occur in the rock-salt of Vizakna in Transylvania:—

	CaO	SO ^a	H ² O	Cl	Sp. gr.
A 39.37		54.73	1.20	0.72	2.901
B 31.99		46.93	16.05	1.50	2.423

The proximate composition of the nucleus and crust is—

Gypsum	5.71	76.44
Anhydrite	91.09	17.28
Sodium chloride	1.20	2.48
Excess of sulphuric acid	0.50	1.25

(Posepny, *Verh. geolog. Reichsanstalt*, 1869, 140).

ANILINE. See PHENYLAMINES.

ANILINE COLOURS. *Preparation without the use of Arsenic.*—All attempts hitherto made to produce aniline-red on the manufacturing scale without the use of arsenic, or to dispose economically of the arsenical residues, have proved unsuccessful. As, however, only a small proportion, not more than one-tenth of the rosaniline manufactured is used for dyeing, the greater part being consumed in the preparation of other aniline colours, it is very desirable that these latter should be obtained from other sources.

The process of Girard and De Laire for obtaining diphenylamine blue by heating diphenylamine with carbon trichloride is said to have proved commercially successful, and the same chemists have obtained, without the use of arsenic, the violet colours usually produced by acting on rosaniline with alcoholic iodides, the process consisting in oxidising the secondary monamines, methyl-aniline, methyl-toluidine, &c. They expect also to be able to produce a green colour in a similar way (*Compt. rend. lxxiv.* 1556).

New Sources of Methyl- and Ethyl-aniline.—In the process of manufacturing the Hofmann violet by the action of ethylic or methylic iodide upon rosaniline or one of its salts, there is always produced a considerable quantity of a dark-coloured resinous substance, which has received the name of 'Hofmann gum.' When the water is expelled from this gum by fusion, and the residue is submitted to destructive distillation at a higher temperature, it yields nearly pure methylaniline or ethylaniline, according as the gum has been derived from the methylic or ethylic iodide. The methylaniline is an oily body boiling at 200°, and forming permanently liquid compounds with acids. With arsenic acid it furnishes a reddish violet dye, which may be converted into the bluer shades by the Hofmann process. The ethylaniline boils at 205°–210°. Both these oils, when heated with rosolic acid or rosaniline, do not yield Girard's blue, but change slightly towards violet and then suddenly become decolorised (Spiller, *Proc. Roy. Soc.* xxi. 204).

Tinctorial Power of Aniline Colours.—A solution of 1 part of a rosaniline salt in a million parts of water containing acetic acid still exhibits a deep crimson colour. A skein of silk moistened with dilute acetic acid is instantly dyed a fine red by this solution. In a solution of 1 part rosaniline salt in 25 million parts of water, the red tint is still very perceptible, and silk dropped into it is dyed light red in a quarter of an hour. With a solution of 1 part of salt in 100 million parts of water, the limit is attained at which the colour is still visible. Thin films of such a solution appear quite colourless, the tint being perceptible only in thick layers (about 18 inches). A silk thread immersed in such a solution acquires in 24 hours a red colour, deeper than that of the liquid. This phenomenon points to a state of movement among the molecules, in consequence of which, currents are established in the apparently motionless liquid, and in this manner the particles of the liquid are carried successively to the surface of the thread. The colours of aniline violet and iodine-green are still visible in solutions of 100 millions, and fix the corresponding colour faintly on fabrics after 24 hours' time; but they are not so well adapted as the red for these limit experiments, as much as violet and green in the dilute state approach more nearly to the colour seen on looking through considerable thicknesses of pure water (*A. N. H. Ber. deut. Chem. Ges.* iii. 661).

Complementary Colours of Aniline Dyes.—Rosaniline salts exhibit by transmitted light a deep purple-red; their larger crystals reflect a splendid cantharides-green—the two tints coinciding, according to Dove's experiments (*Deut. Chem. Ges. Ber.* iii. 660), with the complementary colours of a plate of gypsum having a difference of $\frac{1}{4}$ of a wave-length in polarised light. A concentrated solution of iodine-green in alcohol left to evaporate on a glass dish leaves a homogeneous transparent varnish which transmits a splendid green light, and exhibits by reflected light a highly characteristic red copper lustre, which comes out with peculiar brilliancy on friction: these two colours coincide, according to Dove, with those of a gypsum lamina having a difference of $\frac{1}{2}$ of a wave-length. On warming the glass plate, the green passes into violet, and the reflected tint becomes brass-yellow, corresponding, according to Dove, with a difference of $\frac{3}{4}$ to $\frac{1}{2}$ of a wave-length (*Hofmann, Deut. Chem. Ges. Ber.* iii. 660).

Valuation of Aniline Colours.—Two-tenths of a gram of the particular colour in a pure state is to be dissolved in 100 c.c. of collodion, and the solution poured over a clean glass plate laid at an angle of 60° . An equal weight of the material to be valued is to be dissolved in 50 c.c. of the same collodion and a drop or two poured on another glass plate at the same angle. If after drying the two films have an equal depth of colour, the material obviously contains 50 per cent. of pure colouring matter; if, however, the second film be darker, the solution from which it proceeds is to be gradually let down, by addition of measured quantities of the collodion, till it gives a film of the same depth of tint as the standard. The number of cubic centimeters of collodion employed in all expresses the percentage of pure colouring matter (*A. Müller, Dingl. polyt. J.* ccii. 458).

Adulteration of Aniline Colours.—Bronze powder and crystals of sugar are frequently used for this purpose, especially for adulterating fuchsine. Bronze powder is easily detected by its insolubility; sugar by spreading the sample on a sheet of white paper and examining it with a lens. The pure crystals of fuchsine are recognised by their acicular forms and by appearing red (by transmitted light) at the edges only. The appearance of more rounded crystals, especially of such as have a garnet or faint amethyst-red tint is suspicious. Such crystals should be picked out and heated on the point of a spatula, when, if they consist of sugar, the characteristic odour of caramel will be given off (*W. F. Gintl, Dingl. polyt. J.* cciv. 163).

On the constitution of aniline colours, see Zulkowsky (*Wien. Akad. Ber.* lix. [2] p. 133; *Jahresb.* 1869, p. 698).

Reduction (Enleavage) of Aniline Colours.—This may be effected by zinc-dust, as follows: 100 parts of zinc-dust are very intimately mixed with 50 parts of a gum solution of 20 Bm. and 20 parts of a solution of sodium thiosulphate of sp. gr. 26° Bm. are added. The dyed fabrics are printed with this mixture, then dried and steamed, and lastly washed with very weak hydrochloric acid.

Aniline Black. The various kinds of oil which are used for the manufacture of aniline black never consist of pure aniline, their composition varying with their boiling points and specific gravities. Those anilines ordinarily consist of from—(a) 60 to 65 per cent. of a product boiling between 180° and 185° , which may be regarded as almost pure aniline. (b) 18 to 22 per cent. of a product boiling from 185° to 192° , which may be considered to be a mixture of aniline and toluidine. (c) 8 per cent. of a product boiling from 192° to 198° , which is toluidine; and (d) 4 to 6 per cent. of other products, as xylydine, cumidine, &c.

The specific gravities of the above fractions are about as follow:—

(a) From 2.75° to 3.4° , Baumé.	
(b) " 1.6° " 2.1° "	Pure aniline of Couper, 3.5° , Baumé.
(c) " 0.6° " 1° "	Ordinary toluidine, 0.88° "
(d) about 0.5°	Pseudotoluidine, 0.50° "

Pure aniline oil of Couper, as also all products boiling from 180° to 185° , yield beautiful brilliant blacks. Pseudotoluidine, and the products boiling from 185° to 192° , yielded a black with a blue shade. Ordinary toluidine of Couper, and the products boiling above 192° , gave unsatisfactory shades between brown and black.

It appears then, that in testing the quality of aniline for the production of black dyes, the specific gravity affords important indications. For quick determinations, Baumé's areometer may be used with advantage.

Aniline oil of sp. gr. 2° to $3\frac{1}{2}^\circ$ B., if not wilfully adulterated, will yield a good black at more than $3\frac{1}{2}^\circ$ B. it generally contains nitro-benzene; and at less than 2° B. it contains too much toluidine, which is decidedly injurious.

Fractional distillation gives a still more accurate idea of the value of the oil, the quantity coming over between 180° and 190° being taken as the measure.

The value of a given sample of aniline oil may also be estimated by comparing the quantity of it required to produce a certain quantity of black dye with the quantity of pure Coupler's aniline required for the same purpose (C. Hartmann, *Dingl. polyt. J.* ccii. 389).

A. Müller (*ibid.* cci. 363) prepares an oxidised aniline-black by dissolving 20 grams of potassium chlorate, 40 grams of copper sulphate, 16 grams of ammonium chloride, and 40 grams of aniline hydrochloride in 500 c.c. water, warming the liquid to about 60°, and then removing it from the water-bath. In about three minutes the solution froths up and gives off vapours which strongly attack the breathing organs. If the mass does not become quite black after the lapse of a few hours, it is again heated to 60°, and then exposed in an open place for a day or two, and afterwards carefully washed out till no salts are to be found in the filtrate. For use in printing, the black paste is mixed with a somewhat large quantity of albumin, and the goods after printing are strongly steamed. The paste can be pressed into moulds and used as a substitute for Indian ink. When thoroughly dried *in vacuo* it appears as a black powder, which contains 39.28 p.c. C, 7.41 H, and 7.41 N, agreeing approximately with the formula $C^{12}H^{11}N^{2}O^{11}$, which requires 30.78 C, 3.86 H, and 7.72 N.

According to H. Rheineck (*Dingl. polyt. J.* cciii. 485), an equally good black may be obtained without the use of sal-ammoniac. On mixing equal weights of aniline (containing toluidine), hydrochloric acid and potassium chlorate with a minute quantity of cupric chloride and a sufficient quantity of water, and leaving the mixture to evaporate spontaneously, a black powder was obtained, which when washed with water, burnt without residue. 100 parts of aniline thus treated yielded 1206 parts of aniline black. With pure aniline only 114.8 p.c. of black was obtained, and it was of very poor quality.

Rheineck finds that aniline-black is a powerful base, and proposes to designate it by the name of *Nigraniline*. When any fabric is immersed in the mixture above described, it first acquires a dark green colour, but after treatment with alkalis this colour changes to dark violet. The dark green body is the hydrochloride of the aniline black, and the dark violet body the free base. With soda or ammonia, 8.9 p.c. of hydrochloric acid can be extracted: therefore the molecular weight of the hydrochloride is about $100 \times \frac{36.5}{8.9} = 410$, and that of the free base 373.5. This base has the power

of abstracting the acids from the salts of aniline. A small piece of cotton, on which a very thin layer of the dark violet colour is brought, is immediately coloured green by aniline hydrochloride, even in presence of excess of aniline. A piece of cotton moderately coloured with aniline black is a good test for the presence of free acids or alkalis, and the same piece may be used several times without losing its colour. When turned green by an acid, it should be well washed with distilled water, when it will be found to change quickly to violet, in presence of an alkaline solution as weak as that found in spring water. The black-green body (not previously treated with alkalis) treated with concentrated sulphuric acid, gives off hydrochloric acid gas, and yields a violet solution, which on evaporation leaves a black-green residue, doubtless the sulphate.

Action of various Metals in the Production of Aniline Black.—The presence of copper in some form has hitherto been regarded as essential to the formation of aniline-black; indeed, all black colours believed to be formed in the ordinary processes without the aid of copper are said to owe their formation to its presence in the vessels in which they are prepared, or in the rollers employed in printing. Mere traces of copper are sufficient to produce a black colour, but the presence of this metal in some quantity is generally regarded as indispensable. Cupric sulphate was first used, but for various reasons was subsequently replaced by the sulphide.

Lightfoot, however, finds that the copper in this preparation may be replaced by a few other metals. A mixture of basic aniline hydrochloride and ammonium chlorate, thickened with starch, was printed by a wooden roller on well bleached cotton, and whilst the fabric was still damp, the following metals were brought in contact with it and allowed to remain so for 15 minutes:—Copper, iron, vanadium, uranium, nickel, lead, zinc, antimony, tin, manganese, chromium, bismuth, arsenic, titanium, tungsten, cadmium, tellurium, molybdenum, mercury, silver, gold, platinum, palladium, rhodium, iridium, aluminium, osmium, cobalt, ruthenium, thallium, magnesium, lithium, lanthanum, didymium, erbium, yttrium, selenium, tantalum, niobium. After this, the fabric was hung up in a warm and damp place for 12 hours, and then passed through an alkaline bath. The result was that the best black was obtained with vanadium, next with copper, then with uranium, and lastly with iron. All other metals give either very little colour, or none at all. A sovereign and a shilling

previously found to have no effect, were shaken in a bag with some copper coins, and then placed in contact with the piece of cotton, when the sovereign produced a grey, and the shilling an almost black tint (*Dingl. polyt. J.* cciii. 483).

Dyeing of Cotton Fabrics with Aniline-black (*J. Persoz, Bull. Soc. Mtd. de Mulhouse*, xlii. 47; *Dingl. polyt. J.* cciv. 491).—In dyeing these fabrics black by immersion in a bath of potassium dichromate and an aniline salt, considerable difficulty has been experienced in regulating the strength of the solutions so as to produce a uniform tint. If the solutions are too dilute, no black is obtained; if they are too strong, it is precipitated in the bath instead of on the fabric: and if to retard the precipitation the solution is cooled to 0°, aniline chromate crystallises out and makes spots on the cloth; and when the influence of the low temperature is removed there is danger of the cloth taking fire in the neighbourhood of these spots from the reaction between the elements of the chromate and the organic matter.

These difficulties may be overcome by sprinkling the solutions, either successively or together, on the cloth, by means of a horizontal brush made to move quickly up and down, the cloth being tightly stretched and passed under it at a uniform rate. In working in this manner the production of the black cannot take place till the solutions are intimately mixed in the cloth and the latter is well soaked with the mixture.

The aniline salts best adapted for the purpose are the acid sulphates, nitrates, and hydrochlorides; * neutral salts do not give a good result; neither can the acetate, oxalate, or any other organic salt be used. The acid sulphates give a reddish black, whilst the hydrochlorides and nitrates give a black with violet or blue lustre. A mixture of equal volumes of the disulphate and dihydrochloride gives very good results. The dichromate must be used in rather strong solution, not less than 80 grams to the litre.

The method above described gives first a dark green colour, which changes to pure black when the cloth is washed in water, and then passed through a hot soap-bath. By printing the cloth with resins or fats previous to dyeing, white patterns on a black ground may be obtained.

Lauth (*Moniteur scientifique*, xi. 600; *Bull. Soc. Chim.* [2] xix. 437) has invented a process for dyeing and printing all vegetable and animal substances with aniline-black. Cotton, linen, hemp, wood, &c., are first mordanted with a manganous salt, then passed through a bath of caustic soda, and afterwards treated with chloride of lime to peroxidise the precipitated manganous oxide. The mordanted fibre is then washed, and immersed in a bath of 1 litre of water, 50 grams of aniline, and 100 grams of hydrochloric, or 150 of sulphuric acid. The green colour at first produced is changed by treatment with alkalis or soap to a deep black, which may be further intensified by treatment with potassium dichromate or with salts of copper, chromium, or mercury, especially with a mixture of potassium chlorate, copper sulphate, and sal-ammoniac (1 gram of each to the litre). Lastly, the dyed material is washed with water and boiled with soap.

On wool, silk, leather, hair, feathers, ivory, &c., the precipitate of manganic oxide is produced by immersion in a solution of alkaline manganate or permanganate, the remainder of the process being the same as above described. By varying the concentration of the mordants and of the dye-bath to which also other bases, such as toluidine, cumidine, naphthylamine, may be added, grey-blue and brown-violet tints may be produced.

This process gives fine permanent blacks, but the mordanting is somewhat troublesome, and the black rubs off a little.

Gonin & Glanzmann (*Monats. sci.* xi. 302), employ the following mixture for printing a pure black on silk and wool:—1000 grams of gum-solution; 100 potassium chlorate; 100 sal-ammoniac; 250 aniline hydrochloride; 125 aniline nitrate of 50° Bm. If the thickening material be partly or wholly omitted, the mixture may be used for dyeing.

Aniline Blue for Printing. A blue paste for printing may be prepared by mixing 100 grams of starch with a litre of water, and adding to it while warm 40 grams of potassium chlorate, 3 to 4 grams of ferrous sulphate, and 10 grams of sal-ammoniac. The well-mixed paste, when quite cold, is mixed with 70 grams of aniline hydrochloride, or an equivalent quantity of the tartrate, and immediately used. The printed goods are oxidised, then passed through warm or faintly alkaline water, whereby the blue colour is developed. (*Blumer-Zweefel, Dingl. polyt. J.* ccii. 103).

* The recommendation of acid salts is contrary to the experience of Lightfoot, who used basic salts (*vide sup.*). As no copper salt is added in the process of Persoz, it is possible that the use of the free acid may be to take a trace of copper from the vessels, &c., with which the solutions come in contact.

Sulphoacids of Aniline Blue. (Bulk, *Dent. Chem. Ges. Ber.* v. 417.) Four different acids are obtained by the action of strong sulphuric acid on aniline blue, viz.:—

1. *Triphenylrosaniline-monosulphonic acid*, $C^{20}H^{14}(C^6H^5)_3(C^6H^4SO^3H)N^3$, is formed by dissolving triphenylrosaniline hydrochloride in strong sulphuric acid and heating the solution for five or six hours. On adding water, the sulpho-acid is obtained as a dark blue bulky precipitate, which, when dried at 100° , appears as small grains having a metallic lustre:

This acid forms with the alkalis, salts which are easily soluble in water; with the earths and heavy metals, sparingly soluble salts. The sodium salt $C^{20}H^{14}(C^6H^5)_3(C^6H^4SO^3Na)N^3$ is known as 'Nicholson's blue.' It is obtained perfectly pure by digesting the acid with a quantity of soda-ley not quite sufficient for saturation, filtering the solution, and evaporating. Dried at 100° , it forms a grey-black amorphous mass, which dissolves easily and with blue colour in hot water.—The ammonium salt obtained by dissolving the acid in ammonia, gives off a large quantity of ammonia when evaporated over the water-bath, and the residual colouring matter effloresces in rolled-up feathery masses, which move briskly about after drying, probably in consequence of a change of crystalline form.

The solutions of triphenylrosaniline-monosulphenates are but faintly coloured; the colour comes out with great intensity on acidulating the solution. If the solution is acidulated with acetic acid in the cold, the colouring matter remains unaltered; but it is precipitated by acetic acid from hot, and by mineral acids likewise from cold solutions. Wool dipped into the hot aqueous solution, especially if borax or water-glass be added, extracts the salts in the colourless state, and holds them so fast that they cannot be washed out by water; but, on dipping the wool thus prepared into an acid, the salt is decomposed and the colouring matter is set free, with its full lustre and great tinctorial power.

Under the influence of reducing agents, the triphenylrosaniline-sulphonates are easily converted into the corresponding leucaniline. Thus, on digesting the sodium-salt with excess of ammonium sulphide for two hours at 100° , and adding hydrochloric acid, leucaniline is separated as a white flocculent precipitate, easily soluble in acids and in alcohol, and reconverted by oxidising agents into the original compound.

2. *Triphenylrosaniline-disulphonic acid* is always obtained, together with the trisulphonic acid, when a solution of triphenylrosaniline hydrochloride is digested at 60° for five hours with a sixfold quantity of sulphuric acid. On pouring the solution into water the greater part of the colouring matter is precipitated in blue flocks consisting mainly of the disulphonic acid, whilst the trisulphonic acid remains dissolved, forming a liquid of fine blue colour.

The disulphonic acid is slightly soluble in water, insoluble in acid liquids. Its salts are more soluble than those of the monosulphonic acid, less soluble than those of the sulphonic acids of higher orders. Those of the alkali-metals are easily soluble in cold water. The sodium-salt is known commercially as 'soluble blue.' Those of the alkaline-earth-metals and heavy metals are mostly slightly soluble blue precipitates.

Triphenylrosaniline-trisulphonic acid is precipitated on adding hydrochloric acid or common salt to the blue liquid filtered from the disulphonic acid, in a mass of fine flocks. It is soluble in water and alcohol, and forms easily soluble salts with alkalis.

Triphenylrosaniline-tetrasulphonic acid, the highest sulpho-acid of the series, is obtained by digesting aniline blue in ten times its volume of fuming sulphuric acid at 140° for some hours. The product, poured into water, forms a deep blue solution, from which the excess of sulphuric acid may be removed by lead carbonate. The filtrate evaporated to dryness leaves the lead-salt of the tetrasulphonic acid, which, when purified by solution in a small quantity of water, precipitation with alcohol, and drying at 100° , has the composition $C^{20}H^{14}(C^6H^5)_4(C^6H^4SO^3)_4Pb^2N^4$.

The acid dissolves easily in water, forming a blue liquid, which dries up in the water-bath to a metallically lustrous amorphous mass: the salts which it forms with the alkalis are easily soluble in water, and dissolve with brown-red colour in excess of the alkali. Even the heavy metal salts are moderately soluble in water: the silver salt decomposes on boiling, with deposition of a silver speculum. Most of these tetrasulphonates are precipitated by alcohol from their aqueous solutions. Silk immersed in the alkaline or neutral solution removes the colouring matter with difficulty, from the acidulated solution with moderate facility.

The Sulpho-acids of the Aniline-violet (mono- and di-phenylrosaniline) are

obtained in a similar manner to those of aniline-blue, to which they are closely analogous in physical and chemical properties; but they are somewhat more difficult to prepare. A monosulphonic acid of *ethylphenylrosaniline* has also been obtained.

Aniline Grey is prepared by prolonged heating of 1 part of aniline with 5 parts liquid arsenic acid (? anhydride). The crude product is treated with a boiling mixture of 20 parts water and 5 parts hydrochloric acid, then filtered, and the undissolved portion is washed with water, then with dilute solution of sodium carbonate. The dry colouring matter is dissolved in alcohol mixed with $\frac{1}{10}$ th part of sulphuric acid. Wool or silk may be coloured directly by very small quantities of it (Bloch, *Monsieur scientifique*, xi. 71).

Aniline Lacquers. F. Springmühl (*Dingl. polyt. J.* c.c. 224) prepares these lacquers by mixing alcoholic solutions of various resins with suitable aniline salts possessing the requisite tinctorial power. Bleached shellac, mixed in some cases with other resins, is dissolved in spirit containing 90-95 per cent. of real alcohol, by allowing the powdered resin to digest at a gentle heat in close vessels for about 24 hours before filtering through asbestos. Dilute solutions are concentrated on a water-bath. Sandarac added in small quantity increases the elasticity and durability of the lacquer, and oil of turpentine increases its lustre. Other resins are sometimes added, according as they suit the colours. A concentrated alcoholic solution of the colour is prepared separately, and added to the lacquer just before it is used. The objects to be covered with coloured lacquers should be bright and clear, and not too thick. Mica is treated in its settings, and, like glass, previously heated to about 30° C., to cause it to receive an uniform lacquer.

Aniline-violet is dissolved in the strongest alcohol; a few drops of acetic acid are added, and the whole gently heated with the alcoholic solution of the resin, so as not to produce any turbidity. The intensely coloured solution of the lacquer is then placed on the warm glass or mica, and is left to dry in a warm place (20° to 25° C.), till a clear and smooth, but intensely coloured coating has been formed on it, which is not affected by water or air.

Aniline-yellow, when transferred in like manner on transparent objects, lacks intensity. This can only be supplied by repeated coatings, generally, however, at the expense of uniformity.

Aniline-blue may be prepared in several ways. By boiling a shellac solution containing magenta with sodium carbonate, a blue lacquer is obtained, which is, however, little suitable for covering glass or mica, as the lacquer shrinks on drying, owing to the sodium carbonate retaining water. A shellac solution containing magenta, when gently heated on a glass plate, likewise turns blue, but the transparency is impaired by numerous small blisters; and it is best to use pure commercial aniline-blue dissolved in the lacquer, whenever it is desired to coat delicate articles, such as spectacles and other glasses, with a fine blue film.

Magenta produces with shellac a brilliant and perfectly transparent red, provided it has not to be exposed to a high temperature; the colour acquires considerable consistency by an admixture of gum-arabic. It is likewise recommended to employ alcoholic solutions of other resins, such as sandarac, Venice turpentine, &c.

Zinnilino, prepared from magenta by the action of nitrous acid, is employed in a similar manner for the production of yellow lacquers on account of its solubility in alcohol. It cannot, however, be heated above 100° C.

Aniline-green dissolved in alcohol, and added in moderate quantities to the lacquer, produces a bright lustrous and permanent covering; coralline, a lacquer acted upon by light. Emeraldine and ethylrosaniline-green should be dissolved just before being brought together with the concentrated lacquer.

Nearly all aniline colours may thus be employed for lacquers, provided they are pure enough, and do not contain too much water. They are for the most part better suited than extracts of dye-woods and other colouring matters, such as indigo, &c. Remarkably fine colours were obtained on glass and mica by employing solutions of gun-cotton in ether mixed with a little alcohol, and coloured by means of small quantities of aniline dyes. They leave on evaporation transparent layers, proportionate in thickness to the concentration of the solutions employed. The coating is rendered more elastic by the addition of a little oil of turpentine, and when put on cold glass plates can be detached readily and in a compact form. These coloured collodium skins may be cut into various shapes and figures, and fixed firmly by means of a little colourless gum to different transparent objects. Partially etched glass or mica may likewise be coated over with coloured lacquers, the etched portions becoming translucent, the others transparent. In case of failure, the lacquer can be easily removed by means of the respective solvents for the resins.

Mixtures of aniline colours and resins in alcoholic solution may be used for

colouring paper, leather, linen, &c.; but an easily soluble lake must be employed, and for equal bulks of alcohol used in dissolving, much less of the resin containing the lake must be taken. The colour may be applied to the paper as a pigment, or the paper may be soaked in the solution and hung up to dry (Springmühl, *ibid.* cii. 382).

On the question whether phosphoretted animal substances give off phosphoretted hydrogen during putrefaction, see PUTREFACTION.

ANISHYDRANILIDE, $C^8H^8NO = C^6H^5 \left\{ \begin{smallmatrix} OCH^3 \\ CH.N.C^6H^5 \end{smallmatrix} \right.$ isomeric with methyl-anhydruilide (see SALICYLID), is obtained by mixing anisic aldehyde with aniline. The mixture is clear at first, but soon becomes turbid, and separates into water and a lower layer, which when freed from excess of aniline, forms a yellow, scentless, tasteless, neutral oil, solidifying after several weeks to golden-yellow, fatty crystals of anishydranilide, easily soluble in alcohol, ether, and benzene (Schiff, *Ann. Ch. Pharm.* cl. 193).

ANISIC ACID, $C^8H^8O^3$.—*Methyl-amidanisic acid*, $C^8H^8NO^3 = C^6H^5(NH.CH^3)O^3$, isomeric with tyrosine, is formed by the action of methyl iodide on amidanisic acid. It crystallises in slender white needles, sparingly soluble in water, ether, and cold alcohol, but freely soluble in hot alcohol; melts above 200° . It unites with hydrochloric acid, forming the compound $C^8H^8NO^3.HCl + H^2O$, which crystallises in very small narrow plates, freely soluble in cold water and in hot hydrochloric acid, sparingly in cold hydrochloric acid. The silver salt is a white granular precipitate (Griess, *Deut. Chem. Ges. Ber.* v. 1042).

On the Action of Ammonia on Nitranisic Acid, see AMIDOBENZOIC ACID under BENZOIC ACID.

ANISIC ALCOHOL, $C^8H^8O^2 = C^6H^5 \left\{ \begin{smallmatrix} OCH^3 \\ CH^2OH \end{smallmatrix} \right.$.—The following directions for obtaining this alcohol in the pure state are given by Cannizzaro (*Gazzetta chimica italiana*, ii. 61). Anisic aldehyde—prepared by Rosso's method (1st Suppl. 172), and purified by combining it with acid sodium sulphite and decomposing the resulting compound with potassium carbonate, is mixed with three volumes of alcohol and four or five volumes of concentrated alcoholic solution of potash, and allowed to stand for some hours. When the mixture has become solid, water is added, and the alcohol removed by careful distillation in a current of steam. The residue, when cold, deposits an oily layer of impure anisic alcohol, the clear, supernatant liquid consisting of an aqueous solution of potassium hydrate and anisic alcohol, from which the latter may be removed by agitation with ether. The residue left on evaporating the ethereal solution yields anisic alcohol when submitted to fractional distillation, the portions which come over between 250° and 260° being collected apart. The first portions which come over should be tested with acid sodium sulphite, and if they give indication of the presence of anisic aldehyde, must be again submitted to the action of alcoholic potash. The alcohol, when purified by careful fractional distillation, melts at 24° to 25° ; by repeated distillation, however, it becomes oxidised and reconverted into anisic aldehyde. Long contact with alcoholic potash at an elevated temperature produces a change in this alcohol similar to that which benzylic alcohol undergoes, a methylated cresol being formed, whose boiling point is 174° .

Methyl-salicylic alcohol, $C^8H^8O^3$, isomeric with anisic alcohol, is prepared from saligenin, $C^8H^8.CH^2OH.OH$, by adding to it a molecule of potassium hydrate dissolved in methylic alcohol, and subsequently digesting the mixture with methylic iodide. When the action is terminated, an aqueous solution of potash is added and the methylic alcohol removed by distillation in a current of steam; the methylsalicylic alcohol can then be extracted from the residue by agitating it with ether. The impure alcohol left on the evaporation of the ethereal solution is submitted to fractional distillation, collecting apart the portion boiling at about 240° .

The boiling point of anisic alcohol at a pressure of 760 mm. reduced to 0° , is 258.8° (corrected), and that of methylsalicylic alcohol, 247.5° (corrected) under a pressure of 765.0 mm. Anisic alcohol when free from moisture melts at 35° and has a density of 1.10934 at 25.85° , and 1.06007 at 49.75° . Methylsalicylic alcohol maintains its transparency when surrounded by a bath of solid carbonic anhydride.

and ether, but gradually thickens and becomes semifluid: in one experiment it solidified. Its density is 1.389 at 0°, and 1.0532 at 100°.

The indices of refraction of these two isomeric alcohols have been determined by Blaserna (*ibid.* 60), for four lines of the spectrum, at the temperatures 28°, 29°, and 30°. The following table exhibits the values for the temperature 28°:—

	D	D	b	F
Anisic Alcohol:				
Sp. gr. 1.10934 at 25.85° .	1.53813	1.54308	1.55093	1.55594
" 1.10899 " 27.15° .	1.53802	1.54301	1.55080	1.55576
Methyl-salicylic Alcohol:				
Sp. gr. 1.12009 at 28° . .	1.53951	1.54440	1.55201	1.55703
" 1.12007 " 28° . .	1.54046	1.54534	1.55310	1.55796

Denoting the indices of refraction at a given temperature by n , n' , and the densities by d , d' , we may enquire whether the well-known formula of Laplace:

$$\frac{n^2 - 1}{d} = \frac{n'^2 - 1}{d'}$$

holds good with regard to these isomeric compounds.

The observations on the first portion of the anisic alcohol and the second portion of the methyl-salicylic alcohol, which are regarded as the best, give:

$$\begin{aligned} \text{for } t = 25.85^\circ, d = 1.10938; d' = 1.1176 \\ \text{and for } t = 28^\circ \quad n' = 1.54046 \text{ for the line C.} \end{aligned}$$

With these values the preceding equation gives $n = 1.53717$, whereas the observed value of n is 1.53813; the small difference between the observed and calculated values is most probably due to slight impurity in one or both of the alcohols.

ANISIC ALDEHYDE, $C^6H^5O^2 = C^6H^4 \begin{smallmatrix} \text{OCH}^3 \\ \text{CHO} \end{smallmatrix}$, is rapidly attacked at ordinary temperatures by phosphorus pentachloride, and on treating the product with water, the original aldehyde is reproduced (L. Henry, *Zeitschr. f. Chem.* [2] vi. 208). When 1 mol. anisic aldehyde and 2 mol. *acetamide* are heated together for some time to 120°–180°, and the yellow crystallised mass which forms on cooling is washed with water till it is nearly white, and then recrystallised from boiling water, the compound $C^6H^4N^2O^2 (= C^6H^4O^2 + 2C^2H^3NO - H^2O)$ is obtained in nodular groups of shining needles, melting at 180°, insoluble in alcohol and ether, and precipitated from aqueous solution by alcohol.

Benzamide and anisaldehyde yield in like manner the compound $C^6H^4N^2O^2$, which however, must be recrystallised from alcohol, since it is insoluble in water and in ether. It likewise forms shining needle-shaped crystals melting at 192°. Both these compounds are decomposed by hydrochloric acid, with separation of anisic aldehyde, but they are not altered by potash, even at the boiling heat (A. Schuster, *Ann. Ch. Pharm.* cliv. 80).

ANISOL, $C^6H^5O = C^6H^4(OCH^3)$. *Action of Ammonia on the Nitro-anisols.*—Dinitranisol, $C^6H^4(NO^2)_2.OCH^3$, heated with strong aqueous ammonia in sealed tubes for three or four hours to 110°–120°, exchanges the group OCH^3 for NH^2 , and is converted into a dinitramidobenzene or dinitraniline, $C^6H^4(NO^2)_2.NH^2$, which is identical with the only dinitraniline hitherto known, inasmuch as both, when treated with nitrous acid, yield paranitrobenzene melting at 87°. This dinitraniline has, therefore, the constitution represented by the formula:

A similar structure must also belong to dinitranisol, dinitranisic acid, and their derivatives: dinitro-amidobenzoic (chrysanic acid), dinitroparaoxybenzoic acid, triamidobenzoic acid and triamidobenzene. Moreover, as the two lateral chains in anisic (methyl-paraoxybenzoic) acid undoubtedly also occupy the para-position, it

follows that the bodies above mentioned must be represented by the following formulæ:—

		1	2	3	4	5	6
Dinitranisol	C ⁶	OCH ³	NO ²	H	H	NO ²	H
Dinitroanisic acid	C ⁶	OCH ³	NO ²	H	CO ² H	NO ²	H
Chrysanisic acid	C ⁶	NH ²	NO ²	H	CO ² H	NO ²	H
Dinitroparaoxybenzoic acid	C ⁶	OH	NO ²	H	CO ² H	NO ²	H
Triamidobenzoic acid . . .	C ⁶	NH ²	NH ²	H	CO ² H	NH ²	H
Triamidobenzene	C ⁶	NH ²	NH ²	H	H	NH ²	H

The dinitranisol above mentioned is easily converted by the action of a mixture of nitric and sulphuric acids into trinitranisol, C⁶H³(NO²)³.OCH³, identical with that which is well known as methyl picrate, inasmuch as it is converted by potash into picric acid and by ammonia into picramide, which may also be formed by the action of ammonia on picryl chloride.

Now whichever of the three hydrogen-atoms in the dinitranisol may be replaced by the group NO², it is clear that the three nitro-groups in the resulting trinitranisol must stand in relative positions which may be denoted by 1 : 2 : 4, and the same must be true respecting the three nitro-groups in picric acid (H. Salkowski, *Deut. Chem. Ges. Ber.* v. 872).

ANISONITRIL, C⁶H⁴NO = C⁶H⁴ $\begin{Bmatrix} \text{OCH}^3 \\ \text{CN} \end{Bmatrix}$ (L. Henry, *Zeitschr. f. Chem.* [2]

vi. 209). Produced: 1. By dehydration of anisamide under the influence of heat. Anisamide melts at 137°–138°, and, when quickly heated in a small tubulated retort, distils gradually and almost without decomposition at about 295°, and sublimes in broad laminae; but, if heated for some time above its boiling point, it is partly converted into anisonitril, which distils over, more or less mixed with unaltered anisamide; the two bodies may be separated by ether, which easily dissolves the nitril. 2. By the action of pentasulphide, or pentachloride, of phosphorus on the amide. A mixture of anisamide with the pentachloride is distilled in a small tubulated retort passing into a condensing tube and provided with a thermometer. The reaction begins at ordinary temperatures; and on distilling the mixture, phosphorus oxychloride passes over first, the temperature then rising quickly to 250°–255°, where it remains constant, and a colourless liquid passes over, which solidifies in the condensing tube to a white crystalline mass.

Anisonitril separates from solution in ether in shining crystals, 1–2 centimeters long, and apparently consisting of oblique rectangular prisms. It has a pungent odour, dissolves very easily in ether, is soluble also in alcohol, carbon sulphide, and paraffin oils, insoluble in cold water, but moderately soluble in hot water, from which it separates on cooling in the form of small needles. It melts at 56°–57° to a colourless transparent liquid, which solidifies on cooling to a hard, brittle, crystalline mass; boils without decomposition under the ordinary atmospheric pressure at 253°–254°. Heated in a sealed tube to 120°–130° with a moderately concentrated solution of caustic potash, it is converted into anisic acid (melting at 175°). Fuming nitric acid acts on it very violently, converting it into nitro-anisonitril, C⁶H³(NO²) $\begin{Bmatrix} \text{OCH}^3 \\ \text{CN} \end{Bmatrix}$, which crystallises from alcoholic solution in small nacreous needles, insoluble in water, soluble in alcohol, especially when hot, also in ether; melting at 149°–150°, and volatilising, when heated a little above its melting point, in thin transparent laminae.

ANISURANIC ACID, C⁶H³N²O⁴, is obtained on mixing the cold saturated solutions of potassium cyanate and hydrochloride of amidanisic acid, as a white amorphous precipitate; it is nearly insoluble in cold water, dissolves in about 2,000 parts of boiling water, and separates therefrom in delicate white needles. The calcium salt Ca(C⁶H³N²O⁴)² + 7H²O is precipitated in stellate groups of white needles on mixing the boiling ammoniacal solution of the acid with calcium chloride (Menschutkin, *Ann. Ch. Pharm.* cliii. 83).

ANORTHITE. See FELSPAR.

ANTHRACENAMINE, C¹⁴H¹¹N = C¹⁴H⁹(NH²) (Phipson, *Chemical News*, xxvii. 97). A base obtained by treating mononitroanthracene with tin and hydrochloric acid. The immediate product of the reaction is a compound of anthracenamine hydrochloride with tin chloride, from which the base may be separated by potash, which dissolves out the tin; the operation must, however, be repeated to get rid of the tin completely.

Anthracenamine is a pale yellow powder, forming soluble and crystallisable salts with sulphuric and hydrochloric acids. It is very soluble in alcohol, but slightly

2nd Sup.

G

soluble in water; its odour is very slight, and its taste hot, pungent, and persistent, very like that of the unknown substance which exists in the *Arum maculatum*. It is easily decomposed. Its acid salts produce with potassium dichromate a characteristic emerald-green colour, and finally precipitate a powder of this colour which is soluble in alcohol. This solution presents no marked peculiarity when viewed in the spectro-scope. The reaction is as characteristic of anthracenamine as the blue colour produced in similar circumstances is of naphthylamine. It is not obtained, however, with lead peroxide or with calcium hypochlorite, but it is obtained with concentrated nitric acid.

ANTHRACENE, $C^{14}H^{10}$. *Formation*.—1. The formation of anthracene from dibenzyl (1st Suppl. 176), is accompanied by that of a hydrocarbon, $C^{14}H^{14}$, boiling at about 280° , which has hitherto been regarded as dibenzyl, $C^6H^5\{CH^2[CH^2(C^6H^5)]\}$. Van Dorp, however, has shown (*Deut. Chem. Ges. Ber.* v. 1070), that when oxidised by potassium dichromate and sulphuric acid, it yields benzoyl-benzoic acid, $C^6H^5(C^6H^5O).CO^2H$; hence it must consist of benzyl-toluene, $C^6H^5.CH^2[C^6H^4(CH^3)]$:

Now, when this hydrocarbon, obtained as above, is passed over red-hot pumice, it is resolved into free hydrogen and anthracene:

and the same result is obtained when benzyl-toluene, prepared by Zincke's method, viz., by heating a mixture of benzyl chloride and toluene with zinc-dust (see BENZYL-TOLUENE), is treated in a similar manner. The anthracene condensed in the receiver is saturated with unaltered benzyl-toluene, which may be separated by draining and pressure, and when subjected to the same treatment, yields a further quantity of anthracene. The anthracene thus obtained is quite pure, and agrees in every respect with anthracene from coal-tar. The quantity obtained in the first operation is about 10 p. c. of the benzyl-toluene.

The constitutional formula of benzyl-toluene, obtained by Zincke's process, has not been exactly determined; but whichever of the possible isomerides of the formula, $C^6H^5.CH^2.C^6H^4.CH^3$, may be supposed to represent its constitution, it is impossible to explain the formation of anthracene from it by elimination of hydrogen, if anthracene be supposed to have the constitution originally suggested by Gräbe and Liebermann (1st Suppl. 214). If, however, anthracene be represented by the second constitutional formula proposed by those chemists (*Ann. Ch. Pharm. Suppl.* vii. 251), its synthesis from benzyl-toluene is easily explained, supposing the latter to be an ortho-derivative (1 : 2) of benzene. The following formulae may represent the transformation:

Berthelot, by passing toluene vapour through a red-hot tube, obtained—besides other products—anthracene and a liquid hydrocarbon, $C^{14}H^{14}$, boiling at 179° ; this was doubtless benzyl-toluene, and the anthracene was produced by its decomposition as above.

2. Anthracene is formed by reduction of oxidised organic compounds containing the same number of carbon-atoms: a. From anthroquinone, by the action of zinc-dust in presence of hydrochloric acid or of strong potash- or soda-ley at the boiling heat (Böttger, *J. pr. Chem.* [2] ii. 133).

b. From rufgallie acid, $C^{14}H^8O^8$,

Now, ruffgallic acid contains the elements of 2 mol. gallic (dioxysalicylic) acid, minus 2 mol. water: $2C^7H^5O^3 - 2H^2O = C^{14}H^{10}O^3$, and is formed by heating gallic acid with sulphuric acid. The reaction above mentioned affords, therefore, the means of passing, by a definite transformation at a moderate heat, from the benzene series to the anthracene series (Jaffé, *Deut. Chem. Ges. Ber.* iii. 694).

γ. Anthracene is also said to be formed by the action of zinc-dust on curcumin (Kachler, *ibid.* 713).

Preparation and Purification.—For the preparation of anthracene from coal-tar, J. Gessert introduces the last pasty portions (green grease) of the coal-tar distillation (which should not be carried beyond the point at which white pitch is produced), first into a centrifugal machine, and then into a hydraulic press at 40° , or subjects the mass heated to 30° – 40° directly to pressure in a filter-press. The pressed mass contains about 60 p. c. of anthracene; for further purification it is boiled out with light tar-oil or petroleum-naphtha, and finally heated till it melts. The residue contains 95 p. c. anthracene (*Dingl. polyt. J. exvi.* 543).

For the purification of crude anthracene contaminated with oily matters, Schuller (*ibid.* 546) recommends the following process:—The crude anthracene is carefully heated to commencing ebullition in a capacious retort connected with a tubulated receiver of glass or earthenware, the lower aperture of which is closed with a fine wire sieve. A strong current of air is then blown into the retort with a pair of bellows, whereby the anthracene is driven over in a very short time nearly pure and dry, and condenses in the receiver as a faintly yellowish snowy mass. By this method a quantity of anthracene, the purification of which by recrystallisation or sublimation would take several days, may be purified in as many hours; moreover, it is obtained in a pulverulent form, in which it is very readily acted on by oxidising agents. Anthraquinone, prepared from crude anthracene, may also be obtained by this method in the form of a light yellow powder resembling flowers of sulphur.

Fritzsche, by exposing a solution of anthracene in coal-tar naphtha to sunshine till it became colourless, obtained the anthracene in crystals exhibiting a beautiful violet-blue fluorescence (*1st Suppl.* 177). The same fluorescent crystals are obtained, according to v. Wartha (*Zeitschr. f. Chem.* [2] vi. 695), by melting anthracene with sulphur. Streams of hydrogen sulphide are then given off, and part of the anthracene which is in excess, sublimes in fine crystals exhibiting the violet-blue fluorescence, whereas the same anthracene, if repeatedly recrystallised without treatment with sulphur, and then sublimed in a vacuum, yields snow-white, non-fluorescent crystals.

The sublimation of anthracene is best effected according to v. Wartha (*ibid.* 545) in a vacuum, the apparatus consisting of a wide tube connected with a mercury- or water-pump.

For the valuation of commercial anthracene, 5 or 10 grams of the substance may be pressed between paper and warm plates, then boiled with at least an equal weight of alcohol, separated by filtration after cooling, then washed with alcohol, dried, and weighed (Gessert).

On the preparation of Anthracene from coal-tar and of Dyo-stuffs from anthracene, see Brönnner u. Gutzkow (*Dingl. polyt. J.* cxi. 545; *Chem. Soc. J.* [2] ix. 1222).

Action of Carbonyl Chloride (phosgene) on Anthracene.—Graebe u. Liebermann, by heating anthracene with liquid carbonyl chloride in sealed tubes, obtained a yellow crystalline chlorinated compound, which when heated with aqueous sodium carbonate was converted into anthracene-carbonic acid, $C^{14}H^8.CO^2H$ (*1st Suppl.* 179). Berthelot, on the other hand (*Bull. Soc. Chim.* [2] xiii. 391), obtained, by the same process, nothing but a mixture of hydrocarbons having a percentage composition agreeing with the formula $C^{14}H^8$: whence it would appear that the action of phosgene at high temperatures on anthracene consists merely in the abstraction of hydrogen. But the results obtained by Graebe and Liebermann, according to which the reaction takes place in the manner represented by the equation, $C^{14}H^{10} + COCl^2 = HCl + C^{14}H^8.COCl$, appear too definite to be doubted.

Action of Chromic Oxychloride. This acid chloride converts anthracene into anthraquinone together with a small quantity of dichloranthraquinone (Carstanjen, *Zeitschr. f. Chem.* [2] vi. 206).

Nitroanthracenes.—When nitric acid and anthracene in equal numbers of molecules are heated in alcoholic solution, the liquid assumes a red colour, and after some time red crystals of mononitro-anthracene, $C^{14}H^9NO^2$, separate out (about 80 p. c. of the anthracene). This compound is insoluble in cold alcohol and benzene; from a hot alcoholic solution it crystallises in needles grouped in stars. When heated it sublimes in needles, which have the greatest resemblance to sublimed alizarin. The formation of this compound in alcoholic solution is the more interest-

ing, as the pure nitro-compounds are not formed by the action of nitric acid on solid anthracene.

Besides the mononitro-compound, dinitro-anthracene is also formed, the quantity of it increasing if more nitric acid is employed. It is moderately soluble in hot alcohol and benzene, and sublimes in colourless plates (Bolley, *Zeitschr. f. Chem.*, [2] vii. 45).

When mononitro-anthracene is heated with zinc and a solution of caustic potash, the solution acquires first a red and afterwards a yellow colour. On exhausting it with hot alcohol and mixing this solution with water and hydrochloric acid, a body is precipitated, which is soluble in alcohol and benzene, and when heated sublimes in colourless plates.

DIMETHYL-ANTHRACENE, $C^{10}H^{14} = C^{11}H^8(CH^3)^2$, is formed, together with an oily body (probably *xylyl-xylene*, $C^{10}H^{18}$), by exposing *xylyl chloride*, $C^8H^4.CH^3.(CH^2Cl)$ (prepared by the action of chlorine on boiling coal-tar xylene), to the action of water at 200° in sealed tubes:

the reaction being analogous to that by which anthracene and benzyl-toluene are formed from benzyl chloride (p. 82).

The product is a brown aromatic oil, which when distilled, gives off *xylyl-xylene*, as a pale yellow oil at about the boiling point of mercury, and towards the end of the distillation, dimethyl-anthracene, which crystallises in the neck of the retort. The *xylyl-xylene* passed through a red-hot tube is almost wholly resolved into dimethyl-anthracene and free hydrogen.

Dimethyl-anthracene closely resembles anthracene; it crystallises in large glistening plates, which are white and fluorescent when perfectly pure, and melt at about 200° . By oxidation with chromic acid it yields a product which may be sublimed in yellow plates melting at 153° ; probably dimethyl-anthraquinone. A small quantity of a second body of higher melting point is also formed (A. van Dorp, *Deut. Chem. Ges. Ber.* v. 674.).

ANTHRACENE, ISOMERIDES OF.—I. PHENANTHRENE (Graebe, *Deut. Chem. Ges. Ber.* v. 861; *Ann. Ch. Pharm.* clxvii. 131. Fittig a. Ostermayer, *Deut. Chem. Ges. Ber.* v. 933; *Ann. Ch. Pharm.* clxvi. 361).—*Occurrence.* This hydrocarbon, differing from anthracene in its melting point and in several of its reactions, has been obtained from crude anthracene, and from the liquid portion of coal-tar oil which boils above 300° .—1. In the purification of crude anthracene on the large scale, Glaser obtained a dark yellowish brown crystalline mass, melting at a few degrees below 100° , and boiling between 310° and 360° . From this product phenanthrene may be isolated by distillation and repeated crystallisation from alcohol. It is better, however, first to prepare the *picric acid* compound, by dissolving 1 part of the crude material and $1\frac{1}{2}$ part of *picric acid* in hot coal-tar naphtha boiling between 100° and 140° ; the solution on cooling deposits the *picrate* $C^{14}H^{10}.C^8H^4(NO_2^3)O^3H$ in long golden-yellow needles or prisms melting at 145° . This compound is resolved, slowly by water, and quickly by alkalis, into *picric acid* and phenanthrene (Graebe).

2. Fittig a. Ostermayer obtained phenanthrene from a neutral coal-tar oil boiling between 300° and 400° , by subjecting this oil to fractional distillation, and cooling the portions which boiled above 300° , to 0° . The crystals thereby separated were dried in bibulous paper and repeatedly crystallised from alcohol to remove anthracene and other bodies.

Formation. Phenanthrene is formed, together with toluene, by passing *stilbene* through a red-hot tube:

It is also formed by the same reaction from dibenzyl, which, as Dreher a. Otto have shown, is first resolved into toluene and stilbene: $2C^{10}H^{14} = 2C^8H^8 + C^{10}H^{12}$.

These reactions render it probable that phenanthrene has the constitution originally assigned by Graebe a. Liebermann to anthracene, that is to say, that it is diphenyl $C^8H^8-C^8H^8$, in which two atoms of hydrogen are replaced by the group $-CH=CH-$ (Graebe).

Phenanthrene crystallises in small plates, which generally have a yellowish colour, but when quite pure, are brilliant and colourless, and exhibit a blue fluorescence, fainter, however, than that of anthracene. It is sparingly soluble in cold alcohol, but dissolves readily in hot alcohol, ether, benzene, acetic acid, and carbon sulphide. It melts at 99° – 100° , and sublimates very readily, but boils only at a temperature much above 300° (Fittig & Ostermayer); melts at 100° and boils at 340° , with the whole column of mercury in the vapour (Graebe).

Oxidation. Phenanthrene gently heated with potassium dichromate and dilute sulphuric acid is oxidised to phenanthrenequinone, $C^{14}H^{10}O^2$ (Fittig & Ostermayer). The same compound is formed by gradually adding a solution of chromic acid in acetic acid to a solution of phenanthrene in hot glacial acetic acid (Graebe). This reaction affords the means of detecting the presence of phenanthrene in crude anthracene. On heating that substance with acetic acid and chromic acid, treating the product with sodium carbonate to remove acids, and heating the undissolved portion with a solution of *acid sodium sulphite*, the phenanthrenequinone is alone dissolved, and may be precipitated from the solution by acids, and recognised by its properties (see ANTHRAQUINONE, p. 93).

Reduction. Phenanthrene is not reduced by sodium-amalgam in alcoholic solution; but by heating it with hydriodic acid and phosphorus to 200° , it is converted into tetrahydrophenanthrene, $C^{14}H^{14}$, a liquid boiling at 300° – 310° , whilst at 240° the hydrocarbon $C^{14}H^{12}$ is formed, which is also liquid, and boils below 300° (Graebe).

Phenanthrene Dibromide, $C^{14}H^{10}Br^2$, is formed on adding bromine drop by drop to an ethereal solution of phenanthrene, and crystallises in four-sided prisms: it is very unstable, decomposing spontaneously on keeping (F. and O.).

Phenanthrene Picrate, $C^{14}H^9 \cdot C^6H^3(NO^2)^3O$, is obtained in the manner already mentioned (p. 84), in long, golden yellow or reddish-yellow prisms; from a mixture of the cold alcoholic solutions of phenanthrene and picric acid it separates in red needles. It melts at 145° (Graebe), at 143° (F. and O.). It may be boiled with a large quantity of alcohol without decomposition, but water resolves it into phenanthrene and picric acid.

Nitrophenanthrenes. Cold concentrated nitric acid converts phenanthrene into the mononitro-compound $C^{14}H^9(NO^2)$, which, by solution in acetic acid and addition of water, is obtained as a yellow crystalline precipitate melting between 70° and 80° . If the nitric acid is not kept cold, dinitrophenanthrene, $C^{14}H^8(NO^2)^2$, is formed, and may be obtained in quantity by heating to 100° ; it separates from acetic acid in yellow crystals melting between 150° – 160° (Graebe).

Phenanthrene-sulphonic acid, $C^{14}H^9SO^3H$, is produced, together with a small quantity of the disulphonic acid, by heating phenanthrene with sulphuric acid to 100° . Separated from the lead salt by hydrogen sulphide, it forms a crystalline mass, more freely soluble in hot than in cold water. The *calcium salt* $Ca(C^{14}H^8SO^3)^2 + 4H^2O$ crystallises in small plates, and dissolves readily in alcohol and in hot water. The *lead salt* $Pb(C^{14}H^8SO^3)^2 + 2H^2O$ is freely soluble in water and in alcohol, and does not crystallise well. The *barium salt* has similar properties (Graebe).

II. Another isomeride of anthracene, distinguished by its much higher melting point, is said by Ernst Schmidt (*Deut. Chem. Ges. Ber.* v. 930) to be formed by the reduction of a red modification of mononitro-anthracene. When anthracene is nitrated by Bolley's method in alcoholic solution, a mixture of isomeric mononitro-derivatives is obtained, consisting of a red and a white mononitro-anthracene. If the former be acted upon by tin and hydrochloric acid, the red body disappears after a time, and is replaced by a yellowish-grey substance, readily purified by recrystallisation from alcohol or benzene. The same compound is formed in small quantity on subliming red mononitro-anthracene, together with a yellow substance (possibly dinitro-anthracene), of lower melting point.

This body has the composition $C^{14}H^{10}$; it crystallises in thin, silky, glistening plates, which exhibit a violet-blue fluorescence; melts at 247° . It is almost insoluble in cold, but more soluble in hot alcohol; benzene, chloroform, and carbon sulphide dissolve it readily. It unites with picric acid, forming a compound which crystallises in reddish-yellow needles. It is not affected, even by prolonged heating, with nitric acid of sp. gr. 1.2, but is readily acted upon by more concentrated or fuming acid. Sulphuric acid does not act upon it at 100° , but on further heating dissolves it, and converts it into a sulpho-acid, forming a bluish-green solution, without the least carbonisation.

The action of tin and hydrochloric acid on mononitro-anthracene likewise gives rise to *amidanthracene* or *anthracenamine* (p. 81), (Schmidt).

ANTHRACENE-ORANGE (Böttger, *J. pr. Chem.* [2] ii. 130; *Chem. Centrbl.* 1870, 559).—A derivative of nitro-anthracene obtained by the action of reducing agents on nitro-anthraquinone. Anthraquinone is heated to about 140° with about 16 parts by weight of a mixture of equal volumes of sulphuric acid (sp. gr. 1.84) and nitric acid (sp. gr. 1.5), and the resulting solution is immediately poured into cold water. The nitro-compound which separates is washed and treated with a solution of potassium or sodium stannite (prepared by adding a fresh solution of stannous chloride to potash- or soda-ley, till the liquid begins to show turbidity, and filtering after clarification), whereby an emerald-green liquid is produced, which, when heated to the boiling point, soon deposits anthracene-orange as a flocculent powder of a nearly vermilion-red colour.

Anthracene-orange melts at 225° , and sublimes at a higher temperature in splendid garnet-red feathery needles, having a greenish surface-lustre. It dissolves in ether, acetic ether, acetone, aldehyde, alcohol, and wood-spirit, also in benzene and amyl-alcohol, only slightly in carbon sulphide, not at all in light petroleum oil. Sulphuric acid dissolves it without decomposition, even at the boiling heat, and the solution is precipitated by water. Nitric acid of sp. gr. 1.2 likewise exerts at ordinary temperatures only a solvent action. Potash and soda have no action on this compound; mercuric nitrate converts it, on heating, into a deep violet powder, which dissolves with the same colour in alcohol or ether.

The above mentioned emerald-green solution, if mixed, without warming, with an excess of dilute sulphuric acid, deposits a brownish-red precipitate, which, when dried and dissolved in alcohol, yields, after the alcohol has been distilled off, a brown colouring matter, soluble, with deep purple-red colour, in acetic ether and in alcohol.

ANTHRACHRYSONE, $C^{14}H^{10}O^2$ (Barth n. Senhofer, *Ann. Ch. Pharm.* clxiv. 109).—A compound produced by the dry distillation of dioxybenzoic acid, or by heating that compound for an hour with four or five times its weight of strong sulphuric acid:

On adding water to the dark blood-red solution obtained by the latter process, the anthrachryson separates as a dark green powder, which may be purified by dissolving it in alcohol and boiling the solution with animal charcoal. From the yellow filtrate it is precipitated by water in crystalline flocks, having the composition $C^{14}H^{10}O^2 + 2H^2O$, and becoming anhydrous when dried at 100° .

This body is not an anhydride of dioxybenzoic acid, as by heating it with water or potash it is, according to the temperature, either not altered at all or completely destroyed. By heating it with zinc-dust it is reduced to anthracene; it is, therefore, a *tetraoxyanthraquinone*, and its formation is analogous to that of rufigallic acid from gallic acid, or of rufopin from opianic acid.

Anthrachryson forms a golden-yellow crystalline powder, which, when heated, gives off a quinone-like smell, but does not melt even at 320° . It can be distilled without decomposition, and is but sparingly soluble in alcohol, and less so in benzene and toluene. Water dissolves only traces of it; in dilute sulphuric acid or hydrochloric acid or carbon sulphide it is quite insoluble. The best solvent for it is glacial acetic acid; water precipitates it from this solution in greenish-yellow flakes. Although possessing the characteristic properties of a quinone, anthrachryson is not acted upon by sodium-amalgam.

On heating it with a large quantity of water and freshly-precipitated barium carbonate, the compound $(C^{14}H^{10}O^2)_2Ba + 11H^2O$ separates on standing in dark red crystalline flakes. The same salt is obtained in needles half an inch long when anthrachryson is heated with the right quantity of baryta-water and the solution is concentrated. On adding barium chloride to a solution of the ammonium salt, dark red needles, having the composition $C^{14}H^{10}O^2Ba$, gradually crystallise out. When calcium chloride is added to the ammoniacal solution, the calcium salt is obtained as a precipitate consisting of light red microscopic needles. The magnesium and aluminium salts are amorphous red precipitates; the copper- and silver-salts, brown amorphous masses. By fusing anthrachryson with potash, a large quantity of a humus-like substance is formed, together with a small quantity of a crystalline body. Anthrachryson dyes on iron-mordants a brown colour, and on alumina-mordants it produces a colour like that of alizarin, but duller.

ANTHRAFLAVIC ACID, $C^{14}H^{10}O^4$ (Schunck, *Proc. Lit. Phil. Soc. of Manchester*, x. 133. Liebermann, *Deut. Chem. Ges. Ber.* iv. 103. Perkin, *Chem. Soc. J.* [2] ix. 1109; xi. 19).—An acid, isomeric with alizarin, obtained as a bye-product in the preparation of the latter by melting disulphanthraquinone acid with potash (1st Suppl. 84), especially when the action is weakened by admixture of chalk.

To prepare it, commercial artificial alizarin is boiled with baryta-water, and the orange-coloured filtered solution of barium anthraflavate is precipitated with hydrochloric acid; or the crude alizarin is dissolved in boiling dilute soda-ley; milk of lime is added till the solution, still kept boiling, becomes yellow or orange; this liquid is filtered from the purple calcium salt; and the anthraflavic acid is precipitated by hydrochloric acid, washed on a filter, and dried. It is then powdered and boiled with alcohol; the dark coloured liquid, when cold, is filtered off; the undissolved portion is treated with weak caustic soda; and the resulting solution is filtered to remove insoluble impurities,* then boiled, mixed with excess of barium chloride, and rapidly filtered. On cooling, the barium anthraflavate is deposited in needles, which may be purified by three or four crystallisations from water (Perkin).

Schunck assigned to anthraflavic acid the formula $C^{12}H^{10}O^4$. Liebermann regards it as monoxyanthraquinone, $C^{12}H^{10}O^4$, identical with that produced by the action of potash on monobromanthraquinone or anthraquinone-monosulphonic acid (p. 92). But from Perkin's analysis of the product obtained from commercial alizarin, and of its derivatives, it appears to be isomeric with alizarin, that is to say, to have the composition of dioxyanthraquinone. Perkin, moreover, points out that both these oxyanthraquinones are probably formed in the manufacture of alizarin, and are separated in the treatment with baryta-water above described, anthraflavic acid being nearly insoluble in cold baryta-water, and separating out as a barium-salt, whereas monoxyanthraquinone, which, according to Liebermann, is easily soluble in cold baryta-water, remains in the mother-liquor.

Anthraflavic acid separated from the pure barium-salt by hydrochloric acid, and purified by washing, drying, and crystallisation from boiling alcohol, forms beautiful bright yellow silky needles, generally arranged in radiate groups. After drying in a vacuum, it is perfectly anhydrous, and does not lose weight even when heated to 180° (Perkin).

It is chiefly the presence of anthraflavic acid in crude alizarin that affects the colour of the alkaline solution, changing the violet due to alizarin into purple, or when present in larger quantity, into red. For the same reason an alkaline solution of crude alizarin does not show the absorption-bands in the spectrum so distinctly as one of pure alizarin. Alkaline, as well as alcoholic solutions of anthraflavic acid, absorb the blue end of the spectrum very powerfully, though no bands are visible, even with very dilute solutions. A solution of the acid in concentrated sulphuric acid, if not too dark, shows, however, a broad but well defined absorption-band at the extreme edge of the blue, bordering on the green, accompanied by a total absorption of the violet, as seen with the other solutions (Schunck).

When pure anthraflavic acid is dissolved in excess of caustic potash, and the solution is boiled down to dryness, a yellow residue is left, which, after being carefully heated almost to fusion, dissolves in water with a red colour; this solution contains alizarin.

Anthraflavic acid, like alizarin, appears to be reduced to anthracene by zinc-powder (Schunck).

Anthraflavic acid is bibasic. It is but a weak acid, though it forms well defined salts, some of which are regularly crystallised. All its soluble salts give yellow solutions, but it has no dyeing properties.

Barium anthraflavate crystallises in reddish-brown hydrated needles, which, when dried at 150° , have the composition, $2C^{12}H^8BaO^4 \cdot H^2O$, and do not undergo any further diminution in weight even when heated to 180° . When dried in a vacuum or at 100° , it contains a larger quantity of water, corresponding with the formula $2C^{12}H^8BaO^4 \cdot 3H^2O$. When freshly prepared, it contains a much larger quantity. An air-dried specimen heated to 100° lost 18.2 p. c., answering to the formula $2C^{12}H^8BaO^4 \cdot 3H^2O + 10aq.$, which requires 18.3 p. c. for 10aq. (Perkin).

Diacetyl-anthraflavic acid, $C^{12}H^{10}O^6 = C^{12}H^8O^2 \cdot \begin{Bmatrix} C^2H^3O \\ OC^2H^3O \end{Bmatrix}$. — Anthraflavic acid, heated to about 160° in sealed tubes with acetic anhydride, gradually dissolves, and if the temperature be kept up for four or five hours, entirely disappears, the liquid on cooling depositing diacetyl-anthraflavic acid, which may be purified by one or two recrystallisations from glacial acetic acid. It then forms small, beautiful crystals of a very yellow colour, and somewhat like benzoic acid in shape. It melts at $228^\circ - 229^\circ$, and may be volatilised without decomposition. It dissolves sparingly in alcohol; with moderate facility in glacial acetic acid. Strong sulphuric acid dissolves it, forming an orange-red liquid, from which water throws down a yellow precipitate, apparently consisting of anthraflavic acid. Alcoholic potash decomposes it, reproducing anthraflavic acid.

* These impurities are present in considerable quantities, and when heated, give a sublimate of pale yellow needles, like anthraquinone, leaving a carbonaceous residue.

Dibenzoyl-anthraflavic acid, $C^{28}H^{16}O^6 = C^{14}H^8O^2 \left\{ \begin{smallmatrix} OC^7H^3O \\ OC^7H^3O \end{smallmatrix} \right.$, is formed by boiling anthraflavic acid with excess of benzoyl chloride, and separates from the liquid, on cooling, in needle-shaped crystals, which may be purified by repeated washing with glacial acetic acid, and then with alcohol. It is of a pale yellow colour, melts at 275° ; is insoluble, or nearly so, in alcohol, very slightly soluble in boiling glacial acetic acid, from which it is deposited in fine needles on cooling. Alcoholic potash acts upon it but slowly. With strong sulphuric it reacts like acetyl-anthraflavic acid, but dissolves less readily (Perkin).

ANTHRAHYDROQUINONE, $C^{14}H^8O^2 = C^{14}H^8(OH)^2$. When a dilute solution of caustic soda is added to a mixture of anthraquinone and zinc-dust, the liquid assumes a red colour, and the anthraquinone gradually dissolves. On adding an acid to this solution, the product of reduction is obtained as a yellow precipitate, which when exposed to the air is soon reconverted into anthraquinone. To obtain the pure product it must be precipitated, washed, and dried in an atmosphere of carbon dioxide. The analysis of the compound gave numbers corresponding with the formula $C^{14}H^8(OH)^2$, but it probably contained also some anthraquinhydrone $\begin{smallmatrix} C^{14}H^8OH \\ C^{14}H^8OH \end{smallmatrix} (O^2)^2$ (Graebe u. Liebermann, *Deut. Chem. Ges. Ber.* v. 15). Anthrahydroquinone is likewise produced by prolonged fusion of anthraquinone with potassium hydrate at temperatures above 250° (*ibid.* iii. 634).

ANTHRAPURPURIN, $C^{14}H^8O^2$ (Perkin, *Chem. Soc. J.* [2] x. 659; xi. 425). A colouring matter, isomeric with the purpurin of madder, obtained as a secondary product in the preparation of alizarin from anthracene. It may be separated from alizarin by precipitating the two colouring matters together with alumina, and treating the resulting lake with an alkaline carbonate, the anthrapurpurin being then dissolved out, while the alizarin lake remains unattacked. The process, however, is slow, involving tedious filtrations, and it is better to dissolve the crude colouring matter in dilute sodium carbonate, and agitate the resulting solution with freshly precipitated alumina, which combines with the alizarin, leaving the anthrapurpurin in solution. This is filtered off from the alizarin lake, heated to boiling, and acidified with hydrochloric acid. The colouring matter which is precipitated is then collected on a filter, washed, and dried.

The anthrapurpurin thus obtained is very impure, being associated with a substance which dyes alumina-mordant of an orange colour, as well as with anthraflavic acid, &c. These impurities can be removed to a considerable extent by repeatedly boiling the product with alcohol, anthrapurpurin being but little soluble in that liquid. For further purification, it is best to digest the product with boiling alcoholic soda, collect the difficultly soluble sodium-compound which forms, on a filter, and wash it several times with dilute alcoholic soda. It is then dissolved in water and boiled, and the colouring matter is precipitated with barium chloride. The purple barium-compound thus obtained is collected on a filter, washed a few times with hot water, and then decomposed by boiling with sodium carbonate; the resulting purple solution is filtered off, and the anthrapurpurin precipitated with hydrochloric acid. After this precipitate has been collected on a filter, it is well washed with water, dried, and finally twice crystallised from glacial acetic acid.

Anthrapurpurin thus purified gave in several analyses from 65.11 to 66.12 p. c. carbon, and 3.17 to 3.47 hydrogen: the formula $C^{14}H^8O^2$ requires 65.62 carbon and 3.12 hydrogen. This formula is confirmed by the analyses of the acetyl and benzoyl derivatives.

Anthrapurpurin when heated, first fuses and then evolves orange-coloured vapours, which condense as yellowish-red leaves or needles, but by far the largest quantity of the substance is carbonised. It is difficultly soluble in alcohol and ether, but rather more soluble in glacial acetic acid. It is deposited from the boiling acetic solution on standing in small fungoid-looking groups of minute orange-coloured needles. These groups are generally not more than 2 or 3 m.m. in diameter, and from the direction of the crystals, generally appear lighter on the under side than on the upper. They can only be seen to advantage under the microscope. As this substance dissolves but slowly in boiling glacial acetic acid, it is sometimes necessary to distil off part of the acid before the resulting solution can be made to deposit crystals.

Anthrapurpurin is very slightly soluble in water, and may be removed from its aqueous solution by means of ether. When heated with powdered zinc, it yields small quantities of a hydrocarbon, which, when purified, has the melting point and other properties of ordinary anthracene.

The solution of anthrapurpurin in caustic potash gives two absorption-bands situated in the same region of the spectrum as those produced by alkaline solutions of

alizarin; they are also produced by alkaline solutions of triacetyl-alizarin. In solutions prepared with caustic alkalis, these absorption-bands are more decided than in those in which alkaline carbonates are used; in either case, however, they are much fainter than those of alizarin. The ammoniacal solution does not appear to give bands, nor does the ethereal solution of the colouring matter; in the latter case, however, the violet is almost entirely absorbed.

As a dyeing agent, anthrapurpurin has about the same affinity for mordants as alizarin. The colours it produces are also analogous to some extent, as it produces red with alumina, purple and black with iron mordants. There is, however, a considerable difference in the shade of colour produced, the reds being much purer and less blue than those of alizarin, whilst the purples are bluer and the blacks more intense. In fastness against soap and light the colours are quite equal to those produced with alizarin.

When used to dye Turkey-red, anthrapurpurin produces very brilliant colours of a scarlet shade, which are of remarkable permanence.

Ordinary *nitric acid* acts rapidly on anthrapurpurin when heated, evolving a large quantity of red fumes; in one experiment oxalic acid and a nitro-acid were obtained, but no phthalic acid.

Action of Ammonia. When an ammoniacal solution is heated to 100° in a sealed tube for some hours, its purple colour changes to indigo-blue, and the solution acidified with hydrochloric acid deposits a dark purple precipitate, probably isomeric with Stenhouse's purpuramide or purpurein, which dissolves in ammonia and in sodium carbonate with a blue colour, in caustic alkalis with a red-purple colour. It dyes alumina-mordants purple, weak iron-mordants indigo-blue.

Metallic Derivatives. Anthrapurpurin forms metallic derivatives which are insoluble or nearly so in water, except those of the alkali-metals. It dissolves in *potash* and *soda*, producing beautiful violet-coloured liquids, which become blue in the shade when heated. They are not so blue as those obtained with alizarin. The sodium-derivative is difficultly soluble in alcohol. Anthrapurpurin also dissolves in solutions of the alkaline carbonates with a reddish purple colour, and is precipitated by carbonic acid. A solution of sodium bicarbonate, if gently heated, dissolves anthrapurpurin more readily than alizarin. With the chlorides of *calcium*, *magnesium*, *barium*, and *strontium*, the ammoniacal solution of anthrapurpurin gives purple precipitates. Specimens of the barium precipitate dried at 170° – 180° , gave proportions of barium about 2 p. c. lower than that required by the formula, $C^{20}H^{10}Ba^2O^{18}$. With alumina anthrapurpurin forms a lake somewhat similar to that produced with purpurin. *Cupric acetate* added to an alcoholic solution of anthrapurpurin changes it from yellow to a beautiful purple, which cannot be distinguished from that produced with alizarin under the same circumstances. When boiled with *alum* or *sulphate of alumina*, it does not give any special reaction, whereas its isomeride, purpurin, gives a pink solution which is fluorescent. In basic aluminium sulphate, however, it dissolves to some extent, forming an orange-pink solution, which is not fluorescent; acids precipitate the colouring matter from this solution.

Dibromanthrapurpurin.—When anthrapurpurin is digested with bromine and carbon disulphide for several hours in a flask connected with an inverted condenser, the excess of these substances then driven off, and the residue crystallised from glacial acetic acid, an orange-coloured product is obtained, giving a percentage of bromine a little higher than that required by the formula of dibromanthrapurpurin, $C^{18}H^8Br^2O^8$.

Triacetyl-anthrapurpurin, $C^{20}H^{10}O^8 = C^{14}H^4(C^2H^3O)^3O^8$. Anthrapurpurin heated under pressure with acetic anhydride in excess to a temperature of 150° – 160° for four or five hours, dissolves entirely, and the solution on cooling deposits a large quantity of pale yellow scales, which are easily purified by draining off the excess of acetic anhydride, and recrystallising three or four times from glacial acetic acid. For the preparation of this compound, it is not necessary to use pure anthrapurpurin, the crude product before treatment with alcoholic caustic soda answering very well; but in this case the product should be recrystallised till the mother-liquors are of a clear pale yellow colour.

The substance thus obtained gave, in two analyses, 62.90 and 62.77 p. c. carbon, 8 and 3.77 hydrogen: numbers which agree best with the formula of a triacetyl-derivative (62.83 C. and 3.66 H.), but nevertheless, approximate closely to those required by the formula of diacetyl-anthrapurpurin, $C^{18}H^8O^8 = C^{14}H^4(C^2H^3O)^2O^8$, viz., 3.5 C. and 3.5 H. The true composition of the acetyl-derivative is, however, readily

determined by boiling it with alcoholic potash or soda, whereby it is resolved into acetic acid and anthrapurpurin, and weighing the anthrapurpurin thus obtained. For this purpose, a weighed quantity of the acetylic derivative was boiled for some time with alcoholic soda, until the alcohol had been nearly all driven off; water was then added, and the purple solution boiled until quite free from alcohol; the anthrapurpurin was then precipitated with hydrochloric acid, and after standing for twenty-four hours, was collected on a weighed filter, well washed with cold water, dried at 110° , and weighed. As the filtrate contained a small quantity of anthrapurpurin in solution, it was agitated with ether, and the ethereal solution evaporated in a weighed dish. The united weights of the colouring matter on the filter and that extracted from the washings with ether, gave in two experiments 66.61 and 67.21 p. c. anthrapurpurin. Now, the decomposition of triacetyl-anthrapurpurin, according to the equation:—

would yield 67.01 of anthrapurpurin, a number closely agreeing with experiment, whereas a diacetyl-derivative similarly decomposed would give 75.3 p. c. This substance is therefore triacetyl-anthrapurpurin.

Triacetyl-anthrapurpurin melts at 220° – 222° . It is not very soluble in alcohol, but moderately so in glacial acetic acid. It crystallises from this latter solvent in beautiful pale yellow glistening scales; as already mentioned, it decomposes when heated with alkalis.

When added gradually and in small quantities at a time to nitric acid, sp. gr. 1.5, triacetyl-anthrapurpurin dissolves without effervescence, forming a dark yellow solution; this, on being slowly added to a large quantity of cold water, deposits a pale brown precipitate, which, when collected and washed, dissolves in potash with a reddish purple colour. This solution does not appear to give any bands when viewed by the spectroscope, but a considerable absorption in the orange and violet. The addition of acid causes the colouring matter to separate as an orange precipitate. This substance dyes alumina-mordants of an orange colour, and weak iron-mordants of a reddish-purple.

Tribenzoyl-anthrapurpurin, $C^{16}H^2O^3 = C^{14}H^2(C^2H^3O)^2O^3$, is formed by boiling anthrapurpurin with benzoyl chloride. Hydrochloric acid is then evolved, the anthrapurpurin dissolves, and the product on cooling forms a viscid mass, which may be purified by repeated boiling with water, and crystallisation from glacial acetic acid. This latter operation must be repeated, and after a portion of the substance, which first separates as a yellow powder, has been filtered off, the mother-liquor gradually yields small rosette-shaped groups of dark yellow or brownish crystals, which under the microscope, appear well formed and transparent.

The substance thus purified gave by analysis 73.6 to 73.72 p. c. carbon and 3.6–3.68 hydrogen, the formula above given requiring 73.94 p. c. carbon and 3.53 hydrogen. A dibenzoyl-derivative would require 72.75 carbon and 3.45 hydrogen.

Tribenzoyl-anthrapurpurin melts at 183° – 185° , dissolves with moderate facility in boiling glacial acetic acid, and is decomposed by alcoholic potash.

The composition of these acetyl and benzoyl derivatives shows that anthrapurpurin may be regarded as anthraquinone in which 3 at. H. are replaced by 3 at. HO. This compound and its derivatives may therefore be formulated thus:—

ANTHRAQUINONE, $C^{14}H^2O^2$.—The boiling point of this compound is above that of mercury. Its vapour-density, determined by Deville a. Troost's method, is 7.33; by calculation 7.20 (Graebe, *Deut. Chem. Ges. Ber.* v. 15).

Action of Phosphorus Pentachloride.—On heating anthraquinone with phosphorus pentachloride (diluted with phosphorus oxychloride) in sealed tubes for some hours to 190° – 200° , the following reaction takes place:—

The trichloranthracene thus obtained is not pure, but always contains more highly chlorinated products (Graebe a. Liebermann, *Ann. Ch. Pharm.* clx. 121).

Action of Alkalis.—When anthraquinone is heated for some time with caustic potash to 250° , it is decomposed, with formation of benzoic acid:—

(Graebe a. Liebermann, *loc. cit.*). According to Wartha (*ibid.* clxi. 305) the fusion of

anthraquinone with potash gives rise to the formation of alizarin. When anthraquinone is heated with potassium hydrate and water, an alcoholic solution of anthraquinone then added, and the heating continued, with constant stirring, a green colour is first produced which finally passes into the purple-blue of potassium-alizarin; and on dissolving the fused mass in water and adding hydrochloric acid, alizarin is precipitated, and may be extracted by ether. The quantity obtained is, however, but small, as the alizarin is partly decomposed by the excess of alkali present.* A larger product is sometimes obtained by mixing the anthraquinone with sodium or potassium ethylate before adding it to the fused potash.

Nitro-anthraquinones (Böttger a. Petersen, *Deut. Chem. Ges. Ber.* iv. 226; Liebermann, *ibid.* 230; Peterson, *ibid.* 301).—These bodies cannot be obtained directly from anthraquinone by the action of nitric acid; but by oxidising anthracene with nitric acid, there is obtained, together with anthraquinone, a dinitroanthraquinone identical with Anderson's dinitro-oxanthracene and Fritzsche's oxydinitrophenone.

The nitration of anthraquinone is however readily effected by a mixture of concentrated sulphuric and nitric acids. The product is a dinitroanthraquinone which separates, on pouring the acid mixture into water, in yellowish-white flocks, insoluble in water, difficultly soluble in alcohol and benzene, still less soluble in ether, and crystallising from these solvents in minute monoclinic, almost colourless crystals. At about 252° it cakes together to a brown mass, from which, at higher temperatures, with partial decomposition of the residue, yellow to brown needle-like crystals sublime. This body forms crystalline double compounds with various hydrocarbons. It does not yield with anthracene the fine violet compound given by Fritzsche's 'reagent' (*1st Suppl.* 215). On fusion with potassium hydrate, it yields alizarin in considerable quantity, a proof that the two nitro-groups occupy the same positions as the two OH

groups do in alizarin; that is to say, that its rational formula is $C^{11}H^4 \left(\frac{H^1}{(O^2)^2} \right)^2 \left(H^2(NO^2)^2 \right)^2$ (*ibid.* 215).

Action of Sulphuric Acid on Dinitro-anthraquinone.—When dinitro-anthraquinone is dissolved in excess of strong sulphuric acid (about 1 part in 18 parts), and the mixture is heated on a sand-bath at about 200°, a moderate evolution of sulphurous anhydride takes place, the brown-yellow liquid becoming deep brown-red. When the reaction becomes more violent, the source of heat is removed, the whole being afterwards heated again slowly, until the evolution of sulphurous anhydride ceases. The mass is then poured into cold water; the precipitated dark brown-red flocks are well washed, repeatedly dissolved in dilute alkali, reprecipitated by acid, and finally dissolved in alcohol; and the solution is slowly evaporated. The exceedingly stable now colouring matter, which can also be obtained by treating anthraquinone with a mixture of sulphuric and nitric acids (16 to 18 parts conc. sulphuric and 1 part nitric acid, sp. gr. 1.5), is slightly soluble in water, forming a peach-coloured solution; readily soluble in alcohol, ether, acetic ether, and chloroform; less soluble in benzene, with a magnificent red violet colour. It separates from these solvents, on slow evaporation, as a violet-red crystalline-granular mass; on quick evaporation, in violet-brown, metallic-glistening crusts. Cotton is dyed violet by it without the use of mordants. When heated, it melts, but only a small portion sublimes unchanged. Its analysis leads to the formula $C^{14}H^4N^2O^4$. On fusion with potassium hydrate, ammonia is evolved, but no alizarin could be detected. On treatment with zinc and sulphuric acid, gradual decolorisation and decomposition took place (Böttger a. Petersen).

Liebermann is of opinion that this compound was not obtained pure. He finds that when heated with water to 200°, it is converted into a spongy aggregate of dark needle-shaped crystals, which may be sublimed, but with considerable loss by carbonisation. Metallic-green shining needles are thus obtained, very much like naphthazarin. They contain nitrogen, though not in very considerable quantity. The vapour of this body strikingly resembles that of indigo.

According to Petersen (*Deut. Chem. Ges. Ber.* iv. 301), the violet body formed by treating dinitroanthraquinone with concentrated sulphuric acid, is di-imido-hydroxyl-anthraquinone, $C^{14}H^4N^2O^4$. On passing nitrous acid into its solution in alcohol and ether, oximido-dihydroxyl-anthraquinone, $C^{14}H^4NO^3$, is formed, which by sublimation is obtained in yellow or hyacinth-red, flat, feathery needles, which dissolve in caustic alkalis with a raspberry colour, and when fused with caustic potash, give alizarin. When this body is dissolved in concentrated nitric acid,

* Graebe a. Liebermann did not obtain alizarin by fusing anthraquinone with potash, probably on account of this further decomposing action.

dinitro-dihydroxyl-anthraquinone is obtained, which, on the addition of water, separates in yellow, very electric flakes, dissolving in caustic potash with a violet colour.

The formation of the oximido-compound corresponds with that of oximido- α -naphthol which Graebe and Ludwig obtained by the same reaction from di-imido- α -naphthol.

Diamidanthraquinone, $C^{14}H^6(NH^2)^2O^2$, is easily formed by reduction of dinitro-anthraquinone with sodium sulphhydrate (Böttger a. Petersen), or with tin and hydrochloric acid (Liebermann). It separates in the form of a red powder more or less soluble in alcohol, ether, acetic ether, and other solvents. According to Böttger a. Petersen, it dissolves easily in acids, especially when concentrated; according to Liebermann only in concentrated acids. It melts at 236° , and sublimes even at lower temperatures in magnificent garnet-red flat needles, with a greenish reflex, often united in feathery groups (B. and P.); in long capillary needles (L.). From alcohol and ether it crystallises in small needles (B. and P.); crystallises well from benzene (L.). It does not yield any colouring matter when heated with strong sulphuric acid (L.). According to Böttger a. Petersen it yields alizarin when fused with potash; but according to Liebermann, the colouring matter thus obtained differs in some respects from alizarin, especially in the manner in which it sublimes, and its behaviour when its solution in potash is exposed to the air.

When a solution of diamidanthraquinone in concentrated acid is treated with nitrous acid, an azo-derivative is formed, but it remains for the most part in solution, and is decomposed, with reproduction of anthraquinone, by the continued action of nitrous acid. But by acting with nitrous acid on diamidanthraquinone dissolved in common ether or in ethyl acetate, a peculiar azo-derivative is formed, which separates out on passing a current of the gas through the liquid, as a delicate brownish-violet powder, extremely alterable, and decomposed with slight detonation at about 68° , a bulky residue of carbon remaining. Analyses of several preparations led to the formula $C^{14}H^6N^4O$. It is soluble in alcohol and water, with a beautiful violet colour. When heated or left to stand for some time, both the aqueous and alcoholic solutions are decomposed, with reproduction of diamidanthraquinone, which falls down, together with a brown decomposition-product, accompanied by but a slight evolution of nitrogen. Böttger a. Petersen look upon this compound as a dinitroso-amidanthraquinone containing twice the univalent group, $N \begin{Bmatrix} H \\ NO \end{Bmatrix}$, or, in accordance with Graebe and Ludwig's observations on certain naphthol-derivatives, as a dioximido-amidanthraquinone containing twice the univalent group, $N \begin{Bmatrix} HN \\ O \end{Bmatrix} > O^2$, and express the reaction by the equation:—

By fusion with potassium hydrate it yields alizarin, according to Böttger a. Petersen, or according to Liebermann the body resembling alizarin which is obtained by similar treatment of diamidanthraquinone. When boiled with aqueous potash it yields a yellow solution, indicating that only a partial conversion of the amidogen-groups has been effected by the nitrous acid (Liebermann).

Oxyanthraquinones. *Monoxyanthraquinone*, $C^{14}H^6O^3 = C^{14}H^5O^2(OH)$, is formed by the action of melting potash on monobromanthraquinone or anthraquinone-monosulphonic acid; also, according to Liebermann, as a bye-product in the manufacture of alizarin (by fusing anthraquinone-disulphonic acid with potash). It may be separated from alizarin by its solubility in baryta-water, and precipitated from the solution by hydrochloric acid. When purified by sublimation and by crystallisation from acetic acid, it forms yellow needles. It dissolves in alkalis with red-brown colour, but does not give colours with mordants: with lead acetate it forms a bright yellow precipitate. By fusion with potash it is converted into alizarin, the change taking place by assumption of an atom of oxygen (Liebermann, *Deut. Chem. Ges. Ber.* iv. 103; v. 868).

Liebermann regards this compound as identical with anthraflavic acid, which, according to Perkin, on the contrary, is a dioxyanthraquinone isomeric with alizarin. Perkin has, however, pointed out that the two compounds are probably formed together in the manufacture of alizarin, and are separated by treatment with baryta-water, in which the dioxyanthraquinone is insoluble (see p. 87).

Acetyl-monoxyanthraquinone, $C^{14}H^5O^2(OC^2H^3O)$, produced by heating oxyanthraquinone to 100° with acetic anhydride, crystallises from alcohol in very small, nearly colourless fatted needles, melting at 158° (Liebermann).

ANTHRAQUINONE, ISOMERIDE OF. PHENANTHRENE-QUINONE, $C^{18}H^{10}O^2$ (Graebe, *Deut. Chem. Ges. Ber.* v. 861; *Ann. Ch. Pharm.* clxvii. 139. Fittig a. Oster

mayer, *Deut. Chem. Ges. Ber.* v. 933; *Ann. Ch. Pharm.* clxvi. 365). This compound is produced by gently heating phenanthrene with a mixture of 1 part. potassium dichromate, 1½ part sulphuric acid, and 3 parts water. A brisk reaction soon commences and goes on without further application of heat. The product may be freed from a small quantity of anthraquinone, formed by oxidation of admixed anthracene, by partial crystallisation from alcohol, or better from a mixture of equal volumes of glacial acetic acid and water, in both of which solvents it dissolves more easily than anthraquinone (F. and O.). Graebe prepares the quinone by dissolving phenanthrene in hot glacial acetic acid, and gradually adding a solution of chromic acid in acetic acid, so as to keep the liquid just at the boiling point; to complete the reaction the solution must be boiled for some time. On distilling off the greater part of the acetic acid, and adding water to the residue, phenanthrene-quinone separates as a crystalline precipitate, which may be purified by crystallisation from glacial acetic acid, or more conveniently by dissolving it in a solution of acid sodium sulphite and reprecipitating with an acid.

Phenanthrene-quinone is almost insoluble in cold water, but dissolves sparingly in hot water, and in cold alcohol somewhat more freely than in boiling alcohol, still more in ether, benzene, and glacial acetic acid. It crystallises in dark reddish-yellow or orange-yellow needles or prisms (Graebe; F. and O.); melts at 198°, and sublimes at a higher temperature, with partial decomposition, in brilliant transparent orange-red plates.

Phenanthrene-quinone heated with bromine to 100° in sealed tubes yields a compound which is but little soluble in ordinary solvents, and appears to be a dibromoquinone.

Phenanthrene-quinone dissolves without alteration in cold sulphuric acid, and no sulphonic acid is formed even at 100°; but on heating the solution more strongly, decomposition takes place. The quinone may, however, be converted into sulphonic acids by acting on it with sulphuric anhydride.

Strong nitric acid dissolves phenanthrene-quinone, forming a red solution, from which the quinone is reprecipitated on addition of water. A boiling mixture of sulphuric and nitric acids converts it, but not readily, into nitro-compounds, from which by crystallisation from acetic acid dinitrophenanthrene-quinone $C^{14}H^8(NO_2)^2O^2$ is obtained, in yellow silky plates.

Phenanthrene-quinone is not reduced by sulphurous acid in the cold, but when heated to 100° with the aqueous acid it is converted into phenanthrene-hydroquinone $C^{14}H^8(OH)^2$. By heating with zinc-dust it is reduced to phenanthrene, but the temperature at which the reduction takes place is higher than with anthracene.

By oxidation with chromic acid, phenanthrene-quinone is converted into diphenic acid, $C^{14}H^{10}O^4$.

Heated with soda-lime, phenanthrene-quinone is resolved into diphenyl, carbon dioxide and hydrogen:

whereas anthracene similarly treated yields chiefly benzene. These reactions conjoined with others show that the two aromatic nuclei C^6H^4 are linked together directly in phenanthrene, but not in anthracene (see further pp. 94, 95).

Compounds of Phenanthrene-quinone with Alkaline Bisulphites.—The sodium salt $C^{14}H^8O^2 \cdot NaHSO^3 + 2H^2O$, or probably $C^{14}H^8 \begin{Bmatrix} OH \\ OSO^3Na \end{Bmatrix} + 2H^2O$, is formed by dissolving the quinone in a warm solution of acid sodium sulphite; and crystallises in small colourless plates. It is slowly decomposed by water, quickly by acids and alkalis; when exposed to the air, it absorbs oxygen, and sulphuric acid is formed. The potassium salt is a very similar body.

Phenanthrene-hydroquinone, $C^{14}H^8(OH)^2$, is produced by the action of sulphurous acid on the quinone, the reduction taking place slowly even in the cold. This is one of the distinguishing reactions between phenanthrene-quinone and anthraquinone, which latter is not acted on by sulphurous acid. When phenanthrene-quinone is heated to 100° with excess of aqueous sulphurous acid, it dissolves, and the solution on cooling deposits the hydroquinone in long colourless needles. An alcoholic solution of sulphurous oxide reduces the quinone still more readily.

Phenanthrene-hydroquinone in the moist state absorbs oxygen, but when dry it is more stable. By boiling with water in an open vessel, it is first converted into a brownish-black quinhydrone, and then into the quinone. The same reaction takes place when it is acted on by ferric chloride, nitric acid, chromic acid, &c. When the hydroquinone is dissolved in caustic potash, and the solution is exposed to the air, a green precipitate is formed, which gradually changes into the quinone. This green

compound, which is coloured brown by acids and green again by alkalis, probably consists of the potassium salt of phenanthrene-quinhydrone; it is also formed by dissolving phenanthrene in ammonium or potassium sulphide, or in caustic soda, with the aid of zinc-dust, and exposing these solutions to the air (Graebe, *Ann. Ch. Pharm.* clxvii. 146).

Diacetyl-phenanthrene-hydroquinone, $C^{14}H^{10}(C^2H^3O)^2O^2$, is produced by heating phenanthrene-hydroquinone with acetic anhydride to 140° – 180° . It crystallises from hot benzene in colourless plates, melting at 202° . It is a very stable compound, which is not oxidised by boiling with solution of potassium dichromate and sulphuric acid, but a solution of chromic acid and acetic acid converts it into the quinone. It is not altered by heating with caustic potash of sp. gr. 1.3, but on concentrating the liquid, decomposition takes place, and water added to the solution throws down the green body above mentioned (Graebe).

Constitution of Anthraquinone and Phenanthrene-quinone.

The synthesis of anthracene from benzyl-toluene (p. 82), and that of phenanthrene from stilbene show that the two aromatic nuclei contained in the former are disconnected, whereas in the latter they are linked together; and this conclusion is corroborated by the fact that phenanthrene, when heated with soda-lime, yields diphenyl, whereas anthracene yields chiefly benzene. These two isomeric aromatic hydrocarbons may accordingly be represented by the formulæ:

According to Graebe's theory, therefore, which represents the quinones as containing two atoms of oxygen linked together so as to form a diatomic group, the corresponding quinones should be represented by the formulæ:

Fittig & Ostermayer, on the other hand, regard the quinones, not as compounds containing the diatomic group (O^2), but as double ketones, in which the oxygen-atoms are not linked together, but each is united to a carbon-atom by two units of affinity; anthraquinone being, according to this view,

and phenanthrene-quinone,

They find that phenanthrene-quinone is converted by oxidation with chromic acid into diphenic acid, $C^{14}H^{10}O^4$, and that this acid, when heated with excess of quicklime yields, not diphenyl, $C^{12}H^{10}$, but diphenylene-ketone, $C^{12}H^8O$. This ketone, fused with potash, is converted into phenyl-benzoic acid, $C^{13}H^{10}O^2$, and when the calcium salt of this acid is heated with quicklime, the ketone is regenerated, and a small quantity of diphenyl, $C^{12}H^{10}$, is produced, which may be obtained in larger quantity by heating the calcium salt without quicklime.—The formation of

diphenyl in this manner shows that phenyl-benzoic acid and diphenic acid are constituted as follows:—

The formation of diphenylene-ketone from diphenic acid is exactly analogous to that of dimethyl-ketone (acetone) from acetic acid:

Fittig a. Ostermayer, however, regard it as more probable that the molecular formula of this ketone is $\text{C}^{20}\text{H}^{16}\text{O}_2$. Kekulé has lately shown (*Deut. Chem. Ges. Ber.* v. 908) that on heating calcium-benzoate, a small quantity of anthraquinone is formed, and Jaffé (*ibid.* iii. 694), as well as Barth a. Sennhofer (*Ann. Ch. Pharm.* clxiv. 109), has found that di- and tri-oxybenzoic acids are easily converted into derivatives of anthracene. Now, phenyl-benzoic acid behaves in a similar manner, as shown by the following equations:—

Diphenylene ketone is therefore diphenyl-anthraquinone; when fused with potash, it again yields phenyl-benzoic acid, just as anthraquinone is resolved by this reaction into 2 molecules of benzoic acid (Fittig a. Ostermayer).

On the other hand, it may be observed that the constitution of diphenylene ketone as diphenylated anthraquinone may be represented on Graebe's view of the constitution of the latter compound, and of quinones in general, as well as by that of Fittig and Ostermayer, namely by the formula,

With regard to the constitution of quinones in general, Graebe observes (*Ann. Ch. Pharm.* clxvii. 163), that, although the formation of anthraquinone by heating calcium benzoate, as well as the formation of rufsallic acid and of anthrachrysone, and the behaviour of anthraquinone and phenanthrene-quinone when fused with potash or heated with lime, may perhaps be more simply explained on the supposition that the quinones are double ketones,—nevertheless, there are other facts which directly contradict this view, and show that these bodies actually contain the bivalent group (O—O)', capable of replacing and being replaced by 2 atoms of hydrogen, chlorine, &c., whereas if the 2 oxygen-atoms were not thus linked, they would be equivalent to 4 atoms of a monatomic radicle. The quinones are, in fact, produced by replacing 2 atoms of hydrogen by 2 of oxygen, whereas in the formation of ketones 2 atoms of hydrogen are replaced by only 1 atom of oxygen. Moreover, ketones take up 2 atoms of hydrogen for each atom of oxygen which they contain, and are thereby converted into secondary alcohols, whereas quinones take up only 1 atom of hydrogen for 1 of oxygen, and are converted into hydroquinones.

ANTHRAQUINONE-SULPHONIC ACIDS (Graebe a. Liebermann, *Ann. Ch. Pharm.* clx. 121).

1. *Anthraquinone-monosulphonic Acid*, or *Sulphanthraquinonic Acid*, $\text{C}^{14}\text{H}^8(\text{O})_2\cdot\text{SO}_3\text{H}$, produced by heating 1 part of anthraquinone and 2-3 parts sulphuric acid to $250^\circ\text{--}260^\circ$.

The pure acid is best obtained by decomposing the lead or barium salt with sulphuric acid. It forms yellow scales, and is readily soluble in water and alcohol, but nearly insoluble in sulphuric acid. The *barium salt* $[C^{14}H^8(O^2)SO^2]_2Ba + H^2O$ forms indistinct yellow crystals, sparingly soluble in cold and a little more readily in hot water. The *calcium salt* has also a yellow colour, and is much more soluble in water. The *sodium salt* forms indistinct yellow crystals, and gives with water a yellowish red solution.

On heating the potassium salt with caustic potash and a little water, the mass gradually assumes a violet colour; and if the heat has been sufficiently high, it contains alizarin, formed according to the equations:—

2. *Anthraquinone-disulphonic Acid*, $C^{14}H^8(O^2)(SO^2H)^2$, is formed by heating anthraquinone with 4-5 parts of sulphuric acid to 270° - 280° . It may also be formed directly from anthracene, namely by heating dichlor- or dibrom-anthracene with a mixture of concentrated and fuming sulphuric acid:

(Graebe & Liebermann, *Deut. Chem. Ges. Ber.* iii. 636). According to Perkin (*Chem. News*, xxii. 37), dichloranthracene dissolves in fuming sulphuric acid, forming *dichloranthracene-monosulphonic acid* $C^{14}H^8Cl^2(SO^2H)$, and *dichloranthracene-disulphonic acid* $C^{14}H^8Cl^2(SO^2H)^2$. Dibromanthracene yields corresponding products. The disulpho-acids, treated with oxidising agents, exchange their bromine or chlorine for oxygen, forming anthraquinone-disulphonic acid.

This acid crystallises from an aqueous solution in yellow crystals, and is less soluble than the monosulpho-acid. It is nearly insoluble in sulphuric acid. Its yellow salts dissolve in water with a yellowish-red colour, and do not crystallise well. The *barium salt* is very sparingly soluble in cold water, but a little more readily in hot water; the *calcium salt* is also not very soluble.

On heating one of the salts with potash or soda, alizarin is produced, the formation of which, however, takes place by two stages: First, the red colour of the mixture gradually changes to a dark blue, the potassium salt of an oxyanthraquinone-sulpho-acid being formed:

On dissolving some of the dark blue mass in water, and adding dilute sulphuric acid, sulphur dioxide is evolved, and the blue colour of the liquid changes into yellow, but no precipitate is formed.

On heating the blue mass longer, its colour becomes more and more purple, alizarin being now formed, which is obtained as a yellowish red precipitate on adding an acid to the solution of the fused mass. It is easy to find the point when most of the intermediate product is decomposed, by shaking the acid solution with ether, which dissolves only the alizarin, whilst the oxyanthraquinone-sulphonic acid remains in the aqueous solution. On adding an alkali to the latter, the intensity of the blue colour shows whether there is still any of this acid present or not. The crude alizarin obtained by this process always contains some oxyanthraquinone and other colouring matters, which modify the colours produced on mordanted cloth. Moreover, a small quantity of anthraquinone is generally formed by reduction, SO^2H being replaced by hydrogen; this reduction is more readily effected by heating the sulpho-acids with quicklime, whereupon anthraquinone sublimates in considerable quantity.

When dichlor-anthracene and dibromanthracene are acted upon by sulphuric acid, sulpho-acids are formed, which when heated are converted into anthraquinone-disulphonic acid, as already observed by Perkin (*1st Suppl.* 179).

Oxyanthraquinone-sulphonic Acid, $C^{14}H^8(O^2)\left\{ \begin{matrix} OH \\ SO^2H \end{matrix} \right\}$ —To prepare this compound, the mixture of potash and anthraquinone-disulphonic acid is heated till the formation of alizarin begins.

After cooling, it is dissolved in water, hydrochloric acid is added, and the liquid filtered. On adding barium chloride to the filtrate, the yellow barium salt of the sulpho-acid separates out, either at once or after evaporation. On decomposing this salt with dilute sulphuric acid, and evaporating the solution, the free acid is obtained in yellow crystals, soluble in alcohol, but not in ether. It forms two series of salts; on dissolving it in caustic potash, a deep blue solution is obtained containing the

compound $\text{C}^{\text{II}}\text{H}^{\text{I}}(\text{O}^{\text{I}})\left\{\begin{smallmatrix}\text{OK} \\ \text{SO}^{\text{I}}\text{K}\end{smallmatrix}\right.$; on adding hydrochloric acid to this solution, it assumes a yellowish-red colour, the salt $\text{C}^{\text{II}}\text{H}^{\text{I}}(\text{O}^{\text{I}})\left\{\begin{smallmatrix}\text{OH} \\ \text{SO}^{\text{I}}\text{K}\end{smallmatrix}\right.$ being formed. The acid barium salt, which has been already mentioned, is moderately soluble in boiling water, but only sparingly in cold water, and still less in dilute hydrochloric acid. Its yellowish-red solution, like those of the other salts of this acid, becomes yellow on addition of hydrochloric acid, and gives with baryta-water a blue precipitate, $\text{C}^{\text{II}}\text{H}^{\text{I}}(\text{O}^{\text{I}})\left\{\begin{smallmatrix}\text{O} \\ \text{SO}^{\text{I}}\end{smallmatrix}\right.\text{Ba}$.

ANTIMONY. *Estimation and Separation.*—When a neutral and concentrated solution of antimonious chloride is mixed with a slight excess of *gallic acid*, the whole of the antimony is separated as insoluble antimonious gallate. This reaction may be utilised for the estimation of antimony, and for the separation of antimony from tin, arsenic, and other metals.

The above mentioned combination of antimony with gallic acid is insoluble in a neutral or slightly acidulated liquor, but dissolves readily in more concentrated solutions of hydrochloric acid; it is necessary, therefore, for the success of the analysis, that the solution be concentrated by evaporation, and any large excess of acid volatilised. The precipitate is somewhat bulky, but settles rapidly. It cannot, however, be washed on a filter, since it invariably passes through the filter as soon as the acidulated mother-liquor has been washed away; the mixed mode of decantation and filtration must, therefore, be resorted to, which in this particular instance presents neither inconvenience nor difficulty.

Antimonious gallate dried at 100° has the composition $\text{Sb}^{\text{I}}\text{O}^{\text{I}}(\text{C}^{\text{II}}\text{H}^{\text{I}}\text{O}^{\text{I}})^2 + 3\text{H}^{\text{I}}\text{O}$, and contains 40.85 p. c. of metallic antimony. It is exceedingly hygroscopic.

The antimony may either be weighed in the form of antimonious gallate, as the composition of the precipitate is perfectly definite, or the salt may be dissolved in hydrochloric acid, and the antimony precipitated by sulphuretted hydrogen in the usual way.

Solutions of antimonious chloride are unfit for the estimation of this metal by gallic acid; they must, therefore, before precipitation, be reduced to the state of antimonious chloride. This reduction is readily effected by mixing the slightly acidulated solution of antimonious chloride with a solution of potassium iodide, when the following reaction ensues—

The iodine and excess of acid having been removed by evaporation, the solution is ready to be precipitated by gallic acid.

Separation of Antimony from Arsenic.—Potassium iodide, which in presence of hydrochloric acid reduces antimonious chloride to the state of antimonious chloride, with evolution of iodine, reacts in a similar manner upon arsenic acid, which it reduces to arsenious acid—

This reaction greatly facilitates the separation of the two metals. The antimony is estimated by gallic acid in the manner already described, and the arsenic is precipitated subsequently by sulphuretted hydrogen.

Separation of Antimony from Tin.—Potassium iodide has no reducing effect upon stannous chloride, but when an excess of iodide is introduced into the solution, a double decomposition takes place, and the liquid consists of a hydrochloric acid solution of stannous iodide. Gallic acid separates antimony from stannous iodide much more readily than from the stannous chloride. If the quantity of potassium iodide employed has been properly adjusted, the antimonious gallate settles very rapidly down; on the contrary, when the operation has been badly conducted, the antimonious gallate is mixed with stannous oxide, and the whole remains in suspension without subsiding. In this case the liquid should be rejected as unfit for a successful operation.

The separation of antimony from arsenic and tin together may also be effected in a manner similar to the separation of antimony from tin; but the results hitherto obtained are not very satisfactory (Hugo Twinn, *Chem. News*, xxiv. 207, 221). See further *Antimony and Tin*.

In the precipitation of antimony from solutions containing tin by metallic iron, according to Tooke's method (1st Suppl. 182), Attfield finds that the quantity of antimony obtained is too small, if the air has exerted an oxidising action on the ferrous salt produced in removing the excess of iron. The cause of the loss is that metallic antimony is soluble in ferric chloride. Hence, in determining antimony by this method,

2nd Sup.

H

it is necessary to exclude the air till the whole of the iron-salt is removed, which may for the most part be effected by adding hot de-aerated water immediately after the iron is dissolved and decanting rapidly; in exact experiments, however, it is necessary to surround the vessel with an atmosphere of carbon dioxide (*Pharm. J. Trans.* [2] x. 512).

Hydride of Antimony, or Stibine, SbH_3 . This compound acts on fused antimonious chloride in such a manner that antimony is separated and hydrogen sulphide given off. Phosphoric chloride is but slightly attacked by it with formation of phosphorous chloride, antimonious chloride, and hydrogen chloride. On phosphorous chloride and stannic chloride stibine does not act.

Oxides. On the isodimorphism of antimonious oxide and arsenious oxide, see ARSENIC (p. 104).

Antimonious oxide dissolves easily in aqueous sodium sulphide, forming a liquid of the colour of chlorine-gas, from which hydrochloric acid precipitates antimony trisulphide, without separation of sulphur (Unger, *Arch. Pharm.* [2] cxlvii. 193).

Antimonious Hydrate. By precipitating a solution of potassium antimonate with nitric acid, washing the precipitate, and leaving it to itself during a whole summer, Geuther (*Jenaische Zeitschr.* vii. 121) has obtained a hydrate having the composition HSbO_3 or $3\text{H}_2\text{O} \cdot \text{Sb}_2\text{O}_3$. When heated to 175° , it gives off 2 mol. water and is transformed into the monohydrate, HSbO_3 or $\text{H}_2\text{O} \cdot \text{Sb}_2\text{O}_3$.

Sodium antimonate differs in composition according to its mode of preparation. By precipitating the product of the action of potash-solution on native antimony trisulphide with soda-solution, the well known compound $\text{Na}_2\text{O} \cdot \text{Sb}_2\text{O}_3 \cdot 7\text{H}_2\text{O}$ is obtained.

a. By boiling the filtrate from this compound with sulphur, $\text{Na}_2\text{O} \cdot \text{Sb}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$ was obtained. b. By boiling antimony ore with potash-solution and sulphur, and precipitating with soda-solution, $6\text{Na}_2\text{O} \cdot 5\text{Sb}_2\text{O}_3 \cdot 33\text{H}_2\text{O}$ was formed. This salt is also produced when the hydrochloric acid solution of sodium antimonate (which separates from the mother-liquors obtained in making Schlippe's salt) is treated with tartaric acid, diluted with water, and precipitated by soda-solution in excess. The solution of this latter salt scarcely alters the colour of litmus. The salt itself is difficultly soluble in pure water; a solution was obtained by long washing on the filter, containing in 100 grams, 0.085 gram of the salt. Sodium antimonate dissolves but slowly in aqueous sodium sulphide, even on warming; in time, however, a large amount is taken up. From the almost colourless solution, the golden sulphide Sb_2S_3 is precipitated by acids without admixture of free sulphur, showing that sulphantimonate of sodium has been formed (Unger, *Arch. Pharm.* [2] cxlvii. 193).

A hydrated calcium antimonate, $3\text{CaO} \cdot 2\text{Sb}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$, occurs on the calcareous matrix of non-arseniferous ullmannite $\text{NiS} \cdot \text{NiSb}_2$, at Waldenstein in Carinthia, partly as a greenish earthy mass, partly in pseudomorphous crystals of the regular system, exhibiting the combination $\infty \text{O} \infty \cdot \text{O} \infty \text{O}$. Its formation appears to be due to the mutual action of the ullmannite and the matrix (Rumpf, a Ullik, *Jahrbuch f. Mineralogie*, 1870, 355).

On antimonate and antimonite of lead from the province of Constantine in Algeria, see NADORITE.

Oxychlorides.—By treating antimonious chloride with various proportions of water, compounds are obtained corresponding with the formulae SbClO and Sb_2ClO_3 . The former of these compounds exhibits two modifications, amorphous and crystalline. The amorphous variety is obtained by treating the chloride with three times its weight of water; the crystalline variety by adding 7 parts water to 10 parts of antimonious chloride, and leaving the mixture to itself for a few days.

The compound $\text{Sb}_2\text{O}_3 \cdot 2\text{SbClO}$ is obtained when the trichloride is treated with 5 to 60 parts of water; when cold water is used it crystallises in oblique prisms having a silky lustre (Sabanejew, *Zeitschr. f. Chem.* [2] vii. 204).

W. C. Williams (*Chem. News*, xxiv. 224), by heating 1 mol. antimony pentoxide with 3 mol. of the pentachloride to 140° in a sealed tube, has obtained two crystalline oxychlorides: one melting at 85° and having the composition $\text{Sb}_2\text{Cl}_3\text{O}$, the other melting at 97.5° , and consisting of $\text{Sb}_2\text{Cl}_3\text{O}$. The simple oxychloride SbClO , analogous to PClO , was not produced.

Sulphides. Trisulphide or Antimonous Sulphide.—When black antimonous sulphide is treated with potash-solution, and the liquid filtered from the resulting 'crocus' is mixed with caustic soda, sodium antimonate is precipitated, and a liquid is obtained, which Unger supposes to contain a bisulphide of antimony, Sb_2S_3 , analogous to realgar, dissolved in aqueous sodium sulphide. This liquid, treated with the necessary amount of sulphur, yields a further quantity of sodium antimonate.

together with a considerable proportion of Schlippe's salt. The two reactions are represented by the following equations:—

When very finely-pounded black antimonious sulphide and a little strong solution of sodium sulphide are rubbed together and warmed to 20° – 30° , a paste is formed, having a fine copper lustre, and from this a body may be obtained having almost the appearance of metallic copper, and the composition $\text{Na}^2\text{Sb}^2\text{S}^{12} + 2\text{H}^2\text{O}$, or, according to Unger, $\text{Na}^2\text{S}.\text{Sb}^2\text{S}^3.2\text{H}^2\text{O} + 3\text{Sb}^2\text{S}^2$. When decomposed by an acid, however, it yields only the trisulphide. The mother-liquor of the copper-coloured body treated with an additional quantity of sodium sulphide, yields a considerable quantity of Schlippe's salt.

The reaction of *antimony trisulphide* with sodium sulphide differs according to the relative quantities of the two bodies employed. When the trisulphide is treated with a small quantity of sodium sulphide in concentrated solution, the copper-coloured body already mentioned is formed, and in large quantity if the ingredients are heated together for some time out of contact with the air. But when an excess of sodium sulphide is used, Schlippe's salt is formed, together with a red tarry body, which, by repeated solution in water and evaporation, may be obtained in deep red flocks, having the composition NaSbS^3 , or $\text{Na}^2\text{S}.\text{Sb}^2\text{S}^3$. The oxygen of the air is concerned in the reaction; for when the materials are placed together in a closed vessel, very little Schlippe's salt is formed. The result may be explained, by supposing that a body having the composition Na^2SbS^2 , or $2\text{Na}^2\text{S}.\text{Sb}^2\text{S}^2$, is first formed, together with Schlippe's salt, and that the former is converted by oxidation into sodium sulphantimonite and caustic soda, thus:—

The precipitate produced when the solution of antimony trisulphide in sodium sulphide is poured into acids is very different from the beautiful penta- and tri-sulphides of antimony produced by the ordinary methods, being of the colour of iron oxide, or kermes: it is very bulky and gelatinous. It appears to be anhydrous, and when once dried, is scarcely at all hygroscopic.

This kermes-coloured precipitate possesses the peculiar property of persistently retaining from 1.5 to 2 p.c. sodium sulphide, in such a manner as to be difficultly decomposable by acids (Unger).

Crocus of Antimony, the well-known yellow body formed when antimonious sulphide is treated with caustic alkaline solution (i. 328) has, according to Unger, a somewhat complex constitution. When prepared with potash it remains as an ochre-brown powder if dried at a gentle heat, and if heated more strongly, gives off water, melts with intumescence to a glassy mass, without any sublimation of trisulphide, and has the composition $3(\text{Sb}^2\text{S}^3.\text{H}^2\text{O}) + 6(\text{K}^2\text{O}.\text{Sb}^2\text{O}^3) + 2\text{Sb}^2\text{O}^3$.

2. Pentasulphide.—According to Fr. Wurtz (*J. Pharm.* [4] xi. 456), this compound, prepared from sodium-sulphantimonate, always contains free sulphur (which may be dissolved out by carbon sulphide); he attributes its occurrence to the fact that the mutual action of sodium carbonate, quicklime, sulphur, and antimony trisulphide, likewise gives rise to sodium thiosulphate, which, when decomposed by hydrochloric acids, yields sulphur. The same fact appears to have been noticed by several other observers (*Jahresb. f. Chem.* 1870, 365).

Compound of Sulphantimonate and Thiosulphate of Sodium.—By crystallisation of the red mother-liquors obtained in the preparation of Schlippe's salt, which contain much sodium thiosulphate, a salt is obtained in large crystals, having the composition $3\text{Na}^2\text{S}.\text{Sb}^2\text{S}^3 + 2(\text{Na}^2\text{O}.\text{S}^2\text{O}^3) + 4\text{H}^2\text{O}$. If the antimony ore from which the Schlippe's salt is obtained contains arsenic, the double salt will also be arsenical. This salt crystallises in a form different from that of Schlippe's salt, viz., in six-sided rhombic pyramids, very much like potassium sulphate. They have a faint greenish tint, effloresce, but not rapidly, and in time become opaque and brown. Treated with acids, they yield a mixture of golden sulphide with free sulphur, amounting to one-third of the weight of the whole precipitate. The saturated hot solution of this salt first deposits tetrahedrons of Schlippe's salt, and then sodium thiosulphate. The crystals melt when gently heated. This compound is of all known inorganic salts the one which contains the largest number of molecules of water (Unger).

APATITE. This mineral appears to be of very frequent occurrence in eruptive rocks, being found in such rocks of the most various character, both chemically and petrographically (*E. Zirkel, Jahrbuch f. Mineralogie*, 1870, 301).

Apatite from Canada, occurring in a bed about 1 m. thick, sometimes in crude

masses of sp. gr. 3.142, sometimes in well-defined six-sided prisms, sp. gr. 3.166, has been analysed by R. Hutton (*Chem. News*, xxi. 150), with the following results:—

	$\text{Ca}^2\text{P}^2\text{O}^8$	CaF^2	CaCl^2	CaCO^3	Fe^2O^3	H^2O	Sand
Massive	86.61	7.22	0.06	4.47	—	0.08	0.10 = 98.54
Crystals	90.82	5.70	0.14	0.38	0.40	0.32	0.10 = 97.86

Iodine and Bromine in Apatite.—The apatite from the beds in the departments of Lot and of Tarn-et-Garonne gave, when treated with sulphuric acid for the manufacture of superphosphate, violet vapours of iodine. The distillate treated for bromine by Bouis' process, gave only faint traces of that element. This phosphate may perhaps be utilised as a commercial source of iodine (Kuhlmann, *Compt. rend.* lxxvi. 1678).

ARABIN. *Acetyl-derivatives.*—Arabin heated with 2 parts of acetic anhydride to 150° , swells up to a mass which, when heated with hot water and with alcohol, yields diacetyl-arabin $\text{C}^6\text{H}^7(\text{C}^2\text{H}^3\text{O})^2\text{O}^2$, as an amorphous white powder insoluble in hot water, and yielding soluble arabin by saponification. If an excess of acetic anhydride be used, and the temperature raised to 180° , triacetyl-arabin $\text{C}^6\text{H}^7(\text{C}^2\text{H}^3\text{O})^3\text{O}^2$ is obtained, exactly resembling the diacetyl-compound (Schützenberger a. Naudin, *Zeitschr. f. Chem.* [2] v. 264).

ARITE, or AARITE, is a nickelliferous mineral found on the Ar Mountain (*Basses Pyrénées*), associated with and intimately disseminated throughout a mixture of petrosilox, chalk, blonde, ullmannite, and galena. It is amorphous, and has the colour of breithauptite. Density 7.19. Analysis gave

R.	As.	Sb.	Ni.	Zn.
1.7	11.5	48.6	37.3	2.4 = 101.5.

These numbers calculate to the formula $\text{Ni}^2(\text{Sb}; \text{As})$, which is that of an arseniferous breithauptite (iv. 35). It would appear, therefore, that arite should be considered more as a variety of breithauptite, in the same manner as the nickeline, or copper-nickel, from Allemont, which contains 8 p. c. of antimony, is considered a variety of ordinary nickeline (iv. 36). (Pisani, *Compt. rend.* lxxvi. 230.)

ARRAGONITE. On the formation of this variety of calcium carbonate, see CARBONATES.

ARSENIC. *Occurrence.*—Arsenic occurs frequently in soils, being introduced therein by the weathering of arseniferous pyrites, or in the refuse from manufacturing operations, &c. With reference to chemico-legal investigations, it is important to observe that arsenic may in this manner be introduced into the earth of cemeteries (Sonnenschein, *Arch. Pharm.* [2] cxliii. 245).

Purification.—Metallic arsenic may be freed from the dirty deposit which it acquires by keeping in contact with the air, and restored to its pure metallic lustre, by boiling it with a moderately concentrated solution of potassium dichromate acidulated with sulphuric acid, then washing it with alcohol and ether, and fusing it in glass tubes (Böttger, *J. pr. Chem.* [2] ii. 134).

Detection.—On the application of Bottondorff's method of detecting arsenic by means of an acidulated solution of stannous chloride (*1st Suppl.* 216) to pharmaceutical purposes, see Hager (*Pharm. Centralt.* 1870, 201; *Jahresb.* 1870, 066).

When a person is suspected to have been poisoned with arsenic, and nothing but the skeleton is left for investigation, the arsenic should be looked for especially in the bones of the pelvis and the neighbouring spinal vertebrae. For this purpose the following process is given by Sonnenschein (*Arch. Pharm.* [2] cxliii. 250). The comminuted bones are introduced into a glass tube about 10 mm. in diameter, 1 m. long, and closed at the bottom; and this tube is filled to $\frac{3}{4}$ ds with strong sulphuric acid, and gently heated in a water-bath, in order to expel the carbonic anhydride contained in the bones, and finally sealed before the blow-pipe. After heating in the water-bath for a week with frequent agitation, the substance of the bone is converted into a gelatinous pulp, which may be examined for arsenic in the ordinary way. It is convenient, however, to combine the qualitative with the quantitative analysis. The metallic sulphide, separated from the solution in sodium sulphide is dissolved in fuming nitric acid, or in a mixture of potassium chlorate and hydrochloric acid; tartaric acid is added, then ammonia in excess; and the clear solution, mixed with a magnesium salt, is left in a warm place for several days. The separated precipitate of ammonio-magnesian arsenate, after drying and weighing, may be used for various experiments with Marsh's apparatus, &c.

Gravimetric Estimation.—R. Fuller (*Zeitschr. anal. Chem.* 1871, 41) has examined the methods most frequently employed for the estimation of arsenic.

precipitation as trisulphide, as ammonio-magnesian arsenate, and as uranic arsenate, with the view of determining their relative accuracy.

1. *Precipitation as Arsenious Sulphide*.—By a number of very careful determinations it was found that arsenious sulphide is not perceptibly soluble in water, but that to ensure complete and speedy precipitation of arsenic by sulphuretted hydrogen from a solution of arsenious acid, it is necessary that the solution be strongly acidulated, with hydrochloric acid, for example. If the excess of sulphuretted hydrogen be afterwards expelled by a current of carbonic anhydride, the precipitated arsenious sulphide does not contain any appreciable quantity of free sulphur that can be dissolved out by carbon sulphide. The precipitate may be completely dried at 100° , and may be further heated in a current of carbonic anhydride to 120° , or even to 150° – 160° , without perceptible loss.

The mixture of arsenious sulphide and free sulphur, obtained by passing sulphuretted hydrogen through an acidulated solution of arsenious acid mixed with ferric chloride, may be completely freed from uncombined sulphur by digestion with carbon sulphide; but the precipitate of arsenious sulphide and sulphur obtained by the action of sulphuretted hydrogen on arsenic acid is more difficult to deal with. If the sulphur is precipitated from a hot solution (at 75°) it becomes very intimately mixed with the arsenious sulphide, in the form of little globules, from which it cannot be completely extracted by ammonia or by digestion in the cold with carbon sulphide. The sulphur may, however, be easily dissolved by removing the precipitate from the filter as completely as possible, and digesting with carbon sulphide in a water-bath.

Good results are likewise obtained by determining the arsenic indirectly in the precipitate produced by sulphuretted hydrogen—after drying till constant and weighing—by oxidation of the sulphur and precipitation as barium sulphate. Oxidation with potassium chlorate and hydrochloric acid generally involves a loss from volatilisation of the arsenic as arsenious chloride. Redfuming nitric acid, however, answers very well, because it boils below the melting point of sulphur. The operation may also be effected after exhausting the sulphide on the filter with ammonia, then filtering and evaporating to dryness.

The method of oxidation in an alkaline solution (KHO) by passing a moderate current of chlorine through a warm solution containing excess of pure alkali, as well as the two other methods, usually gives a little more sulphur; on account of the precipitated barium sulphate retaining, as Fresenius has shown, a little potassium chlorate, chloride or nitrate, especially the latter, which must be removed by fusion of the barium sulphate with sodium carbonate, dissolving the residue in hydrochloric acid, and precipitating again as barium sulphate. It is obvious that the indirect method of estimating the arsenic by determining the sulphur in the precipitate may likewise be controlled by direct estimation as ammonio-magnesian arsenate.

2. *Precipitation as Ammonio-magnesium Arsenate*.—This salt, when dried in a vacuum over sulphuric acid, has the composition $(\text{NH}_4)\text{MgAsO}_4 + 6\text{H}_2\text{O}$. After drying at 100° it contains $2(\text{NH}_4)\text{MgAsO}_4 + \text{H}_2\text{O}$, and on ignition yields magnesium pyro-arsenate, $\text{Mg}_2\text{As}_2\text{O}_7$. The temperature should be raised gradually to avoid reduction of arsenic to arsenious oxide by the escaping ammonia, and consequent loss by volatilisation.

Fuller has carefully determined: (1) the solubility of this salt in the various saline and other solvents with which it is brought into contact during precipitation; (2) the best and readiest methods of drying; (3) the best means of converting the arsenious sulphide into arsenic acid in order to estimate it as ammonio-magnesium arsenate.

The experiments on the solubility of the salt led to the following results:—

Solubility in pure distilled water.—1 part of the precipitate dried at 130° dissolved in 2652, or 1 part of the anhydrous arsenate in 2784 parts of water.

Solubility in weak ammonia (1 part of ammonia of .98 sp. gr., diluted with 3 parts of water).—1 part of the salt dried at 100° dissolved in 15161, and 1 part of the anhydrous arsenate in 15904 parts of this aqueous ammonia.

Solubility in a dilute solution of ammonium chloride (1 part of the salt dissolved in 60 parts of water).—The amount of arsenate dissolved was determined by removing the arsenic as arsenious sulphide, and precipitation of the magnesia in the filtrate by means of sodium phosphate, and weighing as magnesium pyrophosphate. 1 part of the salt dried at 100° dissolved in 1321 parts, and of the anhydrous salt in 1336 parts of this dilute solution of ammonium chloride.

Solubility in a concentrated solution of ammonium chloride (1 part of the salt in 7 parts of water).—1 part of the arsenate dried at 100° required 844.7, and 1 part of the anhydrous salt 882.7 parts of the solution of ammonium chloride.

Solubility in a solution containing 10 parts of ammonium chloride, 10 parts of ammonia, sp. gr. .96, and 60 parts of water.—1 part of the arsenate dried at 100° requires 2879, and of the anhydrous salt 3022 parts of this mixture.

Solubility in a solution of magnesium sulphate (13.3 parts of the crystallised salt dissolved in a litre of water).—1 part of the arsenate dried at 100° required 2763, and of the anhydrous salt 2900 parts of this solution.

Solubility in magnesia mixture (1 part of $MgSO_4$, 1 part of NH_4Cl , 4 parts of ammonia, of sp. gr. .96, and 8 parts of water).—The mixture was diluted with 20 parts of water, and contained 72.58 grams of the crystallised magnesium sulphate per litre. 1 part of the crystallised dried arsenate dissolved in 31483, and 1 part of the anhydrous salt in 32827 parts of the mixture.

Solubility in sodium arsenate (2 parts of the salt in 100 of water).—1 part of the dried arsenate dissolved in 4386, and 1 part of the anhydrous salt in 4604 parts of the solution of sodium arsenate.

Solubility in a 2 p. c. solution of ammonium nitrate, rendered slightly ammoniacal.—1 part of the arsenate dried at 100° required 4184, and 1 part of the anhydrous salt, 4389 parts of the nitrate solution.

Solubility in a 1.5 p. c. solution of potassium chloride.—1 part of the dried arsenate dissolved in 2440, and 1 part of the anhydrous salt in 2661 parts of the solution of potassium chloride.

Solubility in a solution of ammonium tartrate (prepared by dissolving 3.5 grams of tartaric acid in weak ammonia, to slight alkaline reaction, and diluting to 250 c.c.).—1 part of the dried arsenate dissolved in 1410, and 1 part of the anhydrous salt in 1422 parts of the tartrate solution.

Solubility in ammonium citrate (prepared by dissolving 2.5 grams of citric acid in ammonia, to weak alkaline reaction, and diluting to 250 c.c.).—1 part of the arsenate dried at 100° dissolved in 889 parts, and 1 part of the anhydrous salt in 933 parts of the citrate solution.

It appears then that ammonio-magnesium arsenate is somewhat soluble in dilute ammonia, but that an excess of magnesia mixture renders the separation of the precipitate more complete.

With regard to the drying of the precipitated ammonio-magnesium arsenate, Puller finds that when dried for a considerable time over sulphuric acid, it contains 6 mol. water, as found by H. Rose; that after drying over the water-bath, or in an air-bath at 100°–102°, it contains exactly $2(NH_4)MgAsO_4 + H_2O$; but that between 103° and 110° it gives off a portion of this water, and a considerably greater portion when dried at 130°.

To avoid the tedious operation of drying the ammonio-magnesium arsenate, it has been repeatedly proposed by Wittstein and others to ignite, as is done with the corresponding phosphate, and weigh as pyro-arsenate. On igniting portions of the salt dried at 100°, (1) over a small gas jet, (2) over a powerful gas flame, and (3) over the blowpipe, it was found that they lost respectively 3.4 p. c., 4.6 p. c., and 8 p. c. When, however, the salt was ignited, according to Wittstein's method, by first drying at 130° for two hours, then heating cautiously on a sand-bath, heating over a Bunsen burner for another two hours, then on an iron plate for an hour and a half, then for twenty minutes over the bare flame, and lastly, by heating intensely over the blowpipe flame, satisfactory results were obtained. On applying the same operation to the salt dried over sulphuric acid, equally good results were obtained. Filters containing small quantities of the arsenate, when soaked with a solution of ammonium nitrate and then deflagrated, showed but a trifling loss. When the dried salt was heated in a current of oxygen, according to Rose's directions—gently at first, then over a Bunsen burner for a quarter of an hour, and finally very intensely over the blowpipe lamp—good results were obtained, and Puller prefers this method to the extremely tedious method of drying at 100° till the weight becomes constant.

On repeating H. Rose's experiments of reducing ammonio-magnesium arsenate to arsenic with formation of arsenious sulphide (by mixing with powdered or freshly precipitated sulphur and heating in a current of hydrogen gas, Rose's observation that the arsenic cannot be removed entirely in this manner was confirmed.

By heating the arsenate with acid ammonium sulphite, the arsenic acid is completely reduced to arsenic which volatilises. The results obtained by weighing the residuary magnesium sulphate are, however, a little too high, on account of the action of the acid sulphate upon the crucible.

Experiments were also made to determine whether, as is known to be the case with the precipitated ammonio-magnesium phosphate, any basic magnesium sulphate or magnesia is ever carried down by the ammonio-magnesium arsenate, and whether

dissolving in hydrochloric acid and reprecipitation with ammonia eliminates any slight admixture of magnesium compounds. Traces of a sulphate and likewise slight traces of arsenic, as indicated by barium chloride and by sulphuretted hydrogen, were invariably found. By precipitating a standard solution of sodium arsenate with varying quantities of the mixture of sal-ammoniac and magnesia salt, it was found that a trifling quantity only of magnesium hydrate or basic magnesium sulphate is precipitated with the arsenate; that especially, a concentrated solution of sal-ammoniac interferes with the precipitation by holding a little of the ammonio-magnesium arsenate in solution, whereas a small excess of magnesia mixture ensures complete precipitation; lastly, that the errors arising from the precipitation of a little basic magnesium sulphate, and from the solubility of the ammonio-magnesium arsenate, nearly neutralise each other, unless an excessive amount of magnesia mixture and sal-ammoniac is employed. Puller proposes to allow for every 16 c. c. of the filtrate '001 gram of arsenate, and recommends precipitating only once, on account of the solubility of the arsenate in sal-ammoniac.

He arrives at the conclusion that the determination as magnesium pyro-arsenate according to Wittstein, when carefully executed, is as accurate as could well be desired, and far more expeditious than drying at 100° . For like reasons, he recommends the use of red fuming nitric acid, in preference to all other methods of oxidation (especially after removing the greater part of the precipitated arsenious sulphide mechanically from the filter-paper, and extracting the last traces with ammonia), in order to convert the trisulphide into arsenic acid. The excess of acid is evaporated, and the residue dissolved in a little hydrochloric acid.

3. Determination as Uranic Pyro-arsenate, $2(\text{UO}_2)^{\cdot\cdot}\text{As}_2\text{O}_7$.

On adding uranic acetate to a solution of an arsenate in water or in acetic acid, a precipitate of uranic arsenate $(\text{UO}_2)^{\cdot\cdot}\text{HAsO}_4 + 4\text{H}_2\text{O}$, is obtained, which loses its water at 123° . In presence of ammonium salts a glutinous yellowish green precipitate of ammonio-uranic arsenate $(\text{UO}_2)^{\cdot\cdot}\text{NH}_4\text{AsO}_4 + \text{aq}$ is left, insoluble in water and acetic acid, but soluble in mineral acids. On ignition, light yellow uranic pyro-arsenate $2(\text{UO}_2)^{\cdot\cdot}\text{As}_2\text{O}_7$ is obtained. The precipitation is assisted by boiling, and the precipitate subsides more readily on adding a few drops of chloroform to the warm solution, and then boiling up again. The quantitative results being, however, unsatisfactory, Puller found that, on ignition, a small portion of the salt is reduced by the escaping ammonia gas. This source of error was to a great extent eliminated by igniting, as in the case of the corresponding magnesium arsenate, with great care, heating first over a sand-bath, then on a hot iron plate, and lastly over the bare flame, or by igniting at once in a current of oxygen.

Excess of ammonia or sal-ammoniac exerted no disturbing influence. Conversion of freshly precipitated arsenious sulphide into arsenic acid by means of potassium chlorate and hydrochloric acid, or by treating with fuming nitric acid and subsequent precipitation in an acetic solution as ammonio-uranic arsenate, gave very good results; and since the precipitate could be readily washed out—a desideratum of no small importance—this method of determining arsenic is strongly recommended as preferable to all other methods.

Volumetric Estimation (Waits, *Zeitschr. anal. Chem.* x. 158). The methods generally used for estimating arsenious acid volumetrically are: 1. by means of free iodine; 2. by means of potassium dichromate; 3. by means of potassium permanganate.

The iodine method depends upon the conversion of arsenious into arsenic acid in alkaline solution; in an acid solution arsenious acid can exist in presence of iodine or chlorine, and is only partly converted into the higher oxide. The alkali must be in the form of a carbonate, for a caustic alkali combines with the iodine.

Normal sodium carbonate fixes iodine, but the acid carbonate does not; a solution saturated in the cold should be used. In employing a standard solution of arsenious acid in hydrochloric acid, the free acid must be neutralised with caustic soda or acid sodium carbonate. With an excess of this latter salt, good results are obtained.

Experiments made with the view of converting precipitated arsenious sulphide into arsenious acid by the action of an ammoniacal solution of silver nitrate upon the sulphide dissolved in ammonia, as well as by means of freshly precipitated bismuthous hydrate, and of substituting in this the trisulphide—which can be obtained in a state of great purity—for the trioxide, were unsuccessful, as the reaction is never quite complete, owing to the formation of sulpho-salts of silver and bismuth.

The method first proposed by Kessler (*Zeitschr. anal. Chem.* x. 205) of determining arsenious acid in an acid solution by means of potassium dichromate, and standardising back by means of a ferrous sulphate solution, gave good results. Excess of hydro-

chloric acid must be avoided. Kessler succeeded in oxidising arsenious sulphide by treating it in a hydrochloric acid solution with mercuric chloride, a saturated solution of which converts the sulphide, slowly at the ordinary temperature, more rapidly on the application of a gentle heat, into the trioxide. The reaction is over when the mass has become white. The experiments of Waitz show further, that the mixture of trisulphide and sulphur which is obtained when a solution of arsenic acid is precipitated with sulphuretted hydrogen, cannot be converted directly into arsenious acid by digestion with mercuric chloride, on account of the dense nature of the precipitate, but that it is readily acted upon, after dissolving out the trisulphide by means of dilute ammonia, and reprecipitating with hydrochloric acid.

The oxidation of arsenious into arsenic acid by means of potassium permanganate is not perfect (*Zeitschr. anal. Chem.* x. 158), and a volumetric method based upon this reaction was found to be most untrustworthy; but, by adding excess of permanganate, more than double the amount required according to theory, and standardising back with a solution of ferrous sulphate, very accurate results were obtained.

The volumetric determination of arsenic acid by means of uranic acetate in presence of free acetic acid and an alkaline acetate was not found to yield trustworthy results.

On the Separation of Arsenic from tin, see TIN.

Arsenic and Arsenious Acids and Oxides. *Crystalline Form of Arsenious Oxide.*—Crystals of this body from the Halsbrück Works, near Freiberg, have been examined by P. Groth (*Pogg. Ann.* cxxxvii. 414). They are rhombic prisms, having a broadly tabular form from predominance of the faces which truncate the acute edges. The axial ratio is $a : b : c = 0.3758 : 1 : 0.3500$, which is sufficiently near to that of rhombic antimonious oxide (antimony-bloom), viz. $0.3869 : 1 : 0.3710$, to show that these two similarly constituted bodies are isomorphous. In their optical properties the two oxides differ considerably. Their specific gravities in both forms are as follows:—

		As ² O ³	Sb ² O ³
Regular	3.70	5.26
Rhombic	4.25	5.57

Reaction of Arsenic Acid with Hydrochloric Acid.—Rosa (*Pogg. Ann.* cv. 573) found that a concentrated aqueous solution of arsenic acid distilled with fuming hydrochloric acid yielded a distillate free from arsenic, no volatile chloride of arsenic being formed. According to Mayerhofer, however (*Ann. Ch. Pharm.* clviii. 326), the distillate thus obtained always contains arsenic, hydrochloric acid of sp. gr. 1.1 yielding traces, and fuming hydrochloric and considerable quantities of arsenic in the distillate. This result depends upon the reducing action of hydrochloric acid on arsenic acid, whereby arsenious acid and chlorine are produced, the arsenious acid being thus converted by the excess of hydrochloric acid into arsenious chloride, which distils over. Arsenic anhydride reacts with hydrochloric acid gas, even in the cold, forming chlorine-water and arsenious chloride:—

It follows from these results that hydrochloric acid cannot be freed from arsenic by heating it with chlorine or with manganese dioxide, to convert arsenious into arsenic acid, and then distilling. The purification may however be effected by Bettendorff's method with stannous chloride (*1st Suppl.* 216), or by diluting it with water, and submitting it to prolonged treatment with hydrogen sulphide.

Preparation of Crystallised Arsenates.—W. Skoy (*Chem. News*, xxii. 61) has obtained the arsenates of calcium and zinc in the crystalline form by mixing the solution of a calcium or a zinc salt with a soluble arsenate, in such proportion that the liquid shall remain acid, and the precipitation shall take place slowly. Similar and more complete results have previously been obtained by Debray and by Lechartier (*1st Suppl.* 222).

When arsenious acid or an arsenite is treated with sodium-amalgam, a substance is produced which reduces potassium permanganate and the salts of gold, silver, mercury, and copper at ordinary temperatures. The colourless aqueous solution decomposes gradually, turning brown and giving off arsenetted hydrogen (Frémy, *Compt. rend.* lxx. 61).

Arsenious oxide is attacked by phosphorus trichloride at 110°, becoming brown from separation of arsenic. On raising the heat to 180° to ensure the completion of the reaction, the liquid, which is very much diminished in quantity, exhibits the characters of arsenious chloride, AsCl₃, boiling at 132°. The separated

solid bodies consist of metallic arsenic and phosphoric oxide. The reaction may therefore be represented by the equation:—

Arsenic oxide, As_2O_3 , is not acted on by phosphorus trichloride, even at 200° (Michaelis, *Jenaische Zeitschr.* vi. 239).

Separation of Arsenious and Arsenic Acids.—The mixture is distilled with sulphuric acid and sodium chloride, whereby the arsenious acid is converted into arsenious chloride, which distils over, while the arsenic acid, being unacted on, remains in the retort. The distillate is treated with hydrogen sulphide. The arsenic acid in the residue of the distillation is reduced to arsenious acid by sulphurous acid; the arsenic then precipitated by hydrogen sulphide; the precipitate dissolved by hydrochloric acid and potassium chlorate; and the arsenic acid thereby produced is precipitated as ammonio-magnesian sulphate. This gives the quantity of arsenic acid originally present. The sulphide precipitated from the distillate is treated in the same manner, and thus the quantity of arsenious acid is determined. This method may be applied to the estimation of arsenic in commercial fuchsine, in which both the acids of arsenic are generally present (Riecker, *Zeitschr. anal. Chem.* ix. 516).

Arsenic Ethers. (Crafts, *J. Pharm.* [4] xiii. 250). *Ethyl Arsenate* has been already described (1st Suppl. 226).

Methyl Arsenate, $(\text{CH}_3)_3\text{AsO}_4$, is prepared by the action of methyl iodide on silver arsenate. It cannot be distilled without decomposition at atmospheric pressure; the greater part, however, distils undecomposed at 213° – 215° . Under the pressure of 60 mm. it distils at 128° – 130° . Its specific gravity at 14.5° is 1.5591, that of water at 4° being 1. It resembles the ethyl-compound in all its properties.

Amyl Arsenate is prepared in the same manner as the preceding compound, but it has not been obtained quite pure, on account of its partial decomposition at the boiling point, even in a vacuum. It undergoes decomposition with water as easily as the other ethers of arsenic acid.

Arsenious Ethers. The properties of *ethyl arsenite* have also been described (1st Suppl. 221). The best mode of preparing it is by the action of sodium ethylate on arsenious chloride or bromide in alcoholic solution:

This mode of preparation is complicated by a secondary reaction, which becomes considerable when a certain proportion of ethyl arsenite is formed in the liquid. Sodium alcoholate, in fact, acts as readily upon ethyl arsenite as upon arsenious bromide, according to the equation:

For this reason a quantity of sodium ethylate is employed, sufficient to react with three-fourths only of the arsenious bromide, so that at the end of the operation there remains a mixture of the bromide and ethyl arsenite. These liquids are separated by passing into the solution a current of dry gaseous ammonia, which forms with the arsenious bromide a compound insoluble in alcohol and ether, whilst it does not affect the ethyl arsenite. The liquid is then filtered, and the ethyl-compound is obtained pure by distilling off the alcohol or ether with which it is mixed.

Ethyl arsenite is not acted on by dry ammonia, and may even be distilled in the gas without alteration. It undergoes with hydrobromic acid a decomposition the reverse of that which usually takes place between haloid acids and ethers, thus:

Methyl Arsenite, $(\text{CH}_3)_3\text{AsO}_3$, is formed under the same conditions as the ethyl-compound. It boils without decomposition at 128° – 129° . Its density is 1.428, that of water at 4° being 1. The density of its vapour at 197° is 6.006. In its other properties it exactly resembles ethyl arsenite.

Amyl Arsenite, $(\text{C}^4\text{H}_9)_3\text{AsO}_3$, obtained by the action of sodium amylate on arsenious bromide, distills under the ordinary pressure at 288° , with partial decomposition, and under the pressure of 60 mm. at 193° – 194° , without decomposition; it resembles the corresponding ethyl- and methyl-compounds, and is easily decomposed by water, the moisture of the atmosphere, or aqueous alcohol.

The differences in boiling point due to the substitution of methyl for ethyl in these ethers are not so great as those which are observed in most ethers of organic acids; the differences for the ethers of arsenic acid are not the same as for those of arsenious acid. (Crafts.)

Arsenic Phosphide, Pa_2 , is produced, with evolution of hydrogen chloride, when dry arsenetted hydrogen is passed over phosphorus trichloride, or phosphoretted hydrogen over arsenic trichloride. It has a bright roddish-brown colour when first deposited, but becomes dark and lustreless when dry. It is insoluble in alcohol, ether, and chloroform, but dissolves slightly in carbon sulphide. Sulphuric and hydrochloric acid have no action on it in the cold, but appear to dissolve it partially when heated. Strong nitric acid oxidises it, with production of flame, and the same acid, when dilute and warm, oxidises it readily to arsenic acid and phosphoric acid. Potash-solution, ammonia, and baryta-water decompose it slowly in the cold, and more rapidly on the application of heat, phosphoretted hydrogen, arsenetted hydrogen, phosphorous acid, arsenious acid, and metallic arsenic being produced. After long heating, the solution contains phosphoric acid and very little arsenious acid, the greater portion of the arsenic having separated in the metallic state. When arsenic phosphide is heated, it burns to arsenious oxide and phosphoric oxide, and when heated in a closed vessel it is decomposed, the phosphorus subliming before the arsenic. When arsenic phosphide is treated with water, a substance having the composition $As^{10}P^{20}O^8$ is obtained. This substance is not much acted on by acids, with the exception of nitric acid. With alkalis it reacts like arsenic phosphide, but a considerable quantity of arsenic is set free even in the cold. It is decomposed slowly when heated to 100° , and rapidly at 250° (Janowsky, *Deut. Chem. Ges. Ber.* vi. 216).

Pellotier described a phosphide of arsenic produced by melting phosphorus and arsenic together under water; but, according to Janowsky, the product thus formed is not a definite compound, since it yields up its phosphorus to carbon sulphide.

Sulphides of Arsenic. These compounds have recently been examined by Nilsson (*Deut. Chem. Ges. Ber.* iv. 989), who has come to the conclusion that arsenic forms only three definite sulphides, viz. As^4S^3 , As^3S^2 and As^2S^3 , the black sulphide $As^{10}S^8$ described by Berzelius, and the higher sulphides, As^4S^{10} and As^2S^{12} , being merely mixtures.

1. The *bisulphide*, As^2S^2 , does not possess the power of forming salts, as stated by Berzelius.

2. *Trisulphide or Arsenious Sulphide*, As^2S^3 .—Alkaline sulphhydrates, saturated under ordinary circumstances with the trisulphide, yield, for the most part, brown amorphous compounds having the general formula, $R^2S.As^2S^3 + x$ aq. Strontium alone yields a bibasic salt. In a vacuum, on the other hand, larger quantities of hydrogen sulphide are driven off, and well crystallised salts of a more basic character are often obtained, the sulphides of barium and strontium yielding the salts, $2R^2S.As^2S^3$ and $3R^2S.As^2S^3$, and calcium sulphide forming the salt $7CaS.As^2S^3 + 25$ aq.—In the case of the true alkaline sulphhydrates, the increased elimination of hydrogen sulphide is accompanied by a totally different reaction. With the sulphhydrates of potassium and sodium, metallic arsenic is separated, and a salt of arsenic sulphide, $3R^2S.As^2S^3 + x$ aq., is formed. Ammonium sulphhydrate, $(NH^4)^2S.H^2S$, forms with arsenious sulphide, under all circumstances, the salt $(NH^4)^2S.3As^2S^3$; rarefaction of the air merely causes the escape of ammonium sulphide, together with the hydrogen sulphide.

Similar acid salts are produced by treating the monobasic salts with water, thus $K^2S.As^2S^3 + 5$ aq., gives at first $K^2S.2As^2S^3$, and after prolonged boiling with water, the triacid salt, $K^2S.3As^2S^3$. When the calcium salt, $CaS.As^2S^3 + 10$ aq., is treated with cold water, the brown salt, $CaS.4As^2S^3 + 10$ aq., remains behind, while warm water leaves the yellow salt, $CaS.9As^2S^3$.

The triacid sulpharsenites of potassium and sodium are also formed, when a boiling solution of the corresponding carbonate is mixed to saturation with arsenious sulphide. The bisulphide As^2S^3 is then also formed, together with well crystallised oxysulpharsenates, namely, with potassium, the previously known salt, $K^2O.As^2S^3O^3 + 2$ aq.; with sodium the salt $Na^2O.2As^2S^3O^3 + 7$ aq.

The saturating capacity of arsenious sulphide appears therefore to be capable of wide variation, inasmuch as salts exist containing 1, 2, 3, 4, 6, and 9 mols. of As^2S^3 to 1 mol. R^2S , besides basic salts with 2, 3, 7 R^2S to $1As^2S^3$, or $3R^2S$ to $2As^2S^3$.

3. *Pentasulphide or Arsenic Sulphide*, As^2S^5 .—The precipitate thrown down by hydrochloric acid from a dilute solution of sodium sulpharsenate, is a sulphhydrate, $3H^2S.As^2S^5$, which gives up the whole of its hydrogen sulphide only after prolonged boiling.

By dissolving the pentasulphide in alkaline sulphhydrates, the following salts are obtained:—

Most of these salts are $\frac{1}{2}$ -basic, and in some of them the pentasulphide of arsenic is partly reduced to trisulphide.

Gélie (*Compt. rend.* lxxvi. 1205) also finds that the compounds of sulphur and arsenic are not so numerous as was formerly supposed. Sulphur heated with excess of arsenic forms only one product, viz., the bisulphide, which is opaque, has a coral-red colour and a crystalline fracture. When the sulphur is in excess, a mixture is obtained consisting of the pentasulphide and free sulphur, from which the former may be dissolved out by ammonia. If the mixture be distilled in an earthenware retort, sulphur goes over first, then a mixture of sulphur and arsenic, and the residue in the retort consists of arsenic pentasulphide. If the distillation be continued, the pentasulphide decomposes into sulphur and arsenic trisulphide, and the latter may be distilled without decomposition.

The mixture of sulphur and arsenic which distils over after the sulphur, when treated several times with carbon sulphide, yields a product containing from 9.27 to 11.41 atoms of sulphur to one of arsenic. As these numbers agree nearly with the formula As_2S^{10} , Gélie suggests that the compound thus obtained may be regarded as an arsenic pentasulphide containing five pairs of sulphur-atoms united into bivalent groups: $\text{As}_2(\text{S}-\text{S})^2$.

When sulphur and arsenic are heated together in proportions within the limits indicated by their two extreme compounds, As_2S^2 and As_2S^{10} , mixtures of di-, tri-, and pentasulphide are obtained according to the quantity of each used; the trisulphide being either formed directly or from the decomposition of the pentasulphide.

ARSENIC-GLANCE. This name has been given to two minerals from the Palm-tree mine at Marionberg, in Saxony: one of which, distinguished by brilliant metallic lustre and perfect monotomic cleavage, was found by Korsten to contain 97 p. c. arsenic and 3 p. c. bismuth; while the other, which occurs in irregular plates and nodules, appears to be merely impure metallic arsenic, its analysis giving:

As.	Sb.	Fe.	Ni.	S.
92.80	2.28	1.60	0.26	1.06 = 98.00.

Both varieties when set on fire continue to burn with a glimmering light. This property was shown by v. Kobell to belong to all varieties of finely divided arsenic, whence he inferred that arsenic-glance is not a distinct mineral species. It is most probable, however, that the first-mentioned mineral is really a distinct species, as its specific gravity, 5.3, is lower than that of either of its constituents, viz., arsenic 5.7 and bismuth 9.7 (*Fronzel, Jahrb. f. Mineralogie*, 1873, 25).

ARSINES. Pure arsine or arsenetted hydrogen, AsH_3 , is best obtained by the action of dilute acids on sodium arsenide, prepared by heating sodium in the impure gas evolved when arsenical zinc is treated with dilute acid.

When dry arsine is passed over *phosphorous chloride* kept cool, hydrogen chloride is evolved, and a phosphide of arsenic, AsP , is deposited.

When arsine is passed into *arsenious chloride*, hydrogen chloride is evolved, and metallic arsenic is deposited:

When arsine comes in contact with concentrated sulphuric acid, hydrochloric acid, or moist hydrochloric acid gas, metallic arsenic is deposited, and this deposited arsenic dissolves in sulphuric acid on the application of heat, sulphurous acid being evolved (*Janowsky, Deut. Chem. Ges. Ber.* vi. 216).

Compounds of Triethylarsine with Platinous Chloride.—When triethylarsine is added by drops and with agitation to a concentrated aqueous solution of *platinic chloride* mixed with an equal volume of alcohol, great heat is evolved, the solution becomes lighter in colour, and ultimately brownish-yellow, and on cooling deposits sulphur-yellow crystals, consisting of a mixture of two isomeric bodies, $2\text{As}(\text{C}_2\text{H}_5)_3 \cdot \text{PtCl}_4$, one soluble, the other insoluble in ether. Their formation is represented by the equation:

The soluble salt separates from the ethereal solution by spontaneous evaporation in transparent amber-coloured crystals, isomorphous with the corresponding phosphine-compound. From boiling alcohol it crystallises in more slender, opaque, sulphur-yellow prisms. The isomeric salt, insoluble in ether, dissolves easily in boiling alcohol, and crystallises therefrom, on cooling, in long prisms of a faint yellow colour. When a solution of either of these salts in absolute alcohol is treated with an alcoholic solution of *bromide, iodide, sulphhydrate, or acetate of potassium*, chloride of potassium separates out, and the solution when evaporated yields well crystallised

compounds, having the composition of the salts above described, with bromine, iodine, &c. substituted for the chlorine. Both the isomeric chlorine salts unite with triethylarsine, forming the compound $4\text{As}(\text{C}^2\text{H}_5)_3 \cdot \text{PtCl}_2$, analogous to tetrammonio-platinous chloride (Cahours a. Gal, *Compt. rend.* lxxi, 208).

Palladium-Compound.—Palladic chloride reacts with triethylarsine in the same manner as platonic chloride, forming the compound $2\text{As}(\text{C}^2\text{H}_5)_3 \cdot \text{PdCl}_2$, which crystallises in large transparent reddish-yellow prisms, isomorphous with the corresponding phosphine compound (Cahours a. Gal).

Gold Compound.—An alcoholic solution of auric chloride, to which triethylarsine is added drop by drop, becomes heated and decolorised: it is necessary, however, to cool the solution, as otherwise metallic gold will be separated. The colourless filtrate yields by spontaneous evaporation splendid long colourless prisms of the salt, $\text{As}(\text{C}^2\text{H}_5)_3 \cdot \text{AuCl}$, isomorphous with the corresponding phosphine compound (Cahours a. Gal).

ASBOLAN. A specimen of this mineral from Saalfeld was found by v. Kobell, (*Münch. Sitzungsber.*, 1870, i. 46) to contain lithia, also 54 p. c. Mn^2O_3 , 4CaO, 0.61 CuO, $13.4\text{H}_2\text{O}$ and $23\text{Al}_2\text{O}_3$.

ASH OF ORGANIC BODIES. *Incineration with Bismuth Oxide.*—Considerable difficulty is often experienced in effecting conveniently, and without loss, the incineration of animal and vegetable substances, especially when some of the mineral constituents are volatile, or when the ashes so obtained are fusible. Many and various remedies have been devised to overcome these obstacles, such as the addition of spongy platinum, the carbonates of barium and sodium, oxide of iron, &c.; but the utility of these substances is questionable; and further, their use violates one of the principal laws of chemical analysis, which forbids the employment of any reagent which cannot be readily eliminated, or which may possibly already exist as a natural constituent of the substance analysed.

Béchamp (*Compt. rend.* lxxiii. 337) recommends the employment of bismuth oxide, in the form of a standard solution of the nitrate, as a reagent fulfilling all the conditions required. It is sufficiently infusible, furnishes a certain quantity of oxygen, is never met with in organised bodies, and can be easily eliminated by a volatile reagent incapable of acting upon the products of combustion; and, finally, it forms with sulphuric and phosphoric acids, and with chlorine, combinations sufficiently stable to resist the moderate degree of heat at which the incineration takes place. The combustion is made in the following manner:—

The material, in a finely divided state, is impregnated with a known volume of the bismuth solution, carefully dried and burnt. The ash is then treated with nitric acid, or, if there is no objection, with dilute hydrochloric acid, in which, if the operation has been successfully conducted, the whole should dissolve. The cold solution is decomposed with sulphuretted hydrogen, and the bismuth sulphide having been filtered off, the liquid is submitted to analysis. When the ash contains phosphates, it may be exhausted with very dilute nitric acid, in which bismuth phosphate is insoluble.

Analysis of Plant-Ashes. Bunsen (*Zeitschr. anal. Chem.* ix. 233) has assimilated the analysis of plant-ashes to that of mineral waters, in so far that, by the introduction of carbonic acid, he obtains a mixture of neutral salts, and analyses the soluble portion separately from the insoluble. By this means it becomes possible to check the analytical results by calculation, since, in a correct analysis the sum total of the bases must be equivalent to that of the acids. The usual method, of comparing the total of the results with the quantity of substance employed, cannot be depended upon as a verification, if caustic compounds are present, as it then becomes impossible to obtain an exact estimation of the water and the carbon.

ASH MANNA. See MANNA.

ASPARAGINE. $\text{C}^4\text{H}^7\text{N}^2\text{O}_3 = \text{COOH} \cdot \text{CHNH}_2 \cdot \text{CH}_2 \cdot \text{CONH}_2$. *Formation in Vetches.*—Piria found asparagine in vetches which had been grown exposed to bright light, as well as in those grown in darkness. Some years afterwards Pastour (*Ann. Chim. Phys.* 1857) grew a large quantity of vetches in the garden of the Academy at Strasburg, but did not obtain a trace of asparagine from 200 litres of the sap, whilst he found abundance in vetches grown in the same soil in a cellar. To throw further light on the question, Coasa (*Gazzetta chimica italiana* i. 888) grew some vetches in the month of July, and from a kilogram of those which had been exposed to light, he obtained 16.25 grams of pure asparagine, while from an equal weight of those grown in a cellar he obtained 13.50 grams, the asparagine being proved to be identical in both cases; similar results were obtained in the months of August and September. Pastour's failure probably arose from the circumstances that

the sap of vetches, especially when grown exposed to light, readily ferments, the asparagine being decomposed and ammonium succinate being formed.

Formation from inactive Aspartic Acid.—When the silver salt of this acid, prepared from asparagine, is gently heated with ethyl iodide and a little alcohol, monethyllic

aspartate $C^2H^3 \begin{Bmatrix} COOH \\ NH^2 \\ COOC^2H^3 \end{Bmatrix}$ is obtained as a crystalline substance, which may be dissolved out by ether, and, when heated with strong aqueous ammonia, is converted into asparagine, exhibiting all the properties of the natural product:

(E. Schaal, *Ann. Oh. Pharm.* clvii. 24).

Action of Hydrochloric Acid.—When dry hydrochloric acid gas is passed over asparagine for three days, and the temperature is gradually raised to 180°, a white hard mass is formed. The same product is obtained by boiling asparagine with strong hydrochloric acid and heating the dried mass in a current of carbon dioxide, first to 120° and afterwards to 200°.

The body thus obtained is a mixture of two compounds, both of which are anhydrides of aspartic acid. One, which is sparingly soluble in cold water, can be extracted by boiling water; it has the composition $C^{16}H^{11}N^4O^3 = 4C^2H^3NO^4 - 7H^2O$. The residue insoluble in water is $C^{12}H^{12}N^4O^{11} = 8C^2H^3NO^4 - 15H^2O$. Both the soluble and the insoluble compound take up water when boiled with ammonia or baryta-water, and are converted into inactive aspartic acid (Schaal).

Action of Potassium Permanganate.—According to Péan de St. Gilles (*Ann. Chim. Phys.* [3] lv. 394), potassium permanganate does not act upon asparagine even at the boiling heat. According to Campani, on the contrary (*Zeitschr. f. Chem.* [2] vi. 87), the reaction takes place, though slowly, even at ordinary temperatures. When a solution of the permanganate containing 1 gram of the salt in a cubic centimeter is gradually added to a cold saturated aqueous solution of asparagine, the chief products formed are ammonia, formic acid, carbon dioxide, and hydrocyanic acid:

When 1 gram of asparagine and 2 grams of permanganate, both in fine powder, were intimately mixed, and the mixture was poured into 40 c.c. of water and stirred, violent frothing took place, and the temperature rose to 64°; and when a similar experiment was made with 1 gram of asparagine and 4 grams of permanganate, the temperature rose to 94°, and the whole was converted into a brown pasty mass. The final products were, however, the same as those above mentioned. In presence of dilute sulphuric acid (1 gram asparagine, 2 grams sulphuric acid diluted with 30 grams water, and 5 grams permanganate dissolved in the smallest possible quantity of water), the oxidation proceeds in the manner represented by the equation:

in presence of potash, according to the equation:

the oxalic acid not being accompanied either by carbonic or by hydrocyanic acid.

Estimation of Asparagine.—R. Sachse (*J. pr. Chem.* [2] vi. 118) describes a method for the estimation of asparagine, depending on the fact that asparagine is converted by prolonged heating with aqueous hydrochloric acid, into ammonia and aspartic acid, and that this acid and asparagine are both unaffected by brominated soda-solution, so that, when the amount of nitrogen liberated on shaking an asparagine solution with the brominated soda-solution, after digestion with hydrochloric acid, is determined by Knop's method (p. 59), the necessary data are obtained for calculating the amount of asparagine present.

The exactness of the method has been tested by a number of experiments with weighed quantities of asparagine (.03–.3 gram) dissolved in 100 c. c. of water, and heated for 12 hours with 10 c. c. of ordinary hydrochloric acid; also with weighed quantities of asparagine mixed with 10 grams of fine pea-flour (which contains no asparagine).

Although an aqueous solution of asparagine may be preserved unchanged, an impure solution containing albuminous substances cannot; it is, therefore, necessary to extract the latter from the vegetable substance in which the amount of asparagine is to be determined, as rapidly as possible. The method adopted by Sachse in the extraction of the asparagine from the mixture with pea-flour, and recommended by

him for general use, is as follows: the 10 grams of flour are heated for 15 minutes with 200 c. c. of a mixture of equal volumes of ordinary alcohol and water in a flask connected with a reversed condenser; the source of heat is then removed; 5 c. c. of a cold saturated solution of mercuric chloride diluted with an equal volume of water added to the hot solution; and the whole, after being well shaken, is filtered through a moderately large fluted filter. The precipitate, which is brought as completely as possible into the filter, is then washed with a second 200 c. c. of heated alcohol and water mixture, afterwards three or four times with cold water. The entire filtrate thus obtained (500–550 c. c.) is evaporated on the water-bath; the residue dissolved as completely as possible in the least possible quantity of water; and the solution and the undissolved matter introduced into a small beaker, and saturated with sulphuretted hydrogen. The precipitate of mercuric sulphide is then removed by filtration and washed with hot water, and the filtrate (100–120 c. c.) is mixed with 10 c. c. of hydrochloric acid and heated to boiling for an hour in a flask attached to a condenser; after cooling, the ammonia is determined by Knop's method. The amount of decomposition which asparagine suffers previous to the treatment with hydrochloric acid, is found to be almost inappreciable. Heating for 1–1.25 hour with the acid is found sufficient to convert the whole of the asparagine into aspartic acid and ammonia; longer heating makes the results too high. It is proposed to employ this method in investigating the formation and movement (*Wanderung*) of asparagine which occurs during the germination of the Leguminosae.

ASPARTIC ACID. $C^4H^7NO_4$.—This acid is formed from animal proteids by the action of dilute sulphuric acid at the boiling heat; also, together with glutamic acid, $C^5H^9NO_4$, by similar treatment of vegetable proteids (1st *Suppl.* 229, 636).

The relative quantities of these two acids obtained from various vegetable proteids differ very considerably. The proteids of wheat-gluten, gluten-casein, maize-fibrin, and conglutin from lupines and almonds, produce glutamic acid in quantity sufficient to crystallise out of the concentrated mother-liquor on standing for a few days, whereas the quantity of aspartic acid obtained is much smaller. Legumin from pulse, on the contrary, gives but little glutamic acid, but a larger quantity of aspartic acid. The following table gives the roughly estimated quantities by weight of the two acids obtained from various substances:—

	Aspartic acid.	Glutamic acid.
1. Mucedin	Not estimated.	25 per cent.
2. Maize-fibrin	1.4 per cent.	10.0 "
3. Mixture of vegetable mucedin, and fibrin	1.1 "	8.8 "
4. Gluten-casein	0.33 "	5.3 "
5. Conglutin (from lupines)	2.0 "	3 to 5 "
6. Legumin (from hog-beans)	3.5 "	1.5 "

The numbers in experiments 1 to 5 under 'Glutamic acid,' give the quantity which crystallised out of the mother-liquor, and was purified by solution in water. In experiment 6, the glutamic acid adhering to the aspartic acid was also extracted (Ritthausen a. Kreusler, *J. pr. Chem.* [2] iii. 314).

Aspartic acid (from conglutin) crystallises, so long as it is not quite pure, in rather large rhombic prisms, which, according to the measurements of vom Rath, have the axial ratio $a : b : c = 0.7929 : 1 : 0.5433$, and are generally combinations of the vertical prism ∞P with the macrodome $P\infty$.

The pure acid can be obtained only in laminae which are not adapted for measurement. The solution of aspartic acid in dilute nitric acid is dextrogyrate: $[\alpha]_D = + 25.16^\circ$.

Cupric aspartate crystallises in slender blue needles which give off 29.1 p. c. water at 140° , and have the composition $C^4H^7CuNO_4 + 4\frac{1}{2}H_2O$ (Dessaignes found $5H_2O$, see i. 424). The barium and silver salts of the acid obtained as above are similar to those already known. Treated with nitrous acid, they ultimately yield malic acid (Ritthausen, *J. pr. Chem.* cvii. 218).

ASPIDOLITE. A rhombic olive-green mica, occurring in oval tabular convex twin-crystals in the chlorite of the Zillerthal. When heated it intumesces, bends, becomes light gray, and acquires a metallic lustre. Hydrochloric acid decomposes it with moderate facility, the silica separating in scales. Hardness = 1.5. Sp. gr. = 2.72:—

SiO_2	Al_2O_3	MgO	FeO	Na_2O	K_2O	H_2O
46.44	10.50	26.30	9.00	4.77	2.52	1.18 = 100.66

(v. Kobell, *J. pr. Chem.* cvii. 167).

ASTEROÏTE (Igelström, *Chem. Centrbl.* 1870, 68). A variety of augite, allied

to Jeffersonite, from the magnetic iron of the iron mines of Nordmark in Wermland, Sweden. It forms stellate groups, composed of broad rays, originally ash-grey or white, but acquiring a brown tarnish. It is but slightly attacked by acids, but melts before the blowpipe to a grey non-magnetic slag. The loss of weight by ignition in the following analysis did not occur in other specimens, and appears to have been due to incipient weathering:—

SiO ²	FeO	MnO	CaO	MgO	Loss by ignition
48.48	22.24	4.12	17.00	4.18	2.83 = 98.85

ASTRACANTITE. $\text{Na}^2\text{SO}^4 \cdot \text{MgSO}^4 + 4\text{H}^2\text{O}$ (Geinitz, *Jahrbuch f. Mineralogie*, 1871, 856; Zincken, *ibid.* 883).—This mineral occurs in the Stassfurt salt-beds, associated with carnallite and kainite. Two specimens (a) of sp. gr. 2.28 and hardness 2-3; (b) of sp. gr. 2.223 and hardness 3.5, gave the following results on analysis:—

		Calculated.	Found.	
			a.	b.
Na ² O	.	18.60	18.25	18.50
MgO	.	12.14	12.64	11.96
2SO ³	.	47.79	47.69	47.97
4H ² O	.	21.47	21.66	21.44
		100.00	100.24	99.87

ATACAMITE. See COPPER OXYCHLORIDES.

ATELESTITE. A mineral occurring, together with the bismuth silicate of Schneeberg, in small sulphur-yellow crystals having an adamantine lustre. Of its chemical composition nothing is known, except that it contains bismuth. It is monoclinic, with the axial ratio 0.869 : 1 : 1.822. Angle of inclined axes = 110° 30'. Angle ∞P : ∞P = 83° 16', P : P (calc.) = 114° 5½'. Observed forms: ∞P , P, $\infty P \infty$, $\frac{1}{2}P \infty$, $\infty R \infty$ (G. vom Rath, *Pogg. Ann.* cxxxvi. 422).

ATMOSPHERE. A very extensive series of observations on the impurities existing in the air in various localities has been made by Dr. R. Angus Smith (*Sixth and Seventh Reports of the Inspector under the Alkali Act of 1863*, also *Air and Rain*, London, 1872). Two methods of examination were employed:—1. The examination of the rain-water of the locality; 2. Subjection of the air to artificial washing, and examination of the washings. The latter method is regarded as best adapted for affording an accurate comparison between different atmospheres, since the composition of rain-water necessarily varies according to the amount which falls in a given time, the rain of a dry season being far more impure than the rain of a wet season.

Numerous examinations of rain-water were made, and always by volumetric methods, the smallness of the volume of water at disposal precluding the use of gravimetric methods. The ammonia existing in the free state, or as chloride, sulphate, or carbonate, the albuminoid ammonia derived from the decomposition of organic matter, and the nitric acid, were estimated by Wanklyn, Chapman, and Smith's methods. The hydrochloric and sulphuric acids were determined from the quantity of water required to produce a certain standard amount of whiteness with solution of silver or barium. The permanganate test was applied to the acidified water, the experiments lasting a few minutes only. The more characteristic results are given in the accompanying table (Table I., see next page):—

It appears that the amount of chlorides in rain-water is dependent on the distance from the sea, and on the direction and force of the prevalent winds; the combustion of coal has a slight effect in increasing the quantity. Sulphuric acid is derived chiefly from the combustion of coal, but is also a product of vegetable and animal decomposition; it always increases as we proceed inland. In sea-water the proportion of hydrochloric to sulphuric acid is 100 to 11.6; excess of sulphuric acid over this proportion is due to terrestrial contamination. Free acids are rarely found, save in the rain-waters of towns. Ammonia is chiefly connected with the combustion of coal, and to a lesser degree with the decomposition of organic matter. Albuminoid ammonia is related solely to animal and vegetable life. Nitric acid may be taken as a measure of 'purified sewage.' The permanganate test denotes a variety of products, both from coal and from organic decomposition.

To examine air by washing, 50 c. c. of water are shaken in an empty 2-litre bottle; the washed air then drawn out by one stroke of a flexible bellows-pump having 1½ times the capacity of the bottle; the fresh air which has entered agitated as before, and the operations repeated 10 to 100 times, according to the purity of the atmosphere. In this plan the volume of air used is only known approximately, the results are therefore comparative instead of absolute.

TABLE I.—RAIN WATER: *Average impurities per million parts.*

Where collected.	Hydrochloric acid.	Sulphuric acid (anhyd.)	Sulphuric acid for 100 hydrochloric.	Free acids calculated as sulphuric acid.	Ammonia (inorganic).	Albuminoid ammonia.	Nitric acid.*	Oxygen required as permanganate.
Ireland, Valencia	48·67	2·73	6	None	·18	·03	·37	·05
Scotland, five sea coast country places, west	12·28	3·61	29	·14	·48	·11	·37	·02
Scotland, eight sea coast country places, east.	12·91	7·66	59	2·44	·09	·11	·47	·65
Scotland, twelve inland country places	3·38	2·06	61	·31	·53	·04	·31	·26
England, twelve inland country places	3·99	5·52	138	None	1·07	·11	·75	·47
Scotland, six towns (Glasgow excluded)	5·86	16·50	282	3·16	3·82	·21	1·16	1·86

The following table shows the quantities of acids and ammonia contained in air from various localities, compared with the quantities of the same substances (taken as 100) in the purest air from Blackpool, on the Lancashire coast, and at Inellan, on the Firth of Clyde:—

TABLE II.—*Impurities in Air.*

Locality of atmosphere.	Hydrochloric acid.	Sulphuric acid (anhyd.)	Locality of atmosphere.	Ammonia (inorganic).	Albuminoid ammonia.
Blackpool	100	100	Inellan	100	100
Didbury	277	282	London	117	109
Buxton	415	315	Metropolitan Railway	138	271
London	320	352	Glasgow	160	221
St. Helens	516	484	A bedroom	194	173
Manchester	396	513	Office at Manchester	235	193
Metropolitan Railway	974	1554	A midden	643	301

By means of these air-washings a chemical climatology may be established.

Dr. Smith has also determined the amount of oxygen and carbon dioxide occurring in air under a variety of circumstances; the more characteristic results are as under:

Where collected.	Oxygen per cent.	Carbon dioxide per cent.
Tops of hills, Scotland	20·980	·0332
London, parks and open places	20·950	·0394
London (average of 68 analyses)	20·885	·0439
Glasgow, open places	20·929	·0461
Glasgow, closer places	20·880	·0539
Metropolitan Railway tunnels	20·700	·1452
Theatres, worst parts	—	·3200
Mines (average of 339 analyses)	—	·7550
When candles go out	18·600	—

A series of daily observations on the amount of carbon dioxide in the air has been made at Rostock, by F. Schulze (*Landwirtschaftliche Versuchs-Stationen*, xiv. 886). The following table gives the means for each month during the duration of the

* Nitrous acid is here included.

† Average of a few specimens only.

experiments, of the parts by volume of carbon dioxide found in 10,000 parts of air:—

1868	1869	1870	1871
October . . 3.0600	January . . 2.7297	January . . 2.9806	January . . 2.9727

	Mean . . . 2.8668	Mean . . . 2.9062	
Total mean, 2.9197. Maximum quantity, 3.44. Minimum, 2.25.			

During the latter period of the experiments the carbon dioxide was determined twice in the day by shaking a standard solution of barium hydrate with 4 litres of air, and titrating with oxalic acid, tincture of turmeric being used as an indicator. The results by this method agreed closely with those obtained by passing 25 litres of air through baryta-solution by means of an aspirator.

The lowness of the results may be due to the vicinity of Rostock to the sea, as they most nearly agree with those obtained by Thorpe in the air over the Irish Sea and Atlantic Ocean.

No definite change in the amount of carbon dioxide was observed at different seasons of the year, or at different times of the day. Fog, and also a fall of snow, were often associated with an increase in carbon dioxide. The action of rain is not so obvious; and the changes are probably more dependent on the wind and temperature at the time, and on the action of the moistened soil, whether forming and liberating carbon dioxide or absorbing it. A north-east wind from the Continent was found to increase the carbon dioxide, and a south-west wind to decrease it, probably owing to absorption by the sea. Distilled water shaken up with air was found to dissolve, as a mean, 0.83 milligram of carbon dioxide per litre; fresh fallen rain-water contained 1.073 milligram per litre.

On the detection of organic and other azotised matter in the air, see A. H. Smee (*Chemical News*, xxvi. 25).

Atmospheric Ozone.—A very extensive series of observations on the varying amount of ozone in the air has been made by Hönzeu (*Ann. Chim. Phys.* [4] xxvii. 5).

The reagent used consisted of red litmus-paper impregnated over half its surface with a 1 p. c. neutral solution of potassium iodide.

This paper in contact with ozone assumes a blue colour only in the part impregnated with the iodide, this change of colour being due, not to the liberation of iodine, but to oxidation of the potassium, the alkali thus formed changing the colour of the litmus. In this respect the iodized litmus-paper is preferable to iodized starch-paper (Schönbein's reagent), which turns blue when the iodine is set free, and will therefore exhibit this reaction over its entire surface under the influence of free acids, especially nitrous acid, as well as of ozone. The part of the litmus-paper which is not iodized serves to reveal the accidental presence in the air of alkaline vapours (free ammonia, ammonium carbonate, &c.) which turn the red litmus-paper blue throughout its whole length; it is impossible, therefore to mistake the indications. Moreover, the iodized litmus-paper cannot be turned blue by chlorine, bromine, &c., since the chloride and bromide of potassium are neutral.

From a large number of observations made with this reagent in various localities and at different times of the year, the following conclusions are drawn:—

1. The air of the country contains an odoriferous and oxidizing principle which imparts to it a peculiar odour, and the power of blueing iodized red litmus-paper;
2nd Sup.

also of decolorising blue litmus-paper without previously roddening it; and of destroying certain bad smells.

2. This principle is ozone.

3. Ozone exists in the air normally, but the intensity with which it acts at any given point of the atmosphere is often very variable.

4. The air of the country contains at most about $\frac{1}{100000}$ of its weight, or $\frac{1}{700000}$ of its volume of ozone.

5. The manifestation of ozone by the iodised litmus-paper is much more frequent in the country than in town.

6. This difference may be due to the greater circulation of air in the fields.

7. At Rouen, the frequency of the ozone-manifestations varies with the seasons, being greatest in spring, strong in summer, weaker in autumn, and still weaker in winter.

8. The maximum of ozone-manifestation occurs in May and June (16 ozone days per month), and the minimum in December and January (4 ozone days per month).

9. With respect to the frequency of ozone-manifestation, the meteorological year in temperate climates may be divided into two great seasons: the *very active season* (spring and summer), comprising 78 ozone days, and the *feebly active season* (autumn and winter, including 32.

10. In general ozone shows itself more frequently on rainy days (48 ozone days in a hundred of rain, to 28 in a hundred of fine weather).

11. Winds, according to their strength, exert the greatest influence on the manifestation of ozone (24 ozone days in 100 when the air was calm or but slightly agitated, and 60 in 100 when the air was greatly disturbed).

12. At Rouen, the largest number of ozone days occur when the wind is in the west or south-west, the smallest number when it is in the east.

13. Most frequently an exaggerated manifestation of ozone is in intimate relation to the great atmospheric perturbations, known as thunder storms, gales and hurricanes.

14. These great commotions of the atmosphere act at very great distances. Sometimes they momentarily affect the ozone of entire towns and localities, which nevertheless continue to enjoy very fine weather.

15. Atmospheric electricity appears to be the most active cause of the formation of atmospheric ozone.

ATOMICITY. A mathematical theory of chemical attraction and atomicity has been proposed by Michaelis (*Deut. Chem. Ges. Ber.* v. 48). The attraction of an atom for other atoms is supposed to be exerted in certain directions only, or rather to exhibit maxima of intensity in these directions, the number of these maxima being in fact the number of units of atomicity exhibited by the atom. The acceleration imparted by any atom to another atom will therefore be a function, not only of the distance between the two, but also of the direction in space of the line joining their centres.

The exact form of the function with regard to the distance is unknown; but it is probably not negative—that is attractive—for all distances, like gravitation, but positive or repulsive for very small distances. Suppose that the force with which the atoms act upon each other varies, like that of gravitation, according to an inverse power of the distance, then the motion of an atom to or from another, regarded as fixed, may be represented by the equation:

$$p = \frac{A}{r^{n+1}} - \frac{A}{r^n}$$

where p is the acceleration, r the distance between the atoms, n and m any positive whole numbers, and A a quantity, the value of which is constant for each element (or rather for each pair of elements), but different for different elements. The value of p is negative or positive according as r is greater or less than 1. Supposing, then, that for $r = 1$, the movable atom has a velocity directed towards the fixed atom; then since for all values less than 1, the acceleration is positive, this velocity will be gradually diminished, as the movable atom approaches the fixed atom, till it is reduced to 0. The repulsion which then ensues carries the atom beyond the point $r = 1$, at which the acceleration again changes sign. In this manner an oscillatory movement is imparted to the movable atom, the amplitude of the vibrations being for the most part restricted within certain limits, but capable of becoming infinite for certain values of the velocity, so that the movable atom then no longer returns to the neighbourhood of the fixed atom, or in other words the combination is broken up.

The smaller attractive forces, not in the directions of the maxima, are perhaps concerned in the formation of the so-called molecular combinations.

ATRACTYLIC ACID, $C^{10}H^{14}S^{10}O^{18}$ (Lefranc, *J. Pharm.* [4] ix. 81; x. 325; xvii. 187, 263; *Compt. rend.* lxxvii. 954; lxxvi. 438).—This acid occurs as potassium salt together with inulin, levorotatory sugar, a balsam, and (in May) asparagin, in the root of *Atractylis gummifera*, L., *Carlina gummifera*, Baulin. To prepare it, the dry root is exhausted with water, the solution evaporated, and the residue exhausted with alcohol of 80 p. c. The alcoholic solution, when evaporated, deposits *acid potassium atractylate*, $C^{10}H^{12}K^2S^{10}O^{18}$, in short, soft, doubly refracting prismatic needles, which are colourless and scentless, have a bitter taste, are soluble in water and in dilute alcohol, and turn the plane of polarisation to the left ($\alpha = -5.77^\circ$). The dilute solution is not precipitated by barium chloride, but the concentrated solution yields a precipitate of *barium atractylate*, which dissolves in excess of water or on addition of hydrochloric or acetic acid.

The dry root of *Atractylis* contains 0.5 p. c. of the acid potassium salt, the fresh root 0.1 p. c. This salt may also be directly extracted from the root by alcohol of 75 p. c.; and if the root, after exhaustion with alcohol at 60° , be treated with cold water, it yields the potassium salt of another acid called carlinic acid (*q. v.*).

To prepare *atractylic acid*, the solution of the potassium salt is treated with basic acetate of lead, and the basic atractylate of lead thereby precipitated is decomposed by hydrogen sulphide. The acid is extremely soluble in water; its solution is scentless and colourless, has a very sour astringent, bitter and saccharine taste, and reddens litmus.

Atractylic acid is tribasic; its neutral potassium salt has the composition $C^{10}H^{12}K^3S^{10}O^{18}$. It resembles tartaric acid in forming crystalline precipitates with concentrated solutions of the chlorides and sulphates of the alkali-metals; it also forms, with concentrated solution of barium chloride, a crystalline precipitate of acid barium atractylate.

Atractylic acid heated with potassium hydrate above the melting point of the latter is decomposed, with evolution of hydrogen and formation of a resinous body of phenolic character, which is left as potassium salt, together with sulphate, and may be separated therefrom by hydrochloric acid; nitric acid transforms it into a yellow substance resembling picric acid. The formation of this resinous body, which is analogous to that of phenols in general by heating the corresponding sulphonic acids with caustic alkalis, shows that atractylic acid bears a certain resemblance to the acids of which benzene-sulphonic acid is the type; while, in other respects, it is analogous to the sulphuric ethers homologous with sulphovinic acid.

Atractylic acid heated with aqueous potash, baryta, or lime, reacts indeed like the divalentsulphuric ether of a neutral substance, $C^{10}H^{12}O^8$, called atractylin. The decomposition, however, takes place by two stages, in the first of which only the elements of valeric acid are separated, the other elements remaining combined in the form of a new acid, also tribasic, called β -atractylic or atractyl-disulphuric acid, $C^{10}H^{12}S^2O^{18}$, while in the second stage the molecule is completely resolved into sulphuric acid, valeric acid, and atractylin:

Beta-atractylic acid.—When atractylic acid is heated with aqueous potash or baryta, the second stage of the reaction above described follows so quickly upon the first, that it is difficult to obtain the β -atractylic acid; but by the use of lime it is easy to regulate the action and arrest it at the first stage. For this purpose, acid potassium atractylate is dissolved in about 20 parts of water, to which a quantity of slaked lime has been added about equal in weight to the salt; the liquid is gently boiled for 10 or 15 minutes, then filtered, freed from excess of lime by carbonic acid, and evaporated to about a fourth of its original bulk. In this state it is syrupy and uncrystallisable; but on adding a slight excess of hydrochloric acid drop by drop, the whole solidifies to a mass of silky nacreous microscopic needles, consisting of an *acid beta-atractylate of potassium and calcium*, which may be purified by draining on a filter, washing with alcohol and ether, crystallising twice from boiling alcohol of 90 p. c., which dissolves about $\frac{1}{10}$ th of its weight of the salt, and finally from water.

The conversion of atractylic into β -atractylic acid may also be effected by means of baryta; for, although the passage from the first to the second stage of the reaction is much more rapid in this case than with lime, it is distinctly indicated by the formation of a precipitate of a barium sulphate, so that the reaction can easily be arrested before it has gone too far. Barium atractylate obtained by precipitation from concentrated solutions of the acid potassium salt and barium chloride is boiled

with baryta-water for about a minute, the liquid quickly cooled as soon as it begins to show turbidity, and freed from excess of baryta by a current of carbonic acid gas. The liquid thus neutralised contains valerate and tribasic beta-atractylate of barium. When evaporated to a syrupy consistence, it quickly solidifies to a crystalline mass of well-defined silky needles.

Tribasic beta-atractylate of barium differs from the corresponding salt of atractylic acid in its capability of crystallising from water. Its concentrated aqueous solution acidulated with hydrochloric acid solidifies almost immediately to a crystalline mass consisting of an *acid atractylate of barium*, $C^{20}H^{22}Ba^2S^2O^{12}$, analogous to the natural acid potassium salt. It crystallises in the same form as the tribasic salt.

The barium-salts of β -atractylic acid are very convenient for preparing the corresponding salts of other metals by double decomposition.

On dissolving the potassio-calcic β -atractylate above described in baryta-water, passing carbonic acid through the liquid to remove the excess of baryta, concentrating the filtrate, diluting it with alcohol till it becomes slightly milky, and leaving it to itself for 24 hours, it solidifies to a mass of very delicate, shining needles, having the aspect and lightness of quinine sulphate and consisting of *potassio-bario-calcic β -atractylate*, $C^{20}H^{22}Kca^2Ba^2S^2O^{12}$.* The composition of this salt confirms the tribasicity of β -atractylic acid.

The β -atractylates resemble the atractylates in most of their reactions, but are distinguished from them by not yielding valeric acid when boiled with alkalis. They are for the most part more soluble both in water and in alcohol than the corresponding atractylates, but crystallise quite as readily. β -atractylic acid further resembles atractylic and also tartaric acid, in forming with the alkali-metals very soluble neutral salts, and acid salts of comparatively sparing solubility.

ATRACTYLIN, $C^{20}H^{24}O^8$ (Lefranc, *loc. cit.*).—This substance is formed as above mentioned by the complete saponification of atractylic acid. To prepare it, however, it is necessary to saponify a beta-atractylate, and not an atractylate, because in the latter case valeric acid is set free as well as atractylin, and these two substances, when thus simultaneously isolated, unite together in such a manner that it is impossible to separate them. The β -atractylic acid, on the other hand, simply splits up, under the influence of alkalis, into sulphuric acid and atractylin:

When potassium β -atractylate is boiled with an equal weight of potassium hydrate dissolved in 30 parts of water, the saponification is complete in less than ten minutes; and if the liquid, which then contains nothing but potassium sulphate and a compound of atractylin with potash, be gradually mixed with a slight excess of hydrochloric acid, the atractylin is set free, together with a varying quantity of atractyligenin (*infra*), resulting from its decomposition, both, however, being retained in solution. To separate them, the liquid is shaken with chloroform, which takes up the atractyligenin, and separates it from the liquid in the form of a white oily soap, while the atractylin remains dissolved, and may be separated by saturating the liquid with common salt. The atractylin then rises to the surface in the form of a flocculent magma, which soon concretes to a solid mass, and may be purified by washing it with ether, and precipitating it several times from a concentrated alcoholic solution by addition of ether.

Atractylin is a white substance having a gummy aspect, no smell, but a strong, peculiar, highly saccharine taste, very soluble in water and alcohol, insoluble in ether and in solution of common salt. It has a slight acid reaction, and unites with alkaline and earthy bases, forming compounds which are very soluble in water, and are gradually decomposed by boiling. Since the atractylates are optically laevogyrate, it is most probable that atractylin possesses the same property; but this point has not yet been verified by experiment.

Atractylin, heated on platinum foil, softens a little above 100° , then swells up and carbonises, giving off white irritating vapours, the odour of which recalls that of frankincense. When cautiously heated in this manner, it leaves a greasy cinder, which burns with a bright flame.

Atractylin dissolves in strong sulphuric acid, with a golden-yellow colour changing to purple-red and then to violet-red under the influence of a slight rise of temperature. This reaction is characteristic of the atractylates and β -atractylates. Nitric acid also dissolves atractylin, without alteration at ordinary temperatures, but on heating slightly, a strong reaction takes place, with production of a yellow substance resembling picric acid (*produit xanthopicroique*).

* $ba = \frac{1}{2}Ba$; $ca = \frac{1}{2}Ca$.

By boiling with very dilute hydrochloric or sulphuric acid, atractylin is partly decomposed in the manner of a glucoside, partly dehydrated. The product of dehydration, called atractyliretin, is a yellowish, non-volatile, insoluble substance, which is likewise produced when the solution of an atractylate or a beta-atractylate is boiled with a strong acid.

The best reagent for effecting the decomposition of atractylin in the manner of a glucoside is solution of caustic potash. Boiled with this liquid, the atractylin splits up into a saccharine substance (different from phloroglucin) and a crystallisable body, atractyligenin, which remains combined with the potash. The formation of atractyligenin in the preparation of atractylin, and the method of separating it by means of chloroform have already been described. It does not appear to have been analysed.

Atractyligenin is a white substance, having a sweetish, somewhat acid taste, nearly insoluble in pure water, but soluble in water containing atractylin, very soluble also in alcohol and in ether, from which it crystallises by spontaneous evaporation in crusts formed of short, brilliant, nacreous needles grouped in stars. Cautiously heated on platinum foil, it melts above 100° , to a limpid glass, then sublimates, for the most part unaltered, in white balsamic irritating vapours.

ATROPINE. The tri-iodide of this base, $C^{17}H^{23}NO^3.HI^3$, is obtained by mixing a solution of the hydriodide with the calculated quantity (2 atoms) of iodine tincture. It forms brown prisms, isomorphous with the corresponding compound of cotarnine. By boiling it with alcohol of 70 p. c., or by precipitating hydrochloride of atropine with periodide of potassium, and crystallising the precipitate from alcohol, the penta-iodide, $C^{17}H^{23}NO^3.HI^5$, is obtained in bluish-green laminæ, having a metallic lustre (Jörgenson, *Zeitschr. f. Chem.* v. 673).

The proportion of alkaloids in *Atropa Belladonna* and *Datura Stramonium* has been determined by N. Günthor (*Russ. Zeitschr. Pharm.* viii. 89; *Jahresb.* 1869, 781): for the method adopted, see *Zeitschr. anal. Chem.* viii. 476; *Jahresb.* 1869, 945.

100 parts of the different parts of the plants in the dried state yielded the following quantities of alkaloid:—

<i>Datura Stramonium.</i>					
Seed	Stalks	Leaves	Root		
0.318—0.365	0.063	0.169—0.307	0.065		
<i>Atropa Belladonna.</i>					
Leaves	Stalks	Fruit (ripe)	Fruit (unripe)	Seed	Root
0.833	0.146	0.813	0.955	0.407	0.810

The proportion of atropine in belladonna leaves is smaller in spring than in autumn after the floral organs have faded. 100 grams of dried May leaves yielded 0.392 to 0.421 gram of atropine; the same quantity of dried August leaves yielded from 0.443 to 0.482 gram. No difference is perceptible in the quantity of atropine obtained from wild and from cultivated plants. Roots two to three years old gave 0.472 and 0.489 p. c.; roots seven to eight years old gave only 0.254 to 0.313 p. c. of atropine. Though the root is occasionally richer in atropine than the leaf, it is much more variable in composition; hence the leaf is likely to be more uniform in its therapeutic properties (Lefort, *Pharm. J. Trans.* [3] ii. 1029).

AUGITE. Tchermak (*Zeitschr. f. Chem.* v. 634) regards the aluminous augite as isomorphous mixtures of the two silicates, $CaO.MgO.2SiO^2$, and $MgO.Al^2O^3.SiO^2$; the aluminous hornblondes as mixture of the three silicates, $CaO.3MgO.4SiO^2$, $CaO.MgO.2Al^2O^3.2SiO^2$, and $Na^2O.Al^2O^3.4SiO^2$.

AURIN, $C^{20}H^{14}O^3$.—A red colouring matter produced by heating phenol with oxalic acid and strong sulphuric acid. It was first obtained by Kolbe & Schmitt in 1861, since which time it has been manufactured, and is known in commerce as aurin or yellow corallin. It has been lately examined by Dale & Scherlemmer (*Proc. Lit. Phil. Soc. of Manchester*, vol. xi. No. 2; *Chem. Soc. J.* [2] ix. 468; x. 74), who find that the commercial product is a mixture, from which the pure colouring matter may be extracted by solution in alcohol and treatment with ammonia. A crystalline compound of aurin and ammonia then separates, whilst the other bodies present remain in solution. The ammonia-compound, after being washed with alcohol by means of a filter-pump, is decomposed by dilute acetic or hydrochloric acid, and further purified by repeated crystallisation from strong acetic acid. The specimens thus obtained obstinately retain varying quantities of water and acetic acid, a fact also observed by H. Fresenius (*J. pr. Chem.* [2] iii. 477).

From strong hydrochloric acid, aurin crystallises in fine hair-like red needles, which

when dried at 110° , contain a large quantity of hydrochloric acid. For further purification, a dilute alkaline solution was precipitated with dilute hydrochloric acid, and the precipitate washed by the filter-pump, but this product also contained hydrochloric acid, which was only given off above 110° . By the spontaneous evaporation of an alcoholic solution, aurin is obtained in dull red crystals with a green lustre, which when dried at 110° do not contain any alcohol, but several p. c. of water, which is given off only at a temperature above 140° .

From a mixture of alcohol and acetic acid it separates in dark red crystals, moderately thick in comparison with their length. These crystals are trimetric, having the axes $a : b : c = 0.5604 : 1 : 0.4719$, and exhibiting the combination 100, 010, 111, or $\infty P_{\infty} \cdot \infty P_{\infty} \cdot P$. The face ∞P_{∞} has a strong steel-blue reflection. The plane of the optic axes appears to be perpendicular to ∞P_{∞} and ∞P_{∞} , and therefore parallel to OP . The red crystals from acetic acid have the same form, but are not so thick in comparison with the length.

Aurin crystallised from acetic acid always retains a portion of that acid, and is therefore unfit for analysis, but by crystallisation from alcohol it is obtained pure and of constant composition. The numbers obtained by analysis agree best with the formula $C^{21}H^{14}O^3$, but the mode of formation, as will be explained further on, shows that the formula $C^{20}H^{14}O^3$, which also agrees nearly with the analytical results, is more probable.

	Calculated for		Mean of analyses
	$C^{21}H^{14}O^3$	$C^{20}H^{14}O^3$	
C . . .	70.75	70.47	70.73
H . . .	5.06	4.63	5.16
O . . . ,	16.19	15.00	15.11
	100.00	100.00	100.00

The compounds and derivatives of aurin hitherto obtained are not well suited for an exact determination of its molecular weight.

Aurin which has been repeatedly crystallised from acetic acid or alcohol does not melt at 220° ; at this temperature the crystals assume a darker shade, which disappears again on cooling, without any appearance of alteration in the substance. When more strongly heated, it melts, emitting at the same time the odour of phenol, and solidifies again on cooling to an amorphous, beetle-green mass. Aurin dissolves readily in alkalis with a magenta-red colour, and is precipitated from this solution by acids as a crystalline powder.

These properties, together with the crystalline form, are sufficient to distinguish aurin from Fresenius's corallin, which melts at 150° and crystallises in combinations of prisms and pinacoid planes, whilst aurin does not melt even at 220° , and contains only pinacoids and octohedra, which latter are not to be found in corallin; moreover, the axial ratios of the two kinds of crystals, which both belong to the trimetric system, are very different (see CORALLIN).

To compare these two products further, aurin was prepared by heating pure phenol with oxalic acid to 100° – 110° for five or six days, precipitating with water, boiling to remove free phenol and further purifying the resinous product by solution in dilute caustic soda, and reprecipitation with weak hydrochloric acid. A crystalline precipitate was thus obtained, which, when dissolved in alcohol, crystallised out in small but distinct needles, having the colour of chromic trioxide and a diamond lustre, and capable of bearing a heat of 220° without alteration. The crystals thus obtained were identical in form with those above described, but the face ∞P_{∞} did not exhibit any steel-blue reflection: Aurin prepared from phenol does not retain water like that obtained from the commercial product; but is anhydrous after drying over sulphuric acid, and does not lose weight when heated to 200° . The mean results of its analysis were 70.38 p.c. carbon and 5.05 hydrogen, agreeing most nearly with the formula $C^{20}H^{14}O^3$.

Aurin from pure phenol is therefore very nearly related to that contained in the commercial product, if not identical with it, and consequently different from Fresenius's corallin. The cause of this difference must be looked for in the different modes of preparation. Fresenius, as well as Kolbe and Schmitt, prepared their compound by heating the mixture to 140° – 150° , whilst the body above described was formed at a temperature not exceeding 110° .

The aurin from pure phenol being obtained without the formation of bye-products, the reaction by which it is formed may be expressed by the following equation:—

The phenol used for the preparation of the commercial product always contains a small quantity of cresol; and it appears probable that the latter takes part in the reaction, which might take place as follows:—

This supposition, however, is negatived by the fact that when aurin is carefully heated in a combustion-tube, a reddish, oily liquid distils over, which dissolves almost completely in potash, and when precipitated by hydrochloric acid, dried, and distilled, yields a distillate which boils at 184° , and solidifies on cooling to a mass of crystals consisting of pure phenol, without a trace of cresol, the formation of which might have been expected if it had originally taken part in the production of the aurin. From this, then, it may be inferred that the aurin contained in the commercial product is identical with that obtained from pure phenol, and therefore has the composition $\text{C}^{20}\text{H}^{14}\text{O}^3$.

Compound of Aurin and Sulphur Dioxide ($\text{C}^{20}\text{H}^{14}\text{O}^3$) SO_2 . When sulphur dioxide is passed into a hot concentrated alcoholic solution of aurin, the dark yellowish-red liquid assumes a lighter colour, and on cooling, a compound of aurin and sulphur dioxide separates out, forming other brick-red crystalline crusts or granular garnet-red crystals having a more or less beetle-green lustre. The compound dried over sulphuric acid does not retain any alcohol, but a considerable quantity of water, which is not expelled at 100° ; but above this temperature it is given off, together with sulphur dioxide. Whether this water is chemically combined or merely adheres to the compound mechanically is not yet decided; if it be in combination, the formula of the hydrated crystals is $(\text{C}^{20}\text{H}^{14}\text{O}^3)\text{SO}_2 + 5\frac{1}{2}\text{H}^2\text{O}$.

Aurin-potassium Bisulphite, $\text{C}^{20}\text{H}^{14}\text{O}^3.\text{KHSO}_3$, is produced by adding a solution of potassium bisulphite to a hot, concentrated, alcoholic solution of aurin, until the yellowish-red colour of the latter has disappeared. A soft, white chalky powder then separates, increasing in quantity when the solution is left at rest. Under the microscope it appears to consist of small rectangular plates. It is more soluble in water than in alcohol, and may be recrystallised from hot water; but, on boiling the aqueous solution, decomposition takes place and aurin is precipitated. Acids as well as alkalis decompose it readily, so that it soon acquires a yellow or reddish tint on exposure to the air.

Aurin-ammonium Bisulphite, $(\text{C}^{20}\text{H}^{14}\text{O}^3).(\text{NH}_4)\text{HSO}_3$, is obtained by a reaction similar to that which yields the potassium-compound, to which it has the greatest resemblance. The *sodium-compound* $\text{C}^{20}\text{H}^{14}\text{O}^3.\text{NaHSO}_3$ is also very much like the two preceding compounds, but appears to be more soluble in water.

Leucaurin, $\text{C}^{20}\text{H}^{14}\text{O}^3$ or $\text{C}^{21}\text{H}^{15}\text{O}^3$.—This body is produced by the action of hydrogenising agents on aurin. Kolbe and Schmitt found that their red compound yielded, on treatment with acetic acid and iron filings, a colourless body soluble in alkalis. On exposing this solution to the air, it gradually assumes a red colour, and on adding potassium ferrieyanide, an intensely red liquid is formed at once. The alkaline solution of the red body also becomes colourless in contact with sodium-amalgam, but turns red again on exposure to the air.

Dale and Schorlemmer prepared leucaurin, either by heating an alkaline solution of aurin with zinc-dust and precipitating the colourless liquid with hydrochloric acid, or by acting with zinc-dust on a solution of aurin in acetic acid, or on an acidulated alcoholic solution. On diluting the colourless liquid with water, leucaurin separates as a crystalline precipitate, and from the mother-liquor a further quantity crystallises out in needles on standing.

Pure leucaurin is perfectly colourless; but when recrystallised it readily assumes a yellowish tint. It is freely soluble in acetic acid, crystallising therefrom in thick and tolerably hard prisms, the faces of which are developed at one extremity only, whilst the other extremity is very irregular; it also shows a strong tendency to twin. From an alcoholic solution it was obtained in extremely friable prisms. It may be heated to 130° without melting, assuming, at the same time, a reddish colour; on heating it more strongly, it gradually softens and assumes a deep red colour. Its alkaline solution readily absorbs oxygen, and becomes of a dark red colour on the addition of potassium ferrieyanide. The red compound thus produced is, however, not aurin, but probably an oxidation-product of that body; on adding an acid to the solution, a brown precipitate is formed, which is almost insoluble in alcohol and acetic acid.

The analysis of leucaurin gave, as a mean, 78.84 p.c. C. and 5.93 H., the formula $\text{C}^{20}\text{H}^{14}\text{O}^3$ requiring 78.94 C. and 5.26 H., and the formula $\text{C}^{21}\text{H}^{15}\text{O}^3$ 79.25 C. and 5.66 H. Leucaurin prepared by heating aurin from pure phenol with acetic acid and zinc-dust gave by analysis (mean) 78.42 C. and 5.70 H., which agrees with the formula $\text{C}^{20}\text{H}^{14}\text{O}^3$ (78.48 C., 5.83 H.) better than with $\text{C}^{21}\text{H}^{15}\text{O}^3$ (78.94 C., 5.26 H.); but, as

most of these bodies retain water very obstinately, and to avoid oxidation, the compound was merely dried over sulphuric acid, the formula $C^{20}H^{18}O^2$ may be regarded as the more probable.

Leucaurin contains three hydroxyls, the hydrogen of which can be easily replaced by acid radicles.

Triacetyl-leucaurin, $C^{30}H^{18}(C^3H^3O)^3O^2$ or $C^{21}H^{18}(C^3H^3O)^3O^2$, is formed by heating leucaurin with excess of acetyl chloride, and purified by brisk agitation with cold water, and crystallisation from warm alcohol. It forms short silky needles readily soluble in alcohol and acetic acid, quickly decomposed by boiling water and by alkalis.

Tribenzoyl-leucaurin, $C^{30}H^{18}(C^7H^5O)^3O^2$ or $C^{21}H^{18}(C^7H^5O)^3O^2$, is readily formed when leucaurin is heated with benzoyl chloride. It is a very stable body, which is not acted upon by boiling it with weak caustic soda, and may be heated to 180° , and even higher, without decomposition. It is but sparingly soluble in alcohol and acetic acid, but freely in benzene, from which it separates in transparent crystals containing benzene, which they lose when exposed to the air or when heated, the crystals falling to powder.

Other derivatives of Aurin. 1. Red Corallin or Pæonin: a colouring matter, which dyes wool and silk with a redder shade than aurin, is prepared by heating aurin with aqueous ammonia to 140° – 150° . (See CORALLIN.)

2. Azurin or Azulin is produced by treating aurin with aniline. When aurin is gently boiled with aniline and a little acetic acid, the solution soon assumes a pure blue colour. On boiling the product with dilute hydrochloric acid, in order to remove an excess of aniline, a blue resinous substance is obtained, consisting of a mixture of different bodies, which are partly soluble in alcohol and acetic acid, and partly insoluble therein. By heating the above mixture on a water-bath, a blue solution is formed in 16–20 hours, which, however, also contains several bodies. A portion of the product is readily soluble in caustic soda with a purple colour, and precipitated by acids from this solution in blue flakes, which dissolve in alcohol and acetic acid. The portion which is insoluble in alkalis dissolves completely in acetic acid and alcohol, with a fine blue colour, but ether takes up only a part of it, forming a dark red solution, which on evaporation leaves a blue resinous body. The portion not dissolving in ether forms a dark blue powder with a golden reflection.

AZOBENZENE. See BENZENE DERIVATIVES

AZODIPHENYL BLUE, $C^{20}H^{18}N^2$ (Hofmann a. Geyger, *Deut. Chem. Ges. Ber.* v. 472). This blue colouring matter, first obtained by Martius a. Griess (*Ber. Monatsb.* 1865, 640), is produced by the action of azodiphenyldiamine on aniline salts:

its formation being analogous to that of the 'Magdala red' of commerce, $C^{20}H^{18}N^2$, by the action of azodinaphthylidiamine, $C^{20}H^{18}N^2$ on naphthylamine, $C^{10}H^7N$.

The blue is prepared by heating equal weights of the azo-base and aniline hydrochloride with twice the weight of alcohol to 160° for four or five hours. The product is treated with boiling water, and the residue is dissolved in alcohol with the aid of hydrochloric acid, and reprecipitated by soda. On dissolving the base in alcohol, adding hydrochloric acid, and concentrating the solution, a dark blue crystalline salt is obtained, insoluble in water and in ether, but readily soluble in alcohol, especially when warm. The solution, which is of a deep violet-blue colour, dyes wool and silk. It is decolorised by zinc and hydrochloric acid, but no corresponding leuco-base is thereby produced. Soda precipitates the base from the concentrated alcoholic solution of its salts, as a dark brown powder, which is insoluble in water, but soluble in alcohol or ether; the addition of hydrochloric acid to the latter solution precipitates the base as hydrochloride.

The *hydrochloride* has the composition, $C^{20}H^{18}N^2.HCl$, but loses part of its acid on being dried at a high temperature, or by recrystallisation from alcohol. The *hydride* $C^{20}H^{18}N^2.HI$ is very similar to the hydrochloride in its properties. The *picrate* $C^{20}H^{18}N^2.C^5H^4(NO^2)_3O$ forms a blue powder, quite insoluble either in water or in ether, and only very sparingly soluble in boiling alcohol. This azodiphenyl blue has the same composition as the *violantiline*, $C^{20}H^{18}N^2$, obtained by Girard, De Laire, and Chapoteaud (*1st Suppl.* 168), by the oxidation of pure aniline, $8C^6H^7N - 3H^2 = C^{20}H^{18}N^2$, but it has not as yet been ascertained whether the two are identical.

Blue colouring matters very similar to the azodiphenyl blue are produced by the action of toluidine or naphthylamine hydrochloride on azodiphenyldiamine. These most likely have the composition, $C^{20}H^{18}N^2$ and $C^{20}H^{18}N^2$, and it is probable that

ditolyldiamine would produce similar compounds. All attempts to prepare azo-ditolyldiamine, however, have as yet been unsuccessful. On passing a rapid stream of nitrous acid through fused toluidine floating on a hot saturated solution of common salt, the base gradually solidifies to a crystalline mass, which, when purified by re-crystallisation from alcohol, forms dark yellow needles of *diasoamido-toluene*, $C^{10}H^{10}N^2$, the isomeride of azoditolyldiamine; on boiling this with hydrochloric acid, it splits up into cresol and toluidine, with evolution of nitrogen:

The action of this compound on aniline, toluidine, and naphthylamine hydrochlorides produces colouring matters, but the byo-products formed at the same time show that the reaction is very complicated.

AZOPHENYLENE. $C^{12}H^{10}N^2$ (A. Claus, *Deut. Chem. Ges. Ber.* v. 367, 610; vi. 723; *Ann. Ch. Pharm.* clxviii. 1).—This compound is formed by distilling calcium azobenzoate or para-azobenzoate with lime. A red oil then passes over, which solidifies after a while to a crystalline mass consisting mainly of two substances, viz., azophenylene, which forms the principal portion, and a dark red body, the nature of which has not yet been ascertained. On slowly heating this mass in small quantities in a platinum crucible, the azophenylene sublimates in light yellow, glistening, slender needles, more than an inch long. It melts at 170° – 171° , and sublimates at a higher temperature. It is very slightly soluble in hot water, but may easily be volatilised with aqueous vapour, whereby it is obtained in small almost colourless needles. It dissolves in 50 parts of cold alcohol, easily in hot alcohol, and to some extent in ether and in benzene. With strong nitric acid, it appears to form a nitro-product.

Constitution of Azophenylene and of Azobenzoic Acid.—The reactions of azophenylene are best explained by the following structural formula:

In the formation of azophenylene bromide and hydrazophenylene, the bromine- or hydrogen-atoms probably attach themselves to the two nitrogen-atoms, the connection between which is thereby loosened.

But a question then arises as to how this body is derived from azobenzoic acid, $C^{10}H^{10}N^2O^4$, which, according to Ströcker, is related to azobenzene in the same manner as benzoic acid to benzene, and therefore ought to yield, by the dry-distillation of its calcium salt, not azophenylene, $C^{12}H^{10}N^2$, but azobenzene, $C^{14}H^{12}N^2$.

The most probable explanation of the apparent anomaly is, that azobenzoic acid contains 2 atoms of hydrogen less, its true formula being $C^{10}H^8N^2O^4$, and this view is supported by the following considerations. If this acid really corresponded with azobenzene, its formation from nitrobenzoic acid by the action of sodium-amalgam (*1st Suppl.* 320) would be represented by the following equation:

But experiment shows that as soon as three-fourths of the quantity of sodium indicated by this equation, that is to say, 6 atoms, have been added, a brisk evolution of hydrogen commences and the reaction is terminated. This shows that it really takes place according to the equation:

Azobenzoic acid is therefore azophenylene-dicarbonic acid, $C^{10}H^8N^2(COOH)^2$, or

The calcium salts of meta- and para-azobenzoic acid likewise yield by dry-distillation an azophenylene identical with that which is obtained from ortho-azobenzoic acid.

Azophenylene would probably be formed also by passing azobenzene through a red-hot tube: $C^{14}H^{12}N^2 - H^2 = C^{12}H^{10}N^2$.

Azophenylene Bromide, $C^{12}H^{10}N^2Br^2$ is formed when bromine is added to a concentrated alcoholic solution of azophenylene, or better when 1 part of azophenylene is

dissolved in 150 parts of benzene and bromine is added as long as yellow needle-shaped crystals continue to separate. These crystals being almost insoluble in benzene containing bromine, the quantity of the bromine-compound obtained by this latter process is very nearly that which is required by calculation.

Hydrazophenylene, $C^6H^4N^2$, is formed by the action of hydrogen sulphide on an ammoniacal solution of azophenylene in alcohol. Sometimes an intermediate compound, forming deep blue needles, is obtained at the same time.

Hydrazophenylene is almost insoluble in water and benzene, and is taken up by cold alcohol in small quantity only. At about 200° it gives off hydrogen, and is retransformed into azophenylene, the formation of the blue intermediate product being again observable. Boiled with dilute acids, it dissolves and forms salts of a green colour, but not of constant composition. In strong sulphuric acid, it dissolves with dark green colour, changing after a while to yellowish brown; but if the solution be left for some time in contact with moist air, the green colour reappears and masses of olive-green needles separate, which give up sulphuric acid when washed with water, the water at the same time acquiring a green colour. Hydrazophenylene treated with an alcoholic solution of platonic chloride containing free hydrochloric acid yields a platinochloride containing $2(C^6H^4N^2.HCl).PtCl^4$, or perhaps $C^6H^4N^2.2HCl.PtCl^4$.

On the whole it seems probable that hydrazophenylene does not itself possess the properties of a base, but that a base is formed from it by the action of acids, probably by union of two molecules, with loss of two atoms of hydrogen: thus—

AZORITE. On the crystalline form of this mineral, see Struvner (*Jahrbuch f. Mineralogie*, 1871, 751).

AZULIN or **AZURIN.** A blue dye, obtained by boiling aurin with aniline (p. 120).

AZOKULMOKIN. } See CYANOGEN, ACTION OF AMMONIA ON.
AZULMIC ACID. }

AZURITE, $Cu^2H^2C^2O^6$ or $3CuO.H^2O.2CO^2$. Webel a. Tüngel (*Deut. Chem. Ges. Ber.* iv. 188) have examined considerable quantities of the Siberian azurite for ammonia, but with negative results, thereby invalidating the supposition that its deep blue colour is due to a combination with ammonia, as is the case with some other salts of copper, and that it has been formed from malachite in presence of nitrogenous matter. They found, moreover, on heating fragments of marble to 200° in a sealed tube, with solution of cupric sulphate, that the marble became covered with a green carbonate, which, on standing for some months, was converted in many places into a deep blue carbonate, whilst at the same time the whole of the water in the tube disappeared, and numerous crystals of gypsum were deposited. The small quantities of the two carbonates formed, and the difficulty of separating them, have hitherto precluded the possibility of analysing the blue compound quantitatively; its external characters, however, agree so perfectly with those of the natural mineral, that it seems highly probable that azurite has been formed from malachite, $Cu^2CO^3 + aq.$, by absorption of carbon dioxide and elimination of water, as in the experiment above described.

B

BABINGTONITE. This mineral from Devonshire has been analysed by D. Forbes (*Phil. Mag.* [4] xxxvii. 328), and from Herbornseelbach in Nassau by John Pogg. (*Ann.* cxliv. 594). The results are given in the following table, together with those of the Arendal mineral, analysed by Rammelsberg (*Mineralchemie*, 477):—

	SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	CuO	MgO	Loss by ignition
Arendal	51.22	—	11.00	10.26	7.91	19.32	9.77	0.44 = 100.92
Devonshire . . .	49.12	1.60	9.78	12.87	1.25	20.87	8.97	0.73 = 99.38
Herbornseelbach .	50.44	—	17.01	7.49	3.22	19.90	1.45	0.43 = 99.44

The composition of the Arendal and Devonshire minerals agrees with Hammelsborg's formula, $9\text{MO} \cdot \text{SiO}_2 + \text{M}^2\text{O} \cdot 3\text{SiO}_2$, in which the oxygen of the monoxides is to that of the sesquioxides as 3 : 1; in the Nassau mineral this ratio is only 8 : 5; but, in both, the ratio of the oxygen of the silica is to that of all the bases together is 2 : 1.

Babingtonite from Devonshire forms black-green radio-fibrous groups having a sp. gr. of 3·431 to 3·436; hardness = 5·5. It is almost undecomposable by acids, gives off a little hygroscopic water when heated, and afterwards exhibits an alkaline reaction (Forbes). The crystalline form of the Nassau mineral is described by G. vom Rath (*Pogg. Ann. Ergänzungsband*, v. 420).

BACTERIA. See FERMENTATION.

BARIUM. On the occurrence of barium in silicates, see SILICATES.

Preparation of Baryta.—E. Nicklès prepares caustic baryta from heavy spar, by decomposing the mineral mixed with coal or charcoal and sawdust in a furnace of peculiar construction, extracting the resulting barium sulphide with boiling water out of contact with the air, and decomposing it with $1\frac{1}{2}$ equiv. of zinc oxide. The barium hydrate obtained by evaporating the solution may be converted into anhydrous baryta by heating it in cast-iron or earthen cylinders in the stream of carbonic oxide evolved by the reduction of the sulphate. The sulphide of zinc, when roasted, yields the quantity of oxide required for another operation (*Bull. Soc. Chim.* [2] xii. 494).

A similar process is described by Rosenstiehl (*Dingl. polyt. J.* cxviii. 64; *Jahresb. f. Chem.* 1870, 1122).

Barium Hydrate.—According to Rosenstiehl a. Rühlmann (*Chem. Centrbl.* 1870, 684), crystallised barium hydrate melts in its water of crystallisation at 75°, the crystals then contain 45·97 p. c. BaO.

The solubility of baryta in water at different temperatures is given in the following table:—

Temp.	Anhydrous BaO in 100 water	Temp.	Anhydrous BaO in 100 water	Temp.	Anhydrous BaO in 100 water
0°	1·5	22°	3·7	59°	17·5
6	1·8	30	5	64	23·8
6·5	1·9	36	6·4	68·5	27·7
12	2·4	41	7·6	69	31·6
12·5	2·9	46	9·5	70	31·9
16	3	54	14	73	44·9
21	3·6	58·5	17·2	77	70

BARLEY. The following observations relating to the life and growth of barley have been made by J. Fittbogen (*Landw. Versuchs-Stationen*, xiii. 81). The plants were reared in pots, and sand purified by ignition, digestion with sulphuric acid, and washing till every trace of acid was removed, was used as an indifferent soil-material. Into glass cylinders were put first a layer of quartz, then of unsized cotton, and lastly the purified sand. 18 barleycorns were sown in each pot, at a depth of 2·5 c.m., having been previously sprouted between two layers of damp filter-paper. The manure for each pot, expressed in milligram-equivalents was:

KH_2PO_4	KCl	MgSO_4	$\text{Ca}(\text{NO}_3)_2$	FeO	SiO_2
2·0	1·0	1·6	16·0	5·0	10·0

Thirty pots were so arranged. Plants were cut twice before the ear appeared, and three times afterwards. There were thus five periods. The plants were merely divided into two parts: that above the surface of the earth, and that beneath it, except in the last two periods, when a separation was made between the straw and the seed.

The aerial organs of 100 plants contained on an average:—

Grams	1st period	2nd period	3rd period	4th period		5th period	
				Grain	Straw and chaff	Grain	Straw and chaff
Organic matter	11.821	44.083	106.667	41.250	99.896	74.654	80.308
Ash	1.854	3.400	4.576	1.000	3.563	1.388	3.767
Dry substance	13.675	47.483	111.234	42.250	103.459	76.042	84.075

* No account is here taken of the ash-constituent in the seed sown.

Deducting 0.108 gram of nitrogen supplied in the seed from the above 0.385 gram, there remains 0.277 gram nitrogen derived from the nitrogenous compounds in the air.

The daily increase in the amount of ash was in the first period 0.386, in the second period 0.116, in the third period 0.078, in the fourth period 0.026, in the fifth period 0.012; whilst that of nitrogen was in the first period 0.113, in the second period 0.083, in the third period 0.011, in the fourth period 0.006, and in the fifth period 0. Consequently, the most active assimilation of mineral matters and of nitrogen occurred during the early stages of growth, comprehending, according to the experiments, the first third of the whole period of vegetation.

The relative proportions of phosphoric acid and nitrogen in the grain were also determined, and it was found that in the unripe state the proportions are 1 : 1.72, and in the ripe grain 1 : 1.66. As regards the migration of nutriment from the root upwards, and from the stalks and leaves into the seed, the following was established. A translation of potash from the root into the upper portion of the plant appears to occur during the third period, and of phosphoric acid and magnesia during the whole period of vegetation. In the fifth period the nitrogen decreased in the root and increased in the aerial portion of the plant. The absolute amount of nitrogen was markedly less in the aerial part of the plant during the period when the seed was forming (fourth period), and higher in the root, than during the preceding stage of development. A passage of potash from the upper part of the aerial portion of the plant into the grain was noted in the fourth period. When the grain ripened, magnesia, phosphoric acid and nitrogen were given up to the seed.

As regards the increase of mineral matters, it was established that this is greatest during the first period. Lime, phosphoric acid, and silica increased up to the time of maturity of the seed; magnesia and soda up to the time of formation of the grain. After the third period, the potash underwent a decrease, and the chlorine after the second period; and this, at the time of the ripening of the grain, had gone on to such a degree that of the former only 72 p. c., and of the latter only 48 p. c. of the maximum amount remained. The magnesia slightly decreased after the fourth period.

BASALT. F. Zirkel (*Jahrbuch f. Mineralogie*, 1870, 358; *Jahresh. f. Chem.* 1870, 1361), divides basalts, according to their microscopic constituents, into the following classes: (1) *Felspathic basalts*, which are the most frequent, and consist mainly of triclinc felspar and augite, always associated with magnetic and titaniferous iron, often with olivine and nepheline, never with leucite.—(2) *Leucitic basalts*, containing white leucite, augite, olivine, and magnetic iron ore, with nepheline always subordinate. (3) *Nepheline basalts*, composed of nepheline, augite, olivine and magnetic iron ore; frequently also with leucite, more rarely with felspar.

BAUXITE or BEAUXITE. The bauxite occurring in the neighbourhood of Béaux (Bouches du Rhône) is largely employed for the preparation of aluminium and alumina. There are two varieties of it, distinguished as ferruginous and aluminiferous; in the former the ferric oxide varies from 25 to 60 p. c. A ferruginous bauxite from the neighbourhood of Nas de Gilles yielded by smelting 42 p. c. iron, and was found by analysis to contain 4 p. c. silica, 18 alumina and titanio oxide, 60 ferric oxide, and 18 water with lime. The aluminiferous bauxite consists, according to five analyses by G. Sainte-Claire Deville, of—

	I.	II.	III.	IV.	V.
Silica	20.7	2.8	4.8	—	2.0
Titanium	3.2	3.1	3.2	—	1.6
Ferric oxide	3.8	25.3	24.8	34.9	48.8
Alumina	58.1	57.6	55.4	39.3	33.2
Calcium carbonate	trace	0.4	0.2	12.7	5.8
					(corandum)
Water	14.2	10.8	11.6	23.1	8.6
	100.0	100.0	100.0	100.0	100.0

I. and II. from Béaux; III. from Allach, near Marseilles; IV. from Béaux; V. from Calabria.

Both varieties of bauxite are compact, earthy, and pisolithic.

The bauxite in the neighbourhood of Béaux is situated between the lowest zone of the tertiary formation and the upper chalk; its origin in this new cretaceous zone is attributed to mineral springs (Coquand, *Bull. Soc. géol. de France*, xxviii. 98; *Jahresh. f. Mineralogie*, 1871, 940).

Nine French bauxites analysed by Siemens (*Chem. Soc. J.* [2] xi. 673) gave the following average result:—

	SiO ²	Al ² O ³	Fe ² O ³	H ² O
Raw	3.5	59.2	24.5	12.1 = 99.3
Calcined	4.01	67.89	28.09	— = 100.19

Eight other samples gave on the average:

	SiO ²	Al ² O ³	Fe ² O ³	H ² O
Raw	1.75	59.50	45.50	12.67 = 99.32
Calcined	2.02	45.53	52.45	— = 100.02.

Irish bauxite analysed by Siemens gave:

	SiO ²	Al ² O ³	Fe ² O ³	TiO ²	H ² O
Raw	3.5	35.0	38.0	2.0	21.5 = 99.0
Calcined	4.45	44.48	48.0	2.54	— = 99.87

Bauxite (or Wocheinite) containing a larger proportion of alumina is found on the Wochein in Carniola. The following are analyses of a dark red, and a light red variety by E. Drechsel (*Dingl. polyt. J.* cciii. 479).

	SiO ²	Al ² O ³	Fe ² O ³	H ² O	K ² O	Na ² O	Li ² O	TiO ²
Dark	4.15	63.16	23.55	8.34	0.79			trace = 99.99
Light	4.25	72.87	13.49	8.50	0.78			trace = 99.89

Bauxite from the same locality analysed by Siemens gave:

	SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	SO ²	P ² O ⁵	H ² O
Raw	6.29	64.24	2.40	0.85	0.38	0.20	0.46	25.74 = 100.52
Calcined	8.40	85.88	3.20	1.13	0.50	0.26	0.51	— = 99.88

Bauxite forms an excellent material for the lining of furnaces which have to bear an intense heat, as in Siemens' rotatory furnace. A series of experiments made by Siemens to form solid lumps by using different binding materials, have shown that 3 p. c. of argillaceous clay suffices to bind the bauxite powder previously calcined. To this mixture about 6 p. c. of plumbago powder is added, which renders the mass practically infusible, because it reduces the ferric oxide contained in the bauxite to the metallic state. Instead of plastic clay as the binding agent, water-glass or silicate of soda may be used, which has the advantage of setting into a hard mass, at such a comparatively low temperature as not to consume the plumbago in the act of burning the brick. When the lining is completed, the interior of the bricks is preserved against oxidation, by fluid cinder added to bind them together, which prevents contact with the flame. A bauxite lining of this description resists both the heat and fluid cinder in a very remarkable degree. A rotative furnace at Siemens' Sample Steel Works at Birmingham was lined partly with bauxite and partly with carefully-selected plumbago bricks. After a fortnight's working the brick lining was reduced from 6 inches to less than half an inch, whereas the bauxite lining was still 5 inches thick and perfectly compact. Moreover, the bauxite, when exposed to intense heat, is converted into a solid mass of emery of such extreme hardness that it can hardly be touched by steel tools, and is capable of resisting mechanical as well as the calorific and chemical actions to which it is exposed. The bauxite used for this lining contained 53.62 p. c. alumina, 42.26 ferric oxide, and 4.12 silica.

BEANS. The following observations on the influence of light on the germination of the kidney-bean (*Phaseolus vulgaris*) have been made by H. Karsten (*Landw. Versuchs-Stationen*, xiii. 176).

The beans selected were as uniform as possible. After weighing, they were allowed to germinate between wet blotting-paper, and the shells removed. When the roots were sufficiently developed, the beans were supported on gauze, with their roots in distilled water. One series was then exposed to direct sunlight, the roots only being shaded; the other series was kept wholly in the dark. Each bean was harvested as soon as the second leaf began to make its appearance; this occurred in 15-20 days in sunlight, and in 25-30 days in darkness. The number of beans germinated in this manner was 564.

The plants grown in the dark were of far greater length than those exposed to sunlight. The proportion of the various parts is shown in the following table; the figures represent the yield of 1,000 grams of air-dried beans, containing 745 grams of dry matter free from husks:—

	Leaves	Stalks of first leaves	Internodes	Roots	Cotyledons	Total plants	Original beans
Light {fresh weight . .	722.0	115.0	615.0	1038.0	1551.0	4041.0	1000
{dry weight . .	114.6	12.3	78.3	87.0	334.3	626.5	745
Darkness {fresh weight	134.0	293.0	2027.0	832.0	1582.0	4886.0	1000
{dry weight .	22.6	19.6	174.0	62.4	277.7	556.2	745

The loss of weight in germination is seen to be greatest in the dark; the leaves had not in this case the nutritive action which they probably exercised in sunlight.

A separate chemical analysis was made of each part of the young plants. The composition of the dried, entire plants is compared below with that of the original beans, 1,000 grams of air-dried beans serving as before for comparison:—

	Composition of original beans	Grown in light		Grown in darkness	
		Composition	Gain or loss per cent.	Composition	Gain or loss per cent.
Crude fat	19.08	19.82	+ 3.92	16.00	— 16.09
Sugar	8.75	13.93	+ 59.16	8.42	— 3.82
Gummy matter . . .	84.92	105.89	+ 24.69	78.60	— 7.45
Starch	146.01	74.40	— 49.04	62.21	— 57.41
Cellulose	17.47	57.97	+ 231.84	65.57	+ 275.84

The water in which the young plants grew was found to contain but a trace of solid matter.

BEET. Numerous analyses of sugar-beets grown in England and Ireland in 1869 and 1870, have been made by Dr. Voelcker, and published in the *Journal of the Royal Agricultural Society*, [2] vii. 60. The season of 1870 proved more favourable to the formation of sugar than 1869. Samples grown in 1869 gave—English roots, 8–12 p. c. sugar; Irish roots, 6–11 p. c. sugar. Samples of the crop of 1870 gave—English roots, 9–13.3 p. c. sugar; Irish roots, 10–14.8 p. c. sugar. Large roots are shown to be more watery, and contain less sugar than smaller roots. Liberal manuring increases the bulk of the crop, but injures its quality; one effect being the increase of albuminous and saline matters, the presence of which prevents the crystallisation of a certain percentage of the sugar. The part of the root grown above the ground contains less sugar and more nitrogen than the buried portion: hence the advisability of deep culture of the soil. The following are characteristic analyses:—

	Lavenham, 1869. Average of fifteen lots	Large root from Buscot, 1869	Single root, Berkshire, 1869		Viewmont, Kilkenny, 1870. Average of ten roots

The distillation of spirit from beetroot is largely practised on the Continent; it has been recently commenced in England on a great scale by Mr. Campbell, of Buscot. This manufacture turns to profit the molasses of the sugar-factories, and utilizes the crops of bad seasons, when the percentage of sugar is below that (about 8 p. c.) required for profitable extraction. It is considered by many more remunerative than the manufacture of sugar, and is certainly more consistent with high farming, the albuminous and saline matters favoured by liberal manuring being no obstacle to the production of spirit.

Beetroot is prepared for fermentation by one of three processes:—I. The roots are pulped or sliced, mixed with a small quantity of sulphuric acid, then pressed, and the juice is fermented. II. (Champonoi's method.) The roots are sliced, and treated with hot wash acidulated with sulphuric acid; no press is used, the sugar being extracted by displacement. III. (Löplay's method.) The slices of beetroot are placed in vats, and fermented without previous treatment. The residual pulp from each of these methods is used as cattle food.

Beetroot spirit is very apt to be contaminated with fusel oil, but the use of good distilling apparatus (as that of the Messrs. Saralle) effectually removes this impurity.

Since sugar-beet contains far more nutritive matter than the best mangolds, it may frequently be of more value for feeding purposes than for the sugar or spirit manufacture.

The distribution of mineral substances by the root of beet has been studied by Corenwinder (*Compt. rend.* lxxiii. 95). Samples of Italian beetroot from Modena, Milan, Bologna, and Vicenza were examined, and their composition compared with that of French beetroot from the departments of Nord and Pas-de-Calais. The Italian beets were poor in sugar and contained much saline matter. 1 litre of juice yielded 52.5 to 85 grams of sugar and 10.2 to 16.2 grams of mineral salts. The juice of the French beets gave 90.7 to 132.4 grams of sugar, and 7.3 to 8.7 grams of salts per litre. The density of the juice from the Italian beets was comparatively high. Density is not a safe indication of saccharine value, owing to the disturbing influence of the saline ingredients. The amount of potash in the Italian beets was very considerable. Taking all the samples into account, it appears that the proportion of potash bore an inverse relation to the amount of sugar. Some of the samples of Italian beet contained a large proportion of chlorides; in these cases the proportion of soda was also excessive. The following analyses show, however, that sodium is taken up by the plant in other forms besides that of chloride. The analyses were made on three samples of French beet grown in the same field with different manures; the quantities refer to 1 litre of juice. (See Table on opposite page.)

	No manure	Chemical manure	Earth-nut cake
	gram	gram	gram
Chloride of sodium	1.238	.798	1.611

On the results of manures applied to beetroots, see also Czech (*Dingl. polyt. J.* cc. 490), and Sestini a. Del Torre (*Gazzetta chimica italiana*, iii. 190; *Chem. Soc. J.*, xxvi. 1254).

BELLIS. The flower-heads of the common daisy (*Bellis perennis*) contain an iron-greening tannin, malic, tartaric, oxalic, and acetic acid, a soft resin (antholeucin), a yellow colouring matter (anthoxanthin), together with chlorophyll, albumin, &c. (J. B. Enz, *Viertelj. f. Pharm.* xix. 1).

BENZAMARONE. $C^9H^{10}O^4$.—A body formed by the prolonged action of alcoholic potash at ordinary temperatures or deoxybenzoïn; 100 grams of deoxybenzoïn digested with a solution of 104 grams potassium hydrate in a litre of 90 p. c. alcohol, yielded about 20 grams of crystallised benzamarone in a fortnight. Benzamarone crystallises in needles, melts at 225° , dissolves in 157 parts of boiling, and 1130 parts of cold alcohol of 77 p. c. in 10 pints of boiling benzene and 35 pints of boiling acetic acid. When heated for some time with alcoholic potash, it is resolved into about equal parts of deoxybenzoïn and amaric acid (p. 55), also benzoic acid and a small quantity of resinous matter (Zinin, *Zeitschr. f. Chem.* vii. 127).

BENZAMIDE. C^7H^7NO .—This compound forms monoclinic crystals, in which the axes $a : b : c = 0.228404 : 1 : 1.06827$, and the angle of the inclined axes $b c = 89^\circ 22'$.—Principal angles $OP : \infty P\infty = 90^\circ 38'$; $+P\infty : \infty P\infty = 135^\circ 10'$; $\infty P : \infty P = 154^\circ 16'$ in the orthodiagonal principal section. Observed forms (Fig. 4):

$$\begin{array}{ccccc} \infty P & \infty P\infty & OP & +P\infty & +\frac{1}{2}P\infty. \\ i & a & b & m & l \end{array}$$

The crystals obtained by fusion are almost always twins, whose twin-axis is the principal axis, and face of combination $\infty P\infty$. A solution of benzamide in ether often yields simple crystals together with twins: an alcoholic solution for the most part, only simple crystals. The crystals are sometimes prismatic, elongated in the direction of ∞P ; sometimes they have also short prismatic forms. Occasionally they are tabular parallel to $\infty P\infty$, and lengthened in the direction of the orthodiagonal. They cleave perfectly parallel to $\infty P\infty$, less easily parallel to $+P\infty$. The faces ∞P and $\infty P\infty$ have a strong lustre; OP , $P\infty$, and $+\frac{1}{2}P\infty$ are more or less striated. The crystals are colourless, seldom quite transparent.

The plane of the optic axes coincides with the clinodiagonal principal section. The two principal directions of vibration are so situated in this plane that one runs nearly parallel to $+P\infty$, the other nearly at right angles to it. The first of these directions is inclined to $\infty P\infty$ at the angles $49^\circ 53'$ and $130^\circ 7'$, the obtuse angle being turned towards OP . Dispersion $\rho < v$. L. Klein, *Ann. Ch. Pharm.* clxvi. 184).

Benzamide heated for several hours with bitter almond oil forms benzylbenzamide, $C^{11}H^{11}N^2O^2$.

2nd Sup.

K

Fig. 4.

$2H = 100^\circ 15'$ red; $102^\circ 10'$ blue

Benzamide heated in sealed tubes to about 120° with ethyl nitrite, yields nitrogen, water, and ethyl benzoate (Meyer a. Stüber, *Deut. Chem. Ges. Ber.* iv. 962).

Benzamide unites with *chloral*, forming the compound $\text{C}^6\text{H}^5\text{Cl}^3\text{NO} = (\text{CCl}^3.\text{CHO}).\text{C}^6\text{H}^5\text{CONH}^2$, which melts at 150°–151° (Wallach, *ibid.* v. 251).

Trichlorobenzamide, $\text{C}^6\text{H}^3\text{Cl}^3\text{CO.NH}^2$, produced by heating trichlorobenzoyl chlorido with ammonia, crystallises in small needles, melting at 176°, easily soluble in alcohol and in ether (Salkowski, *Ann. Ch. Pharm.* clxiii. 1).

Diamidobenzamide, $\text{N}^{\text{H}^2}\{\text{C}^6\text{H}^4(\text{NH}^2)^2\text{O} \text{ or } \text{C}^6\text{H}^3(\text{NH}^2)^2\text{CONH}^2$ (Muretow, *Zeitschr. f. Chem.* [2] vi. 642). Obtained by reduction of dinitrobenzamide. For this purpose dinitrobenzoic acid is gently heated with excess of phosphorus pentachloride till reaction begins, and when it is over the cooled liquid is poured into strong ammonia. The dinitrobenzamide thus formed crystallises in pale yellow laminae, exhibiting the properties described by Voit (i. 541). Melting point 177° (183° according to Voit). A boiling aqueous solution of this nitro-amide, mixed with ammonium sulphide, left to itself for 24 hours, then boiled up, filtered from sulphur and evaporated over the water-bath, yields the diamido-amide in the form of a brown-black syrup, the crystallisation of which is greatly facilitated by the introduction of a crystal of the compound previously prepared. The crystals thus obtained are black, and cannot be decolorised by animal charcoal. The solution of the amide, which is nearly colourless at first, turns yellow after a while, and deposits yellow crystals.

Diamidobenzamide forms large, four-sided, brownish-yellow, needle-shaped crystals, slightly soluble in cold, very easily in hot water. The aqueous solution turns brown in contact with the air, probably from oxidation. Its *hydrochloride*, $\text{C}^6\text{H}^3(\text{NH}^2)^2\text{NO} \cdot 2\text{HCl}$, is precipitated from the aqueous solution by hydrochloric acid in white needles having a silky lustre. The *picrate* is a yellow crystalline precipitate, very slightly soluble in water (1 part in 735), and crystallising from the solution in small yellow needles.

Diacetyl-diamidobenzamide, $\text{C}^6\text{H}^3(\text{NH}^2.\text{C}^2\text{H}^3\text{O})^2\text{CONH}^2 + 2\text{H}^2\text{O}$, is obtained by treating the amide with acetic anhydride, and recrystallising the product from water. It forms long, thin, colourless needles, slightly soluble in cold, freely in hot water. From alcohol, in which it is still more soluble, it separates in tufts of needles. Melts above 265°, and then solidifies in the vitreous form. Gives off its water of crystallisation at 100° (Muretow).

BENZOREATINE. $\text{C}^6\text{H}^5\text{N}^2\text{O}^2$ (Griess, *Deut. Chem. Ges. Ber.* i. 191; iii. 703; *Zeitschr. f. Chem.* iv. 725; vi. 728). A base produced by boiling cyanide of amidobenzoic acid (1st Suppl. 317) with moderately strong caustic potash:—

The solution, when it has become colourless, is left to cool and then mixed with a large excess of acetic acid; the base is thereby precipitated almost completely, and may be purified by repeated crystallisation from hot water, with addition of animal charcoal.

Benzcreatine crystallises in thin, white, shining, right-angled, four-sided plates containing 1 mol. water: it gives off its water of crystallisation at 120°, melts at a higher temperature, and volatilises gradually without decomposition. It is moderately soluble in hot water, but crystallises out almost completely on cooling; in boiling alcohol it dissolves very slowly, and crystallises therefrom in short thick needles; it is almost insoluble in ether, quite insoluble in ammonia. When boiled for a long time with baryta-water, it is resolved into amidobenzoic acid, urea, ammonia, and uramido-benzoic acid, according to the following equations:—

and

Benzcreatine forms salts with mineral acids, but does not unite with acetic acid. The *hydrochloride*, $\text{C}^6\text{H}^5\text{N}^2\text{O}^2.\text{HCl}$, crystallises in somewhat elongated, rectangular four-sided plates, very soluble in hot, sparingly soluble in cold water; it is precipitated from its concentrated aqueous solution by hydrochloric acid. The *platinohydrochloride*

$2(C^6H^5N^3O^4.HCl).PtCl^4$, crystallises in yellow spiculae, moderately soluble in hot, sparingly in cold water.

Benzereatine was at first regarded by Griess as a compound of 2 mol. amidobenzoic and 1 mol. oxamide: $2C^6H^5(NH^2)O^2 + C^2H^2N^2O^2 = C^8H^{10}N^4O^4$; but later experiments have established the formula $C^8H^8N^4O^4$, which gives very nearly the same percentage of carbon and hydrogen as $C^8H^{10}N^4O^4$, or $C^8H^8N^4O^4$.

BENZEREATINE. $C^8H^8N^4O^4$ (Griess, *Proc. Roy. Soc.* xviii. 89; *Deut. Chem. Ges. Ber.* ii. 415; *Zeitschr. f. Chem.* [2] v. 574).—A base produced by heating the compound $C^8H^8N^4O^4$ —resulting from the action of cyanogen on anthranilic (meta-amidobenzoic) acid—with alcoholic ammonia for some days in a sealed tube placed in the water-bath:

It crystallises in nacrous laminae, nearly insoluble in water, slightly soluble in boiling alcohol. Its *nitrate* forms white narrow laminae, nearly insoluble in alcohol; the *platinochloride*, $2(C^8H^8N^4O^4.HCl).PtCl^4$, crystallises in thick yellow needles.

BENZENE. C^6H^6 . *Physical Properties.*—Benzene crystallises in trimetric pyramids, having their axes in the proportion:—

$$a : b : c = 0.801 : 1 : 0.770$$

(Groth, *Zeitschr. f. Chem.* [2] vi. 553). Its index of refraction (in the liquid state) at 9° is 1.4593 for the line A, 1.5050 for D, 1.5307 for H (Gladstone, *Chem. Soc. J.* [2] vii. 101).

Reactions. Benzene, heated with sulphur in sealed tubes to 400° – 500° , forms a product which dissolves for the most part in alcohol, and separates therefrom in long needles and crystalline crusts, smelling like diphenyl, and having also the disagreeable odour of volatile sulphur-compounds. Much hydrogen sulphide escapes on opening the tubes (F. Schulze, *Deut. Chem. Ges. Ber.* iv. 33).

Benzene and potassium heated together in a sealed tube to 240° – 250° , combine into a black mass, which appears blue in thin layers, explodes very easily when dry, and is violently decomposed by water. The gradual action of water on it gives rise to diphenyl (Abeluz, *Deut. Chem. Ges. Ber.* v. 1027).

Berthelot found, in opposition to Harnitzky, that carbonyl chloride does not act on benzene either at ordinary or at higher temperatures (1st *Suppl.* 262). On repeating his experiments he finds that no action takes place at 280° ; but that when liquid carbonyl chloride is heated with 5 or 6 vol. benzene to 320° for 36 hours, the carbonyl chloride disappears almost entirely, being replaced by a mixture of hydrogen chloride and carbon monoxide. Part of the benzene is at the same time charred, but no chrysene is formed; only traces of a volatile, strong-smelling hydrocarbon (? phenylene), and not a trace of benzoyl chloride. Neither is this last compound formed when benzene and carbonyl chloride are heated together for 20 hours to 280° . That this negative result is not due to decomposition of the benzoyl chloride by heat, is shown by the fact that this compound may be heated to 290° for 120 hours without perceptible decomposition. Berthelot concludes, therefore, that benzoyl chloride is not formed by the action of carbonyl chloride on benzene at any temperature (*Bull. Soc. Chim.* [2] xiii. 391).

Chromic oxychloride acts with great violence on benzene, and if the two bodies are brought directly in contact, nothing is formed but resinous products; but if the benzene be diluted with an equal volume of glacial acetic acid (which is not acted upon by chromic oxychloride), a solution of chromic oxide diluted with 2 vol. glacial acetic acid carefully dropped into it as long as any action takes place, and the liquid mixed with a large quantity of water, the benzene rises to the surface in the form of a golden-yellow liquid. On removing this layer, repeatedly agitating the green solution with fresh portions of benzene as long as they acquire a yellow colour, and distilling the united portions of benzene till crystals begin to separate in the retort, the remaining liquid solidifies on cooling to a laminar crystalline mass of trichloro-quinone, which may be purified by recrystallisation from hot alcohol. The reaction is:

If the chromic oxychloride contains free chlorine, tetrachloro-quinone is likewise formed, together with an oil not yet examined (Carstanjen, *J. pr. Chem.* cvii. 31).

Benzene Hexchloride, $C^6H^6Cl^6$.—According to Zachar Heyn (*Zeitschr. f. Chem.* [2] vii. 293), this compound is most readily obtained by acting on boiling benzene with

excess of chlorine, evaporating off the unaltered benzene, pressing the crystals which separate on cooling to free them from mother-liquor, and recrystallising from alcohol or benzene. It melts at 157° (according to Mitscherlich, at 132° ; according to Laurent, at 135° - 140°). According to Vohl (*Zeitschr.* [2] iii. 122), it forms a crystalline compound with fuming nitric acid. Heys, however, finds that it is not in the least altered either by boiling with fuming nitric acid for many hours, or by treating it with a hot mixture of nitric and sulphuric acid. Hence it would appear that the formation of nitro-compounds in the aromatic group depends upon the double linking of the carbon-atoms; it is possible also that the chlorine-atoms may influence the adjacent hydrogen and prevent their replacement by NO^2 .

When the hexachloride is heated to 150° with alcoholic potassium acetate, much potassium chloride is formed; on cooling, the filtrate deposits colourless crystals, insoluble in water, sparingly soluble in cold alcohol, but readily dissolved by boiling alcohol; these crystals melt at 250° . At the same time a fluid compound is produced, probably trichlorobenzene.

Constitution of Benzene.

Kekulé's theory of the constitution of benzene and its compounds and derivatives has been explained in the *First Supplement* to this Dictionary (pp. 193-215). It is there shown that the ring-formula of benzene, in which the carbon-atoms are supposed to be linked together by one and two combining units alternately, affords a satisfactory explanation of all the best established facts relating to the compounds of the aromatic group, and in particular, that it explains, more clearly than any other yet proposed as a substitute for it, the remarkable fact, that benzene, which for the most part exhibits the characters of a saturated molecule, is capable, under certain circumstances, of taking up, without substitution, 2, 4, or 6 atoms of a univalent radicle, and forming such compounds as hexachlorobenzene, $\text{C}_6\text{H}_2\text{Cl}_6$, just as ethylene C_2H_4 , which in the free state is also a saturated molecule, can take up 2 atoms of chlorine to form the compound $\text{C}_2\text{H}_4\text{Cl}_2$.

The chief objections which have been raised against Kekulé's benzene formula are the two following:—1. That, since according to this formula, the six atoms of hydrogen in benzene are of equal value, only one pentachlorobenzene is possible, whereas two are said to exist. This objection cannot, however, be regarded as of much weight, inasmuch as the experimental demonstration of the existence of two such compounds is still incomplete (see p. 14).

The second objection, which at first sight appears of more importance, is the following:—It is argued that those di-derivatives, in which the substituting radicles occupy contiguous positions, should differ according as the replacement has taken place on adjacent carbon-atoms united by one affinity ($\text{C}-\text{C}$), or by two affinities ($\text{C}=\text{C}$); the so-called 1 : 2 derivatives should therefore be isomeric, not identical, with the 1 : 6 derivatives, so that four di-derivatives of benzene are possible, whereas hitherto at most three have been obtained. Such a difference, if it existed, would perhaps be too slight to be recognisable; and Kekulé is of opinion that the assumption of its existence arises rather from the kind of diagram employed to represent the benzene molecule, than from the ideas of which this diagram affords but an imperfect representation. To show that no such difference need be supposed to exist, he brings forward the following hypothesis as to the mode of motion of the atoms in the benzene molecule:—

The atoms in the systems which we term molecules must be considered as in continuous movement; no explanation, however, has hitherto been given as to the nature of the intramolecular motion. A planetary motion appears inadmissible in face of the law of the linking of atoms (*Verkettung*) now recognised in chemistry. The motion must indeed be of such a nature that all the atoms of the system retain the same relative arrangement, or in other words, that all the atoms return to a mean position of equilibrium. The most probable assumption then appears to be that the separate atoms of the system, possessing an essentially rectilinear motion, strike one against the other and, being elastic bodies, then recoil. On this supposition the term *quantivalence* (atomicity) acquires a mechanical signification; denoting, in fact, the relative number of contacts which occur in the unit of time between the atoms. In the same time that the univalent atoms of a monatomic molecule strike against each other once, the bivalent atoms of a diatomic molecule come twice in contact at the same temperature. In a molecule consisting of one bivalent and two univalent atoms the number of contacts in the unit of time is equal to two in the case of the bivalent atom, and to one in the case of each univalent atom. When two atoms of carbon are united by one affinity of each, they strike against each other once in the unit of time, that is to say, in the time during which the univalent hydrogen makes one complete vibration; during the same unit of time they also each encounter three other (univa-

lent) atoms. Carbon atoms united by two affinities of each, strike against each other twice, and during the same time come only twice in contact with other atoms.

Applying this view to benzene, Kekulé's formula is an expression of the following conception:—Each carbon-atom strikes against two other carbon-atoms during the unit of time, once against the one and twice against the other. In the same unit of time it also comes once in contact with the hydrogen-atom, which during the same period makes one complete vibration. Representing benzene by the hexagon formula, and having regard to any one of the six atoms of carbon, that denoted by 1 for example:—

the contacts of this atom during the first unit of time may be thus represented:—

1. 2, 6, h, 2,

in which h denotes hydrogen. The vibrations of the same atom during the second unit of time are then as follows:—

2. 6, 2, h, 6.

The contacts during the first period being represented by the above formula, those occurring during the second unit of time are represented by the following:—

The same carbon-atom is therefore, during the first unit of time, united by two affinities to one of the contiguous carbon-atoms; during the second, by two affinities to the other contiguous atom.

The number of contacts made by the carbon-atom during the first two units of time—the vibrations completed during these intervals being periodically repeated—are then as follows:—

2, 6, h, 2, 6, 2, h, 6,

from which it is evident that each carbon-atom strikes against each of the two carbon-atoms upon which it impinges, an equal number of times, or, in other words, that it bears the same relation to both contiguous atoms. The ordinary benzene formula only represents the contacts made during the first unit of time, and thus it is that the false view has sprung up that di-derivatives in which the radicles occupy the positions 1 : 2 and 1 : 6 respectively must be different. If the above, or some similar conception be correct, it follows that no real difference exists (Kekulé, *Ann. Ch. Pharm.* elxii, 77).

Criticisms of these views have been published by Ladenburg (*Deut. Chem. Ges. Ber.* v. 322) and Michaelis (*ibid.* 463).

Orientation of the Substituted Radicles or Lateral Chains in the Di-derivatives of Benzene.

In the article AROMATIC SERIES in the *First Supplement* it has been explained that the di-derivatives of benzene may be arranged in three isomeric series: the individual members of each of which may be formed one from the other by a series of simple substitutions not involving a complete change in the structure of the molecules, and are therefore supposed to have their lateral chains in similar positions. These series are distinguished by the prefixes *ortho*, *meta*, and *para*: the first including those compounds which may be derived from, or converted into phthalic acid; the second related in like manner to isophthalic acid; and the third to terephthalic acid. It was further explained in the same article that, although the relative positions of the substituted radicles or lateral chains in the three series could not be fixed with certainty, still the facts then ascertained rendered it most probable that the arrangement in the *ortho*-series was

represented by the formula, 1 : 2, in the meta-series, by 1 : 3, and in the para-series by 1 : 4; these three being the only possible arrangements.

Subsequent researches have, in the main, confirmed these views, but at the same time have somewhat modified them so far as regards the individual compounds belonging to each series.

The derivatives in which the position of the lateral chains is most easily determinable, are the dicarbon-acids, phthalic, isophthalic, and terephthalic, represented by the formula $C^2H^4 \begin{Bmatrix} CO^2H \\ CO^2H \end{Bmatrix}$. Of these, phthalic acid is inferred to belong to the 1 : 2 series: first, on account of its formation from naphthalene; secondly, from

the readiness with which it is converted into an anhydride $C^2H^4 \begin{Bmatrix} CO \\ CO \end{Bmatrix} O : a$

property which indicates the contiguity of the two carboxyl groups in phthalic acid, and is not exhibited by isophthalic or terephthalic acid. Isophthalic acid is formed by oxidation of isoxylene, $C^6H^4 \begin{Bmatrix} CH^3 \\ CH^3 \end{Bmatrix}$, which is a derivative of mesitylene. Now, mesitylene has been shown to be a symmetrically constituted trimethyl-benzene, $C^6H^3(CH^3)^3$, having its three methyl-groups in the positions 1 : 3 : 5; consequently, the two methyls in isoxylene, and therefore the two carboxyls in isophthalic acid, must be in the positions 1 : 3. For terephthalic acid, therefore, there remains only the arrangement 1 : 4 (*1st Suppl.* 198).

Another compound in which the relative position of the lateral chains may be determined with comparative facility is hydroquinone, $C^6H^4 \begin{Bmatrix} OH \\ OH \end{Bmatrix}$, the conversion of

which, by oxidation into quinone, $C^6H^4 \begin{Bmatrix} O \\ O \end{Bmatrix}$, indicates that the two hydroxyls

contained in it occupy contiguous positions (1 : 2). Of the two other dioxybenzenes or oxyphenols, viz. pyrocatechin and resorcin, the last is derived from compounds which are convertible more or less directly into terephthalic acid, and is therefore a 1 : 4 compound, while the second is similarly related to compounds of the isophthalic series, and is therefore a 1 : 3 compound.

The constitution of other di-derivatives of benzene is best determined by their convertibility into one of the three dicarbon-acids, or one of the three oxyphenols.

Oxybenzoic acid and the chloro-, bromo-, amido-benzoic acids, &c., related to it have hitherto been generally regarded as 1 : 2 compounds; while salicylic acid and its congeners, chlorosalicylic, bromosalicylic, anthranilic acid, &c., have been referred to the 1 : 3 series. This view, however, is somewhat at variance with the fact that the formation of anhydrides, or similarly constituted bodies, takes place, not in the first or oxybenzoic acid group, but in the second or salicylic acid group (e.g. salicylide, coumarin). It therefore seems more probable that the 1 : 2 arrangement belongs to this latter group. To decide this question, V. Meyer (*Ann. Ch. Pharm.* clvi. 265) has examined the action of sodium formate on sulphobenzoic acid, $C^6H^4 \begin{Bmatrix} SO^2H \\ CO^2H \end{Bmatrix}$, which, according to Barth (*ibid.* cxlviii. 34), yields, by fusion with potash, nothing but oxybenzoic acid, and is therefore a strict analogue of the latter. When equal weights of sodium formate and potassium sulphobenzoate are fused together, the fused mass digested in water, and the aqueous solution, after acidulation, shaken up with ether, an acid is obtained which, when purified by conversion into a barium salt, separation therefrom by hydrochloric acid, and recrystallisation from hot water, melts above 300° , and exhibits the composition and properties of isophthalic acid:—

Since then, isophthalic acid has the two groups, CO^2H , in the position 1 : 3, it follows that the same relative position of the radicles must exist in sulphobenzoic acid, and therefore also in oxybenzoic acid; and that the other derivatives of benzoic acid (chloro-, bromo-, nitro-, amido-) which are convertible into oxybenzoic acid, must also have their lateral chains in the position 1 : 3, not as hitherto supposed, in the position 1 : 2. This conclusion has been experimentally verified in the case of bromobenzoic acid (produced by heating benzoic acid with bromine and water, or by the action of hydrobromic acid on diazobenzo-amidobenzoic acid: *1st Suppl.* 300): the potassium salt of which, when heated with sodium formate, also yields an isophthalate.

Further, since the para-derivatives of benzoic acid, as shown by Graebe (*Ann. Ch. Pharm.* cxlix. 27), have their lateral chains in the position 1 : 4—inasmuch as para-

bromotoluene, which yields parabromo-benzoic acid by oxidation, is further convertible into terephthalic acid—there remains, for salicylic acid and its congeners, only the position 1 : 2. This view, as already observed, is in accordance with the existence of anhydrides in the salicylic series; and salicylic acid likewise resembles acknowledged 1 : 2 compounds, phthalic acid, for example, in volatilising with vapour of water, whereas oxy-benzoic and paraoxy-benzoic acids do not.

These, however, are but indirect proofs of the existence of salicylic acid as a member of the 1 : 2 series; the following direct proof has lately been given by Fittig u. Ramsay (*Ann. Ch. Pharm.* clxix. 242). Toluene treated with sulphuric acid yields two toluene-sulphonic acids, $C^6H^4 \begin{Bmatrix} CH^3 \\ SO^2H \end{Bmatrix}$, the more abundant of which, distinguished

by the sparing solubility of its potassium salt, is known to be the para-compound (1 : 4). The other belongs to the same series as salicylic acid, since by fusion with potash it yields a cresol, which, by the further action of the alkali, is converted into salicylic acid. Now, when this second toluene-sulphonic acid (hitherto regarded as a meta-compound) is distilled with potassium cyanide, the group SO^2H is replaced by CN , and tolyl cyanide, $C^6H^4 \begin{Bmatrix} CH^3 \\ CN \end{Bmatrix}$, is obtained, which, by treatment with alcoholic potash, is converted into toluic acid, $C^6H^4 \begin{Bmatrix} CH^3 \\ COOH \end{Bmatrix}$; and finally this toluic acid, when treated with chromic acid, is completely oxidised to carbonic acid and water—just like the orthotoluic acid obtained by other methods, whereas metatoluic acid, when similarly treated, is converted into isophthalic acid. Consequently the second toluene sulphonic acid—and therefore also salicylic acid—belongs to the 1 : 2 series.

The constitution of a few other di-derivatives of benzene has been determined by Meyer u. Ador (*Ann. Ch. Pharm.* clix. i.).

Sulphanilic acid, $C^6H^4NSO^2 = C^6H^4 \begin{Bmatrix} NH^2 \\ SO^2H \end{Bmatrix}$, is converted by nitrous acid into diazosulphanilic acid; this diazo-acid, heated with hydrobromic acid, yields bromobenzeno-sulphonic acid, $C^6H^4BrSO^2 = C^6H^4 \begin{Bmatrix} Br \\ SO^2H \end{Bmatrix}$; and this last acid, fused with potash, is converted into resorcin, without any admixture of pyrocatechin or hydroquinone. The same brominated sulphuric acid, distilled with potash, yields di-cyanobenzeno $C^6H^4(CN)^2$, which by boiling with potash is converted into terephthalic acid. These reactions show that the bromobenzeno-sulphonic acid, and the sulphanilic acid from which it is derived, belong to the para-series.

Sulphanilic acid treated with nitrous acid yields the diazo-derivative, $C^6H^4 \begin{Bmatrix} N=N \\ SO^2 \end{Bmatrix}$, which, by boiling with water, is converted into a phenolsulphonic acid, $C^6H^4 \begin{Bmatrix} OH \\ SO^2H \end{Bmatrix}$, which yields resorcin when fused with potash, and is therefore identical with the α -phenolsulphonic (or phenyl-sulphuric) acid, which Kekulé obtained by the action of sulphuric acid on phenol. This acid is, therefore, a para-compound, and affords further evidence of the constitution above assigned to sulphanilic acid.

The following table, drawn up by Meyer, exhibits the constitution of the known di-derivatives of benzene. They are arranged as substitution-products:—

(1) Of Benzoic acid; (2) of Toluene; (3) of Phenol; (4) of Aniline; (5) of Benzenesulphonic acid; (6) of Chloro-; (7) of Bromo-; (8) of Iodo-; and (9) of Nitro-benzene, the substituted radicles being introduced in the following order: $COOH$, OH , Cl , Br , I , F , NO^2 , NH^2 , SO^2H , CH^3 .

The less known compounds are characterised by the specification of some special property or mode of formation.

The azo-, diazo-, hydrazo-, thiohydro- (SH) derivatives, &c., are not given in the table, since they naturally belong to the same series as the nitro-, amido-, and sulpho-compounds from which they are prepared. Neither are derivatives introduced in which substitution has taken place in the lateral chains, such as—

as their positions in the table are evident without further explanation. For a similar reason, compounds whose lateral chains contain more than one carbon-atom (derivatives of ethyl-, propyl-, vinyl-, &c. benzene) are likewise excluded.

Di-derivatives of Benzene.

		1 : 4 Nitrotoluene (solid; yields nitrodacrylic acid).
Iodobenzene (from pseudotoluidine, perhaps a mixture of 1 : 2 and 1 : 3 iodotoluene ?) yields 1 : 3 iodobenzoic acid.		
1 : 2 Nitrotoluene (direct from toluene, together with the 1 : 4 compound; liquid; burns away on oxidation).	1 : 3 Nitrotoluene (liquid; yields nitrobenzoic acid).	
1 : 2 Toluidine (liquid; chief constituent of 'pseudotoluidine,' from the nitrotoluene above).	1 : 3 Toluidine (liquid; from the above nitrotoluene).	1 : 4 Toluidine (solid; from the above nitrotoluene: ordinary toluidine).

* The prefixes 'Ortho' and 'Meta' are here used in the sense originally assigned to them by Kekulé. Meyer reverses them, designating the 1 : 2 derivatives as *meta*, and the 1 : 3 derivatives as *ortho*. This change, however, appears inadvisable, since it involves the necessity of altering the designation of a large number of compounds—hydroquinone and pyrocatechin among the rest—whose position in the system, nevertheless, remains unchanged; whereas, by retaining the original signification of the prefixes *ortho* and *meta*, all that is necessary is to reverse their application to certain derivatives of benzoic acid, viz. salicylic acid, oxybenzoic acid, and their congeners, which, as Meyer's experiments have shown, must actually be transferred from one series to the other, salicylic acid having been shown to belong to the 1 : 2, and oxybenzoic acid to the 1 : 3 series.

1 : 2 Bromonitrobenzene (m.p. 125°; by nitration of bromobenzene; yields 1 : 2 bromaniline).	1 : 3 Bromonitrobenzene (m. p. 37°; Hübner a. Alsberg's γ -compound; by nitration of bromobenzene, together with the 1 : 2 compound).	1 : 4 Bromonitrobenzene (m. p. 56°; from dinitrobenzene).
Di-iodobenzene (m.p. 127°; perhaps 1 : 2).		1 : 4 Di-iodobenzene (m. p. 94°; from dinitrobenzene).
1 : 2 Nitro-iodobenzene (m. p. 171.5°; from iodobenzene and from 1 : 2 nitraniline).		1 : 4 Nitro-iodobenzene (m. p. 34°; from dinitrobenzene). Dinitrobenzene (yields resorcin).

Other classifications of the di-derivatives of benzene have also been proposed. V. v. Richter (*Deut. Chem. Ges. Ber.* iv. 553) places resorcin in the same series as salicylic acid, and pyrocatechin with paraoxybenzoic acid. Peterson (*ibid.* vi. 368) deviates still further from the usual arrangement, placing pyrocatechin with salicylic acid in the 1 : 2 series; resorcin and dinitrobenzene in the 1 : 3 series, and hydroquinone in the 1 : 4 series; and the arguments in favour of this last view appear to have considerable weight. See the article **PHENOLS** in this volume (p. 924).

Bromobenzenes.—*Dibromobenzene*, $C_6H_4Br_2$ (F. Riese, *Ann. Ch. Pharm.* clxiv. 176; Meyer a. Stüber, *Deut. Chem. Ges. Ber.* iv. 956, and v. 52). This compound is known in three isomeric modifications, one solid at ordinary temperatures, the other two liquid. The first [a], which is the ordinary modification (commonly called Couper's), is obtained by the action of bromine on benzene or on monobromobenzene. It is a magnificently crystalline body, melting at 89°.

The second [β] was obtained by Riese in small quantity, together with the first, by the action of bromine on benzene. It is a colourless, mobile, strongly refracting liquid, miscible in all proportions with ether and benzene, moderately soluble in cold alcohol. When slowly cooled to -27° , it remains liquid, but solidifies immediately on being touched with a glass rod: the solid melts again at -1° . It dissolves readily in cold fuming nitric acid, forming nitro- β -dibromobenzene which crystallises in pale yellow needles, melting at 58° and boiling at 296° .

The third modification was obtained by Meyer & Stüber by treating dibromaniline (prepared from acetanilide) with a nearly saturated alcoholic solution of nitrous acid. Reaction begins in the cold and is completed by warming. The product separated by water is, when purified, a clear colourless liquid, boiling, like the second modification, at 215° , but not solidifying even at -28° . It is not perceptibly acted upon by the strongest nitric acid in the cold, but dissolves only on warming, and is converted into a nitrodibromobenzene, which crystallises in pure glistening pale yellow needles, melting at 60° - 61° .

The following is a tabular view of the properties of the three dibromobenzenes:—

Dibromobenzenes	Melting point	Boiling point	Behaviour with HNO_3	Mononitro-derivative
Couper's	80°	219°	Dissolved on warming.	Plates or flat needles, melting at 84° .
Riese's	-1°	213° - 215° (corrected)	Dissolved with spontaneous evolution of heat.	Fine needles, melting at 58° .
Meyer & Stüber's . (?) *	Liquid at -28°	About 215° (uncorrected)	Dissolved on warming.	Needles, melting at 60° - 61° .

Action of Sodium on Crystallised Dibromobenzene (Riese, *Zeitschr. f. Chem.* vi. 735; *Ann. Ch. Pharm.* cxiv. 161). When solid dibromobenzene is added to cold anhydrous ether holding in solution a quantity of sodium twice as great as that which should be required for the complete removal of the bromine, and the mixture is heated in a water-bath, reaction sets in after the heating has been continued for several hours, and then goes on without further application of heat, the mixture continuing to boil gently, until, after 5-7 hours, the sodium is entirely covered with a loose green-black mass. On exhausting the product with ether and mixing the ethereal extract with a considerable quantity of alcohol, a yellow-brown mass separates, and the supernatant liquid, when evaporated, gives a moss-like crystallisation, only a portion of which, however, is re-dissolved by alcohol. By repeating the treatment with alcohol, &c., several times, the product may be separated into two portions, one soluble in alcohol and containing but little bromine, the other insoluble and containing much bromine.

On submitting the mixed product to distillation, diphenyl, C_6H_5 , passes over in small quantity as a white crystalline body. The residue, when again distilled, decomposes to a considerable extent, but at the same time yields a crystalline body, which, when purified by repeated distillation, washing with petroleum-naphtha (ligroin), and final recrystallisation from benzene, has the composition of diphenylbenzene, $\text{C}_{12}\text{H}_{10} = \text{C}_6\text{H}_4(\text{C}_6\text{H}_5)_2$. The same body is obtained by the action of sodium on a mixture of mono- and dibromobenzene. It melts at 205° (corr.), and boils at a temperature above 400° (in vapour of boiling sulphur); it is insoluble in alcohol, but dissolves easily in benzene, from which it separates on cooling in small flat white needles. It is scentless in the cold, and smells but faintly when heated; does not volatilise with vapour of water, but sublimates even below its melting point.

The main product of the action of sodium on dibromobenzene is, however, the brown amorphous brominated body above mentioned. This substance is nearly insoluble in alcohol and ether, but dissolves easily in benzene and carbon bisulphide,

* In Riese's first paper (*Deut. Chem. Ges. Ber.* ii. 60 [1869]), the second modification was said to solidify in a freezing mixture, but he now states that it remains liquid at -27° , unless touched with a solid body. The second and third modifications, therefore, resemble one another in their behaviour at low temperatures, as well as in their boiling points, and differ only in their behaviour with fuming nitric acid, and the melting points of the resulting nitro-derivatives.

from which it is again precipitated in the amorphous state on addition of alcohol or ether. A product thus purified gave by analysis 77.49 p. c. carbon, 4.07 hydrogen and 17.68 bromine, which is nearly the composition of monobromopentaphenylene, $C^{10}H^{10}Br$ (calc. 78.43 p. c. C., 4.14 H. and 17.43 Br.). The reaction may perhaps be represented by the equation:

Constitution of Crystallised Dibromobenzene.—When crystallised dibromobenzene, obtained by the direct action of bromine on benzene, is mixed with methyl iodide and sodium in a flask surrounded by ice, reaction does not begin for several hours, not indeed till the ice is melted; it then proceeds quietly and yields a large quantity of a hydrocarbon, the greater part of which passes over between 135° and 140° . This hydrocarbon oxidised with potassium chromate and sulphuric acid yields terephthalic acid without any trace of isophthalic acid. This transformation seems to show that crystallised dibromobenzene belongs to the para-series, the two bromine-atoms being separated by two intervals, as represented by the formula $C^6Br^1H^1Br^4H^4$ (V. Meyer, *Deut. Chem. Ges. Ber.* iii. 753).

On the other hand, V. v. Richter (*ibid.* iv. 459), states that this same dibromobenzene is obtained by acting with phosphorus pentabromide on orthobromophenol, whence it would appear to be itself an ortho-compound, $C^6Br^1Br^2H^3H^3$; and this view is in accordance with the fact that when nitrate of orthobromaniline is heated with nitrous acid and bromine-water, and the nitrate of diazobromobenzene thereby precipitated is decomposed by boiling with alcohol, a dibromobenzene is obtained identical with that which is formed by the direct action of bromine on benzene.

Chlorobenzenes. The statements respecting these compounds given in the 1st Suppl. (pp. 264-266), on the authority of Jungfleisch, have been modified in some respects by subsequent experiments of that chemist (*Ann. Ch. Phys.* [4] xv. 186). They are obtained: (1) By the action of iodine chloride on benzene; (2) By distilling with alcoholic potash the mixture of additive compounds produced by the action of chlorine in sunshine on benzene, monochlorobenzene, or sulphobenzide.

1. Chlorine is passed into commercial crystallisable benzene mixed with iodine, the mixture being gently heated at first, after which the action goes on by itself. Monochlorobenzene is first formed, then dichlorobenzene, whereupon the mass solidifies on cooling; on continuing the passage of the chlorine, trichlorobenzene is formed, and the mass again liquefies. At length it becomes solid again, and must be heated more strongly to melt the tetrachlorobenzene which is then formed; and, finally, when pentachlorobenzene has been formed, the product becomes again more fusible. Hexachlorobenzene is not easily obtained by this process, inasmuch as a high temperature is required, at which iodine and chloride of iodine are driven off. In every case, *all* the substitution-products are formed simultaneously, but *one* of them always predominates, according to the temperature and other circumstances of the reaction. The mixture likewise contains small quantities of iodobenzenes; but by exposing the product to sunshine, or by distillation, these compounds are decomposed, with liberation of iodine, which may then be removed by potash.

2. The oily liquid formed, together with crystals of the compound C^6H^5Cl , by the action of excess of chlorine in sunshine on monochlorobenzene, is separated from the crystals and gently warmed with alcoholic potash, and the resulting brown liquid is treated with water, which throws down a mixture of an oil with crystals, while chlorinated phenols and other products remain in solution. The mixture of oil and crystals yields by fractional distillation a series of chlorinated benzenes.

The monochlorobenzenes obtained by the two processes are the same: but the di-, tri-, tetra- and penta(?)-chlorinated compounds obtained by the second process are different from those produced by the first. It will be convenient to distinguish these modifications by the symbols α and β .

Monochlorobenzene, C^6H^5Cl , prepared as already described (1st Suppl. 265), and finally purified by cooling to -35° , and filtering at that temperature, boils constantly at 131° , and solidifies between -50° and -60° to a hard crystalline mass, which melts at -40° . Its specific gravity is 1.1293 at 0° ; coefficient of expansion 0.00116. Its physical properties are therefore identical with those of phenyl chloride obtained by the action of phosphorus pentachloride on phenol. It is not attacked by potassium hydrate, or at ordinary temperatures by potassium; when heated with sodium it yields diphenyl; this latter compound is also formed, together with other products, when the vapour of chlorobenzene is passed over red-hot copper.

α -Dichlorobenzene, $C^6H^4Cl^2$, forms colourless transparent crystals belonging to the monoclinic system (not orthorhombic, as formerly stated); plane angle of the

rhombic base = $43^{\circ}17'56''$; inclination of principal axis to this face = $46^{\circ}30'$ (Descloizeaux). It melts at 53° , and boils without decomposition at 171° .

Specific gravity	1.4581	1.241	1.2062	1.1366
at	20.5°	63°	93°	161°

Strong sulphuric acid does not act upon it in the cold, but under the prolonged influence of heat unites with it, forming a sulpho-acid.

β-Dichlorobenzene melts below 0° , and boils at about 175° .

α-Trichlorobenzene, $C_6H_3Cl_3$, is difficult to prepare by the method above described, and can be obtained only from perfectly pure benzene. It is best prepared by passing chlorine into purified dichlorobenzene mixed with iodine, separating from time to time the still liquid portion from the crystals, and treating the latter further with chlorine. The product, after washing with water and sodium carbonate, is subjected to fractional distillation, and the higher and lower chlorobenzenes, which crystallise more readily, are separated by cooling the distillate. By further fractional distillation a product boiling at 206° is obtained, which is to be cooled with ice water, and brought in contact with a crystalline fragment obtained by cooling the liquid in a freezing mixture. The liquid in the ice-water then gradually solidifies into crystals, which may be freed from the still fluid portion by decantation. By repetition of this process the portion which still remains fluid may be reduced to a very small amount.

Trichlorobenzene thus prepared, forms large, transparent and colourless crystals, apparently belonging to the rhombic system; it melts at 17° , boils at 206° , and has a rather strong but not unpleasant odour:—

Sp. gr.	1.5740 (cryst.)	1.4658 (liq.)	1.4460	1.4111	1.2427
at	10°	10°	26°	56°	196°

whence the expansion coefficient for the liquid state is 0.000989. A mixture of this compound with *α*-dichlorobenzene, in equal numbers of molecules, may be cooled to 10° , without formation of crystals; but towards 0° part of the dichlorobenzene separates out, and below 0° the whole solidifies. *α*-Trichlorobenzene dissolves in alcohol ether, carbon sulphide and benzene. It is a very stable compound, not being acted on by aqueous potash or decomposed by distillation over caustic baryta, or deprived of any portion of its chlorine by strong heating with alcoholic potash. Heated with strong sulphuric acid nearly to the boiling point, it forms trichlorobenzene-sulphonic acid, $C_6H_2Cl_3SO_3$, which crystallises at ordinary temperatures, and may be precipitated from the sulphuric acid solution by addition of water. Pure trichlorobenzene is converted by fuming nitric acid, with evolution of heat, into nitro-trichlorobenzene, but in the impure state it is but slowly acted on, the nitration taking place only after prolonged boiling.

β-Trichlorobenzene, formed together with the *α*-modification by the second process above described, melts at 60° .

The more highly chlorinated derivatives of benzene are, for the most part, sufficiently described in the *First Supplement*.

α-Tetrachlorobenzene melts at 139° , boils at 210° , and exhibits the following specific gravities:—

Sp. gr.	1.7344	1.4339	1.3958	1.3281
at	10°	149°	170°	230°

β-Tetrachlorobenzene melts at 35° , and boils at 253° .

Of pentachlorobenzene there should, according to Kekulé's theory, be only one modification, but Jungfleisch and Otto assert that there are two; both of which are found amongst the products of the action of alcoholic potash on the additive compounds obtained by the action of chlorine on monochlorobenzene or on sulphobenzide in sunshine, and may be separated by boiling alcohol, in which one is soluble, the other insoluble; one of them (*α*) is also the most abundant of the products formed by the action of chlorine and iodine on benzene. The *α*-modification melts at 74° , and boils at 272° ; the *β*-modification (insoluble in boiling alcohol) forms shining, silky needles, which melt at 175° when quickly heated, but after solidification from fusion do not melt again till heated to 198° , and resolidify at a slightly lower temperature. The *α*-modification exhibits the following specific gravities:—

Sp. gr.	1.8422	1.8342	1.6691 (fused)	1.5732	1.3824
at	10°	16.5°	84°	114°	261°

Ladenburg (*Deut. Chem. Ges. Ber. v. 789*) is of opinion that the existence of the second modification of pentachlorobenzene (melting at 175° – 198°) is by no means satisfactorily proved. On repeating Jungfleisch's mode of preparation, that is to say,

exposing monochlorobenzene to the action of chlorine in sunshine (using, however, moist instead of dry chlorine), distilling the product with alcoholic potash, subjecting the distillate to repeated fractional distillation, and the several fractions to fractional crystallisation from alcohol, till the melting and boiling points of the several portions became nearly constant, he finally obtained the following compounds, and no others:—

$C^6H^5Cl^4$	melting at 27° – 28° ,	boiling at 245° – 248°
C^6HCl^5	" 85° – 86°	" 275° – 277°
C^6Cl^6	" 225°	

From these results Ladenburg concludes that by the action of moist chlorine on monochlorobenzene in sunshine only one pentachlorobenzene is produced (that designated above as a): and, considering that the statements of Jungfleisch and Otto with respect to the properties of the second modification do not quite agree; that, according to Jungfleisch, the melting point of this supposed modification varies from 175° to 198° , and that among the products of the action of moist chlorine on benzene, this particular product is not found, whereas all the others products obtained by the action of dry chlorine do likewise occur in this case; he concludes that the existence of this second modification of pentachlorobenzene must be regarded as doubtful until it is established by new and decisive experiments.

Jungfleisch (*Bull. Soc. Chim.* [2] xviii. 531) replies to these observations, maintaining the existence of the second modification of pentachlorobenzene described by himself and by Otto, and attributing Ladenburg's failure in obtaining it to the fact of his having used moist instead of dry chlorine. He states his intention of publishing further results relating to the second pentachlorobenzene and its derivatives.

Otto (*Ann. Ch. Pharm.* cliv. 182) likewise maintains the existence of two modifications of pentachlorobenzene. When dry sulphobenzene is subjected to the prolonged action of chlorine in sunshine, the product dissolved in alcohol (which leaves undissolved small quantities of dichlorobenzene chloride), decomposed by potash, and water then added, the two pentachlorobenzenes are thrown down, and may be separated by alcohol, in which the less fusible of the two is insoluble. The more fusible modification melts at 85° , the less fusible at 198° – 199° . These statements do not agree very well with those of Jungfleisch. Moreover, Ladenburg, by the analysis of two samples of so-called pentachlorobenzene prepared by Otto, one melting at 224° – 225° , the other at 219° – 223° , found that they contained respectively 74.39 and 74.06 p.c. chlorine, from which it appears that they were both nearly pure hexachlorobenzene, which melts at 226° , and contains 74.74 p.c. chlorine.

Fluobenzene, C^6H^5F , is obtained by heating the calcium salt of fluobenzonic acid with about four times its weight of slaked lime:

The fluobenzene, after being purified by fractional distillation, solidifies to a mass of scales. It melts at 40° , boils at 180° – 183° , and has a vapour-density of 3.476 (calc. 3.937). It is insoluble in water, but dissolves easily in ether and in alcohol; smells like benzene, and burns with a smoky flame (Schmitt u. Gehron, *J. pr. Chem.* [2] i. 394).

Nitrobenzenes. *Mononitrobenzene*, $C^6H^5NO_2$, is but slowly attacked by *chromic oxychloride* mixed with glacial acetic acid. Nitrotrichlorobenzonic acid is probably formed, together with an unknown substance, which strongly attacks the eyes (Carstanjen, *J. pr. Chem.* [2] ii. 83).

Nitrobenzene, heated with *potassium* or *sodium hydrate*, gives off ammonia and aniline, and on pouring the product into dilute hydrochloric acid, a brown tarry matter separates, which solidifies to a crystalline mass of azobenzene. These, however, are only the final products of the reaction; for if it be stopped at a certain stage, the product dissolves almost completely in water, and hydrochloric acid added to the solution throws down dark flocks of a resinous acid (Morz u. Coray, *Dent. Chem. Ges. Ber.* iv. 081).

According to Post u. Hübner (*ibid.* v. 408) nitrobenzene brought in contact for a short time with potassium hydrate heated to fusion, gives off hydrocyanic acid; dinitrobenzene is acted upon in a similar manner when boiled with solution of caustic potash or soda.

Nitrobenzobenzene, $C^6H^5Br(NO_2)$. Three modifications of this compound are known, viz. 1.—1. *Ortho-* or *α -Nitrobromobenzene* (1: 2), produced by the action of fuming nitric acid on monobromobenzene, also, according to Griess, by heating the bromoplatinate of *α -azophenylamine* (from *α -nitraniline*) with sodium carbonate (*ibid.* 416).

It melts at 125° – 126° , crystallises in long white needles, and is converted by ammonium sulphide or ferrous acetate into α -bromaniline melting at $64^{\circ}5'$.

2. *Meta- or β -Nitrobromobenzene* crystallises from the mother-liquor of the preceding compound in long needles, melting at 37° , and boiling almost without decomposition at 250° – 251° . Its formation is most favoured by effecting the nitration at a temperature of 90° – 95° . By reduction with tin and hydrochloric acid it yields β -bromanilino, which when precipitated with soda-ley and distilled with water, passes over as an oil, solidifying in a freezing mixture to crystals, and when quickly pressed and dissolved in alcohol separates therefrom in white needles melting at 31° (Hübner a. Alsberg, *Zeitschr. f. Chem.* [2] vi. 369).

*Para- or γ -Nitrobromobenzene** is the modification which Griess obtained by heating the perbromide of β -azonitrophenyl ammonium with sodium carbonate (iv. 416). It melts at 56° , and is reduced by ammonium sulphide to parabromaniline (Griess, iv. 426, 435).

The three modifications of nitrobromobenzene yield corresponding nitranilines when heated to 180° – 190° in sealed tubes with strong alcoholic ammonia. Ortho-nitraniline thus produced melts at 146° , and agrees in every respect with that obtained from acetanilide; meta-nitraniline, recently discovered by Walker a. Zincke, (*Deut. Chem. Ges. Ber.* v. 114), melts at 66° ; paranitraniline, originally obtained by reduction of dinitrobenzene (iv. 445), at 108° .

Ortho- and meta-nitrobromobenzene, when subjected to the further action of fuming nitric acid, yield one and the same dinitro-bromobenzene, $C^6H^3Br(NO^2)^2$, melting at 72° (Walker a. Zincke). Now, assuming that the bromine and nitryl in these two modifications occupy the positions 1 : 2 and 1 : 3, it is easily seen that dinitrobromobenzene must be either 1 : 2 : 3 or 1 : 3 : 6, as represented below:—

To decide which of these is the actual arrangement, the dinitro-bromobenzene was heated with tin and hydrochloric acid, whereby the two groups NO^2 were replaced by H^2 , and at the same time bromine by hydrogen, the result being paraphenylenediamine, $C^6H^4(NH^2)H^2(NH^2)$, identical with that obtained from dinitrobenzene. This shows that in the dinitro-bromobenzene the two groups NO^2 must be separated by two intervals, and consequently that the bromine and these two nitryls must occupy positions 1 : 3 : 6 (Zincke a. Sintonis, *Deut. Chem. Ges. Ber.* v. 791).

Ortho- and para-nitrobromobenzene heated with pure potassium cyanide and alcohol 180° – 200° , yields cyano-bromobenzene, together with potassium nitrite, according to the equation:

by boiling the product with alcoholic potash as long as ammonia is given off, then distilling with water, filtering, and adding hydrochloric acid, a precipitate is obtained, consisting of bromobenzoic acid:

Dinitrobromobenzene, $C^6H^3Br(NO^2)^2$. The formation of the dinitrobromobenzene melting at 72° by the action of fuming nitric and sulphuric acid on monobromobenzene (1st Suppl. 269) appears, from the observations of Clemm (*J. pr. Chem.* i. 145), to be accompanied by that of another modification melting at a lower temperature. Dinitrobromobenzene melting at 72° heated with strong potash-ley is dinitrophenol, $C^6H^3(NO^2)^2(OH)$, melting at 113° – 114° ; and when heated in alcoholic ammonia, dinitranilino, $C^6H^3(NO^2)^2.NH^2$.—Aniline heated with nitrobromobenzene acts violently on its forming dinitrodiphenylamine identical with that obtained by Hofmann (Clemm).

*There is some confusion about the designation of these isomerides. Hübner a. Alsberg, who described the second modification above described, distinguished it by the prefix β , but Walker a. Zincke (*Deut. Chem. Ges. Ber.* v. 114) designated it as γ , and the para-modification as β : it is better to adopt the mode of distinction adopted by the discoverers.

Nitramidobromobenzene, $C^6H^3Br(NO^2)(NH^2)$, is produced by heating nitrodibromobenzene (prepared by boiling solid dibromobenzene with fuming nitric acid) with concentrated alcoholic ammonia to 200° – 210° for several hours:

On pouring the black liquid into hydrochloric acid, separating the red-brown solution thereby formed from resin, and pouring it into water, nitramidobromobenzene separates in fine felted orange-coloured needles, which may be purified by crystallisation from ether, repeated solution in hydrochloric acid, and reprecipitation by water.

Nitramidobromobenzene melts at 104.5° , sublimes without decomposition, and volatilises readily with vapour of water. It is freely soluble in alcohol and ether, slightly soluble in cold water, somewhat more so in hot water, forming a yellow solution. It has no basic properties, but dissolves in strong hydrochloric or nitric acid, and is reprecipitated on addition of water. Its hot aqueous solution dyes silk and wool of a fine yellow colour. It is not deprived of its bromine even by prolonged digestion with alcoholic ammonia at a very high temperature.

If solid dibromobenzene be a para-compound (p. 136), the mononitro-compound formed from it will probably have the constitution 1 : 2 : 4; and the amido-compound formed from this by substitution of NH^2 for Br, will be similarly formed, thus:—

		1	2	3	4	5	6
Paradibromobenzene	C^6	Br	H	H	Br	H	H
Nitrodibromobenzene	C^6	Br	NO^2	H	Br	H	H
Nitramidobromobenzene	C^6	NH^2	NO^2	H	Br	H	H
or	C^6	Br	NO^2	H	NH^2	H	H

By treating this last compound with tin and hydrochloric acid, the NO^2 is replaced by NH^2 , and a bromophenylene-diamine, $C^6H^3Br(NH^2)^2$, is obtained having the two amidegen groups either in close proximity (1 : 2), or separated by one interval (2 : 4 or 1 : 3). On adding excess of soda, agitating the product with ether, and evaporating the ethereal solution, the bromophenylene-diamine is obtained as a thick liquid, which solidifies over sulphuric acid to a reddish crystalline mass. By heating it with water and sodium-amalgam, the bromine is replaced by hydrogen, and phenylene-diamine, $C^6H^4(NH^2)^2$, is formed, likewise having the two amidegen groups disposed either as 1 : 2 or as 1 : 3; that is to say, it is either ortho- or meta-phenylene-diamine. (In Meyer's table, p. 137, the latter position is assigned to it). This phenylene-diamine melts at 99° , and is identical in characters and reactions with that which Griess obtained by the dry distillation of β -diamidobenzoic acid (Meyer a. Wurster, *Deut. Chem. Ges. Ber.* vi. 362). See PHENYLENE-DIAMINES.

Nitrochlorobenzenes (Jungfleisch, *Ann. Chim. Phys.* [4] xv. 186; Engelhardt a. Latschinoff, *Zeitschr. f. Chem.* [2] vi. 225; Clemm, *ibid.* 444).—**Nitromonochlorobenzene**, $C^6H^4(NO^2)Cl$, is known in two modifications, both of which are formed when monochlorobenzene is poured into cool fuming nitric acid; they are separated by their difference of solubility in cold alcohol. The modification designated as *a*, which is but slightly soluble in this liquid, forms long crystalline laminae, derived from a rhombic prism of about $125^{\circ}30'$; melts at 83° ; and has, after solidification, a specific gravity of 1.380 at 22° : it boils without decomposition at 242° (bar. at 761 mm.); smells like bitter almonds and Tonka beans. Ether, benzene, carbon sulphide, boiling alcohol, and hot nitric acid dissolve it readily. It is not attacked by aqueous potash, but *alcoholic potash* acts strongly upon it, probably forming chlorinated azoxybenzene. Strong sulphuric acid dissolves it easily and turns brown-red when boiled with it, giving off a large quantity of sulphurous oxide; at comparatively low temperatures, the product consists of nitrochlorobenzene-sulphonic acid. *Fuming nitric acid* does not act upon it, but a mixture of strong nitric and sulphuric acids quickly converts it into *a*-dinitro-chlorobenzene. By *tin and hydrochloric acid* the mononitrated compound is reduced to monochloraniline, C^6H^4ClN , which appears to be identical with that which Hofmann obtained from chlorisatin.

β -Nitromonochlorobenzene, the modification which dissolves easily in cold alcohol, is purified by filtration in a small quantity of very cold alcohol and precipitated with water. It solidifies in a freezing mixture. When placed in ice-water and mixed with a few fragments of the portion which has previously solidified in the crystalline form, it crystallises and may be freed from the still liquid portion by decantation. By repeatedly subjecting the crystallised portion to the same treatment, that is, dissolving it in a small quantity of cold alcohol and causing it to solidify by touching it after cooling with a crystal of the same modification, it is finally obtained in tufts of beautiful needle-shaped crystals, having a nacreous lustre, a scarcely perceptible yellowish tinge, and a fragrant odour like that of Tonka beans or clover. It melts at 15° , boils at about 243° , and has a density of 1.368 at 22° . In the fused

state it is miscible with alcohol in all proportions; ether, carbon sulphide, benzene and dilute nitric acid dissolve it readily. With potassium hydrate it reacts like the first modification. Fuming nitric acid acts easily upon it, especially at the boiling heat, converting it into α - and β -dinitromonochlorobenzene. A mixture of nitric and sulphuric acids acts upon it explosively. With strong sulphuric acid it behaves like the α -modification. By *tin* and *hydrochloric acid* it is easily reduced to β -monochloraniline, which is obtained as a liquid not solidifying at low temperatures.

α -Dinitromonochlorobenzene, $C^6H^4(NO^2)_2Cl$, is easily prepared from α - or β -mononitrochlorobenzene, or directly from monochlorobenzene, by the action of a warm mixture of strong nitric and sulphuric acids, and precipitation with water; it may be purified by several recrystallisations from alcohol, or better from boiling ether (Jungfleisch). It is also produced by the action of phosphorus pentachloride on dinitrophenol (Clemm). It forms large, transparent, very faintly yellowish crystals, which, according to Descloizeaux, are orthorhombic prisms of $102^{\circ}5'$. It has a faint odour at ordinary temperatures, but, when heated, gives off very irritating vapours. It has a density of 1.697 at 22° , melts at 50° , and boils with slight decomposition at 315° . It is insoluble in water, and very slightly soluble in cold alcohol, but boiling alcohol, as well as ether, benzene, and carbon sulphide dissolve it freely. *Fuming nitric acid* likewise dissolves it without decomposition. Strong *sulphuric acid* unites with it when heated, forming a sulfo-acid. By *alcoholic potash* it is attacked in the same manner as nitrobenzene. *Tin* and *hydrochloric acid* convert it into nitrochloraniline, which is obtained in fine orthorhombic crystals, melting at 89° , and decomposing partially when volatilised (Jungfleisch).

By strong *aqueous potash*, or by *alcoholic soda-solution*, it is converted into dinitrophenol. Heated for four or five hours to 100° – 120° with *alcoholic ammonia*, it yields α -dinitraniline, $C^6H^3(NO^2)_2NH^2$, which crystallises in light yellow prisms, melting at 175° (Clemm).

β -Dinitrochlorobenzene is obtained with difficulty from mononitrochlorobenzene by heating with nitric acid; it is precipitated with water, washed with water and then with boiling alcohol, and recrystallised from solution in cold ether. According to Descloizeaux' measurements, its crystalline form is similar to, but not identical with that of the α -modification. The primary form is a right rhombic prism of $100^{\circ}18'$. The crystals are faintly yellowish, very brittle, have a density of 1.6867 at $16^{\circ}5$, and melt at 43° ; the boiling point is about 315° (bar. at 0.762 met.). It is scarcely soluble in cold alcohol, more freely in boiling alcohol; ether, benzene, and carbon sulphide dissolve it more readily than the α -modification. With nitric acid and alcoholic potash it reacts like the latter. By reduction with *tin* and *hydrochloric acid*, it yields β -monochloronitraniline, which crystallises in right rhombic prisms of $10^{\circ}22'$.

β -Dinitrochlorobenzene undergoes a remarkable change when touched with the smallest fragment of a crystal of the α -modification, the transparent crystals becoming turbid and passing into the α -modification; by subsequent crystallisation from ether or carbon sulphide, they are obtained in the exact form of the α -modification, exhibiting also the same melting point and the same degree of solubility.

On the other hand, the α -modification may be converted, though less easily, into the β -modification: namely, by suddenly plunging it, while in the fused state, into a freezing mixture, whereupon it solidifies to a homogeneous translucent crystalline mass. Jungfleisch supposes that the substance thus obtained is the β -modification, because it is more fusible than the original α -modification, and because, when touched with a crystal of the latter, it is gradually converted, from the point of contact inwards, into a turbid crystalline mass, made up of crystals of the more stable α -modification. These remarkable changes appear, however, to require further examination.

Nitrodichlorobenzene, $C^6H^3(NO^2)Cl_2$, is prepared by the action of nitric acid of sp. gr. 1.49 on dichlorobenzene (melting at 53°), and purified by precipitation with water and crystallisation from boiling alcohol. From solution in carbon sulphide it separates by spontaneous evaporation in faintly yellow, soft, flexible crystals of the triclinic system. It melts at 54.5° and boils at 266° . Sp. gr. 1.669 at 22° . Boiling alcohol, carbon sulphide, benzene and chloroform dissolve it freely, cold alcohol sparingly. Aqueous potash does not act upon it; alcoholic potash attacks it strongly, probably forming dichlorazoxybenzene. Strong sulphuric acid dissolves it readily, forming a sulfo-acid; in boiling the liquid, sulphurous oxide is given off. By *tin* and *hydrochloric acid*, it is converted into dichloraniline.

Dinitro-dichlorobenzene, $C^6H^2(NO^2)_2Cl_2$, is formed in two modifications by boiling the preceding compound for an hour with a mixture of fuming nitric and

strong sulphuric acids. One of these, distinguished as the α -modification, is less soluble in alcohol than the other, and may therefore be obtained pure by crystallisation from alcohol, and washing with the same liquid. It forms small nacreous laminae, having a slight yellowish tint; smells faintly at ordinary temperatures, but gives off a pungent intolerable odour when heated; melts at 87° (at 104° , according to Engelhardt n. Latschinoff); boils with slight decomposition at 312° . After fusion and solidification, it has a specific gravity of 1.103 at 16° . It is nearly insoluble in cold alcohol, but dissolves more easily in boiling alcohol, and still more in ether, carbon sulphide, and benzene. Strong sulphuric acid unites with it, forming a sulpho-acid whose barium salt crystallises easily. Alcoholic potash decomposes it readily, forming crystallised products. Tin and hydrochloric acid convert it into dichloro-nitraniline (Jungfleisch).

Boiled with sodium carbonate, it yields a sodium salt, $C^6H^2Na(NO^2)^2ClO + 3H^2O$, which, when decomposed by acids, yields a dinitrochlorophenol, $C^6H^2(NO^2)^2ClO$, melting at 80° , and probably identical with that obtained by Dubois and by Faust a. Saamo (1st Suppl. 914). (Engelhardt n. Latschinoff.)

The β -modification of dinitrodichlorobenzene is obtained by evaporation from the mother-liquors of the α -modification, and may be completely freed from the latter by cooling the hot alcoholic solution of the residue, the β -modification then separating in the crystalline form, while the α -modification separates as an oil which may be decanted from the crystals together with mother-liquor. The final purification is effected by repeated crystallisation from alcohol. It forms nearly colourless well-defined crystals, melts at 107° (at 101° , according to Engelhardt a. Latschinoff); boils with slight decomposition at 318° , dissolves somewhat more easily than the α -modification in cold alcohol; but in other solvents the two modifications dissolve with equal facility: they also react in the same manner with sulphuric acid, with alcoholic potash, and with tin and hydrochloric acid (Jungfleisch).—By boiling with sodium carbonate, it is converted into the easily soluble sodium salt of a dinitrochlorophenol, whose barium salt, $[C^6H^2(NO^2)^2ClO]^2Ba + 3H^2O$, crystallises in yellow needles. The dinitrochlorophenol separated from it crystallises from water in tufts of long needles, melting at 70° (Engelhardt n. Latschinoff).

Nitrotrichlorobenzene, $C^6H^2(NO^2)Cl^3$, which Lesimple obtained by the action of fuming nitric acid at the boiling heat on trichlorobenzene (1st Suppl. 269), crystallises from carbon sulphide in light sulphur-yellow, oblique rhombic prisms of $105^\circ 30'$, whose prismatic faces make an angle of $63^\circ 40'$ with the base. It melts at 75° to a yellow liquid, which boils without essential decomposition at 288° . Sp. gr. 1.790 at 22° . It dissolves slightly in cold, more freely in hot alcohol, and with great facility in ether, benzene, and carbon sulphide. Alcoholic potash-ley acts strongly on it; strong sulphuric acid does not act upon it in the cold, but dissolves it when heated, with formation of a sulpho-acid: at the boiling heat the liquid becomes dark, and gives off sulphurous oxide. By tin and hydrochloric acid it is converted into trichloroaniline (Jungfleisch).

Dinitrotrichlorobenzene, $C^6H(NO^2)^2Cl^3$, is obtained by boiling the preceding compound for some hours with a mixture of strong nitric and sulphuric acids, precipitating with water, washing with dilute potash-ley, and crystallisation from alcohol. It forms light yellow, six-sided, needle-shaped prisms, having a density of 1.850 at 26° ; melts at 103.5° , and boils with slight decomposition at 335° . It is insoluble in cold, but soluble in warm alcohol, also in benzene, carbon sulphide, and ether. Alcoholic potash attacks it with violence; tin and hydrochloric acid convert it into nitrochloroaniline (Jungfleisch).

Trinitrochlorobenzene, $C^6H(NO^2)^3Cl$, is produced by the action of phosphorus pentachloride on picric acid. It was originally obtained by Pisani (1st Suppl. 416), who, however, does not appear to have prepared it in the pure state. Clemm (Zeitschr. f. Chem. vi. 444) mixes 100 grams of dry picric acid with twice its weight of phosphorus pentachloride in a capacious vessel provided with a wide condensing tube, applying a gentle heat at first, and when the first violent reaction is over, heating the mixture for some time to the boiling point; the greater part of the resulting phosphorus oxychloride is then distilled off, the residue decomposed by water, and the separated trinitrochlorobenzene is washed with a little ether and crystallised from alcohol or light petroleum oil. It crystallises in nearly colourless shining needles, which become dull in contact with the air; melts at 83° , often remaining liquid for a long time. It is not decomposed by boiling water, but solution of sodium carbonate or caustic alkalis decompose it at the boiling heat, forming metallic chloride and trinitrophenol. By ammonia or ammonium carbonate it is converted into trinitroaniline (Pisani's picramide). Aniline acts violently on it, forming trinitrodiphenylamine, $NH(C^6H^4)[C^6H^2(NO^2)^3]$. With ethyl aniline, nothing but resinous products are formed. With an alcoholic solution of sodium phenate, trinitrochloro-

benzene yields hydrochloric acid, sodium pierate, and phenol. With an alcoholic solution of *potassium sulphocyanate*, a complicated reaction takes place, yielding a crystallisable body, whose composition has not yet been determined (Clemm).

Nitrotetrachlorobenzene, $C^6H(NO^2)Cl^4$, is prepared by treating tetrachlorobenzene with strong nitric acid, or better with a mixture of nitric and sulphuric acids. It crystallises from boiling alcohol in thick striated needles; from carbon sulphide by slow evaporation in large transparent and colourless triclinic crystals. It has a peculiar slightly pungent odour; melts at 99° , and boils with decomposition at 304° . Sp. gr. 1.744 at 25° . Insoluble in cold, easily soluble in hot alcohol, also in benzene, carbon sulphide, and chloroform, slightly in hot strong sulphuric acid. By *tin* and *hydrochloric acid*, it is converted into tetrachloraniline (Jungfleisch).

Nitropentachlorobenzene, $C^6(NO^2)Cl^5$, is formed by the action of fuming nitric acid on pentachlorobenzene (melting at 74°), and separates from the solution on cooling in beautiful six-sided crystalline plates; after washing with water, and boiling with dilute potash, which removes a quantity of adhering brown substance, it recrystallises from alcohol in slender colourless shining needles, from carbon sulphide in large monoclinic tables; melts at 146° , and boils with partial decomposition at 328° . Sp. gr. 1.718 at 25° . Insoluble in cold alcohol, easily in boiling alcohol, especially when mixed with benzene, still more in carbon sulphide and in chloroform. By *tin* and *hydrochloric acid* it is converted into pentachloraniline, $C^6Cl^5NH^2$ (Jungfleisch).

In all the nitrochlorobenzenes, the chlorine has completely lost the passive character which it exhibits in the chlorobenzenes, and is replaceable by other radicals, with greater facility in proportion as the compound contains a larger number of nitryl groups.

α - and β -*Nitrochlorobenzene*, $C^6H(NO^2)Cl$, heated to 130° for three days with solution of sodium carbonate or hydrate give up their chlorine and are converted into nitrophenols, the α -modification (melting at 83°) giving non-volatile nitrophenol, but only in very small quantity, the β -modification yields volatile nitrophenols. Ammonia likewise withdraws the chlorine from these compounds.

Nitrodichlorobenzene, $C^6H^2(NO^2)Cl^2$, is but little acted upon by caustic soda or by ammonia; but *dinitrochlorobenzene*, $C^6H(NO^2)^2Cl$, easily gives up its chlorine, yielding, when boiled with solution of sodium carbonate, a dinitrophenol melting at 114° ; with ammonia, a dinitraniline melting at 177° ; and with toluidine, a compound which melts at 135° , crystallises from ether in long red plates or orange-yellow tables, and probably consists of dinitrophenyl-toluidine, $C^6H^2(NO^2)^2C^6H^3NH$. Still more easy is the decomposition of *trinitrochlorobenzene*, $C^6H^2(NO^2)^3Cl$, and of *dinitro-dichlorobenzene*, $C^6H^2(NO^2)^2Cl^2$; by boiling with alkalis (pp. 145, 146); the former being converted by ammonia or ammonium carbonate into trinitraniline, the latter by sodium carbonate into dinitromonochlorophenol, $C^6H^2(NO^2)^2ClO$ (Engelhardt & Latschinoff).

Compounds formed by Reduction of the Nitrobenzenes.

Amidobenzene, $C^6H^5(NH^2)$. See ANILINE under PHENYLAMINES.

Triamidobenzene, $C^6H^3N^3 + C^6H^4(NH^2)^3$, is obtained by distilling triamidobenzoic acid with pounded glass. It is a crystalline solid, varying in colour between flesh-colour and chocolate. It is readily soluble in water, alcohol, and ether, and remains on evaporation as a radiate crystalline mass, melting at about 103° , distilling at 336° (corrected), and readily subliming at a much lower temperature. The aqueous solution has a strong alkaline reaction, and gives with ferric chloride, first a violet and then a brown precipitate, and with hypochlorites and nitrites brown precipitates. It reduces an ammoniacal silver-solution in the cold. On dissolving triamidobenzene in concentrated sulphuric acid and adding a trace of nitric acid, the liquid assumes at first a dirty green colour, which soon changes into a fine blue and disappears on standing or on dilution with water. The same reaction is shown by triamidobenzoic acid.

Triamidobenzene combines with two molecules of a monobasic or 1 mol. of a dibasic acid, forming very stable salts. *Triamidobenzene hydrochloride*, $C^6H^3(NH^2)^3 \cdot 2HCl$, crystallises in shining needles; it is very soluble in water, but only sparingly in concentrated hydrochloric acid. The *hydriodide* is also readily soluble and forms long radiate needles. *Triamidobenzene sulphate*, $C^6H^3(NH^2)^3H^2SO^4 + 2H^2O$, crystallises in large plates (Salkowsky, *Ann. Ch. Pharm.* clxiii. 23).

Azobenzene, $C^6H^5N^2$ or $C^6H^5-N=N-C^6H^5$.—*Compound with Benzene*, $C^6H^5N^2 \cdot C^6H^5$. This compound separates on cooling from a hot-saturated solution of azobenzene in pure benzene, or better, from a cold-prepared solution by spontaneous evaporation in transparent, thick, oblique rhombic prisms, sometimes an inch long, and differing but little in colour and appearance from azobenzene crystallised from

petroleum. These crystals, when exposed to the air, exhibit an appearance of efflorescence, becoming opaque and of a pale yellowish-red colour, and being converted into easily friable aggregates of small shining crystalline laminae, which retain the external form of the original crystals. This change is due to a loss of benzene. The crystals, heated to 35° in a stream of dry air, give off the whole of their benzene, amounting to 30.6 p. c.; the formula requires 30 p. c. The crystals, heated in a sealed tube, melt at 38° to a dark red liquid, which often retains its fluidity for a long time after cooling to the ordinary temperature.

Azobenzene quickly absorbs benzene vapour. When placed at ordinary temperatures in the state of powder under a bell-jar, together with an open vessel containing benzene, it becomes darker, increases in weight, and is converted into the compound, $C^{12}H^{10}N^2.C^{12}H^6$. The absorption of the benzene does not, however, stop at this point; for in a few days the whole of the powder deliquesces to a clear dark red liquid, which still goes on increasing in volume. The exact limit of the absorption has not yet been determined (G. A. Schmidt, *Deut. Chem. Ges. Ber.* v. 1106).

Bromazobenzenes.—Werigo (*Ann. Ch. Pharm.* clxv. 189). The brominated compound produced by the action of bromine on azobenzene, and formerly regarded as an addition-product, $C^{12}H^{10}N^2Br^2$ (1st *Suppl.* 270), appears on further examination to be a substitution-product, viz. dibromazobenzene, $C^{12}H^8Br^2N^2$. This conclusion is based on the following facts:—1. The compound is remarkably stable, like azobenzene itself, and unlike the addition-products of the latter, which decompose with facility; the two atoms of bromine are indeed so intimately united with the rest of the group, that they cannot be removed either by the action of silver-salts, or by heating with potash in sealed tubes. 2. Fuming nitric acid converts azobenzene into trinitro-azoxybenzene, $C^{12}H^7(NO^2)^3N^2O$ (1st *Suppl.* 272), and the brominated body treated with fuming nitric acid, yields—besides the nitro-brominated compounds of azobenzene formerly described—trinitro-dibromo-azoxybenzene, $C^{12}H^7(NO^2)^3Br^2N^2O$, as ultimate product. 3. The brominated compound is converted by ammonium sulphide into hydrodibromazobenzene, $C^{12}H^{10}Br^2N^2$, just as azobenzene is converted into hydrazobenzene, $C^{12}H^{12}N^2$. 4. Digested with warm fuming sulphuric acid, it yields dibromazobenzene-sulphonic acid, $C^{12}H^8Br^2N^2SO^2.3H^2O$, analogous to Griess's azobenzenesulphonic acid (1st *Suppl.* 270). 5. The brominated body is produced by treating the alcoholic solution of monobromonitrobenzene with potassium hydrate, just as azobenzene is obtained from nitrobenzene.

Dibromazobenzene dissolves easily in boiling benzene, and separates on cooling in large yellow needles. It is also dissolved readily by carbon sulphide and by chloroform. It melts at 205°, and sublimes without decomposition.

Tetrabromazobenzene, $C^{12}H^6Br^4N^2$, is obtained as a byo-product in the preparation of dibromazobenzene, and is likewise produced when bromine is added drop by drop to a hot, strong, alcoholic solution of azobenzene. It forms white crystals, very slightly soluble in alcohol, easily soluble in boiling benzene of high boiling point, from which it crystallises on cooling in white silky needles; it is but slightly soluble in chloroform, ether, and carbon sulphide. It melts at about 320°, and then begins to decompose and blacken. Strong nitric acid dissolves it, and the solution mixed with water yields long yellow needles of a substance which explodes when heated.

Werigo once obtained, in the preparation of dibromazobenzene, another product exhibiting the composition of tribromazobenzene, $C^{12}H^7Br^3N^2$, but it was not produced on any subsequent occasion.

Hydrodibromazobenzene, $C^{12}H^{10}Br^2N^2$, is prepared by passing dry ammonia gas and hydrogen sulphide into an alcoholic solution of dibromazobenzene, mixed with an excess of that substance in the solid state; the excess then gradually dissolves, the solution soon becomes colourless, and, on adding water, the hydrodibromazobenzene separates in slender white silky needles, easily soluble in alcohol and ether, and unaffected by exposure to the air. Like hydrazobenzene, it is decomposed in alcoholic solution by nitrous acid, yielding dibromazobenzene, which separates in yellow crystals. The reaction is:

Hydrodibromazobenzene turns red and melts at 130°, and begins to decompose at 160°. When heated to 150° and then cooled, it solidifies to a mass from which hydrochloric acid removes monobromaniline, leaving dibromazobenzene, the decomposition being precisely analogous to that of hydrazobenzene into aniline and azobenzene:—

It has not yet been converted into a compound analogous to bensidine,

Hydrodibromazobenzene appears to be trimorphous. Its concentrated alcoholic solution left to itself in a closed test-tube, deposits, first transparent prismatic crystals, which gradually become opaque on exposure to the air, then yellowish laminae, and lastly, thick yellow crystals. All three forms have the same melting point (130°), and behave in the same manner when heated.

Additive Bromine and Chlorine Compounds of Azobenzene.

(a) $2C^{12}H^{10}N^2.3HBr$ and $2C^{12}H^{10}N^2.3HCl$. The trihydrobromide separates in carmine-red crystals when dry hydrogen bromide is passed into a solution of azobenzene in carbon sulphide or chloroform. When exposed to the air it quickly decomposes into azobenzene and hydrogen bromide, and must be washed with carbon sulphide saturated with hydrogen bromide, in which it is but slightly soluble. It dissolves in pure carbon sulphide and in chloroform, being, at the same time, resolved into azobenzene and hydrogen bromide. Alcohol, ether, and water decompose it in a similar manner. When cautiously heated, it leaves a residue of azobenzene.

The trihydrochloride, prepared like the trihydrobromide, forms yellow crystals still more unstable than the latter.

(b) $C^{12}H^{10}N^2.HBr.Br^2$. A body having this composition may be obtained in the three following ways:—(1). By adding excess of phosphorus pentabromide to a solution of azobenzene or azoxybenzene in ether or in chloroform, and heating the mixture. The reaction proceeds quietly, with evolution of hydrogen bromide, and the addition-product (b) separates in crystals which must be washed, not with ether but with carbon sulphide. Both these solvents decompose the compound more or less, but the products formed by carbon sulphide are dissolved at the same time and carried away, leaving the rest of the compound on the filter in its original state. (2). By adding bromine to a solution of the hydrobromide, $2C^{12}H^{10}N^2.3HBr$, in chloroform, and washing the crystals which separate with carbon sulphide, containing bromine in solution. (3). By adding bromine and then benzene to a solution of azobenzene in carbon sulphide, and exposing the mixture to sunshine; the bromine-compound then separates in crystals which fill the liquid. The hydrogen bromide required for its formation is generated by the action of the bromine on the benzene: hence the advantage of exposing the mixture to sunshine.

The compound $C^{12}H^{10}N^2.HBr.Br^2$ is a yellow, crystalline, very unstable body, decomposed by ether, alcohol, carbon sulphide, and chloroform, less, however, by chloroform than by any other of these solvents. From its hot concentrated solution in chloroform it may be partly recovered, in crystals, by rapid cooling. The presence of free bromine in these liquids diminishes their action upon it, and an excess of phosphorus pentabromide is essential in preparing it by the first method in order to diminish the action of the ether. Azobenzene is always reproduced in its decomposition by these liquids, and the whole of the bromine may be precipitated from its alcoholic solution by silver nitrate, silver oxide, or barium peroxide. When cautiously heated or exposed to the air, or left over sulphuric acid under a bell-jar, it decomposes, and finally leaves a residue of azobenzene; but, when prepared by the third method, and generally also when prepared by the first, it likewise yields, on exposure over sulphuric acid an intermediate product, consisting of ruby-red, short, prismatic crystals, which increase in size for a time, and then break up, yielding azobenzene as one of the products of their decomposition; whereas, when prepared by the second method, and occasionally also, when prepared by the first, it passes into azobenzene without the previous formation of these ruby-red crystals. This difference of behaviour might induce the supposition that the processes in question yield two different bodies, perhaps $C^{12}H^{10}N^2.HBr.Br^2$, and $C^{12}H^{10}N^2.2HBr.Br$; but, on estimating, by means of sodium thiosulphate, the quantity of free bromine resulting from the decomposition of the compound, this amount is found to be the same in both cases, namely, Br^2 .

(c) The hexbromide, $C^{12}H^{10}N^2.Br^6$, separates after some time from a dilute solution of azobenzene in chloroform to which an excess of bromine has been added, in large, dark red, transparent prisms, which decompose very rapidly when removed from the mother-liquor; they may be washed with a solution of bromine in chloroform, and dried in an atmosphere of bromine. The hexbromide is apt to be mixed with a little dibromazobenzene, unless great care has been taken to prevent rise of temperature during its preparation (Werigo, *Ann. Ch. Pharm.* clxv. 203-216).

Azobenzene heated in sealed tubes with fuming hydrochloric acid, is converted, as shown by Ziinin, into benzidine, $C^{12}H^{12}N^2$. In this case an addition of H^2 takes place, but the product undergoes an isomeric transformation. The same result is

obtained by boiling azobenzene with fuming hydrobromic acid; also, and with still greater facility, with hydriodic acid.

Azoxybenzene, $C^{12}H^{10}N^2O$, or $\begin{array}{c} C^6H^5-N \\ | \\ C^6H^5-N \end{array} \begin{array}{c} \diagup \\ \diagdown \end{array} O$. This compound is not attacked

by strong *hydrobromic acid* at the boiling heat, but when the two substances are heated together in a sealed tube, reaction begins at 250° , and the whole solidifies on cooling to a crystalline mass of dibromaniline hydrobromide. By heating with *hydriodic acid*, azoxybenzene is easily converted into benzidine hydriodide, with separation of iodine. Strong *hydrochloric acid* heated with azoxybenzene in sealed tubes, begins to act upon it at a high temperature, but the tubes then explode (Sendzink, *Zeitschr. f. Chem.* [2] vi. 286).

Azoxybenzene is violently attacked by *phosphorus pentabromide*, with evolution of hydrogen bromide and formation of resinous products; but when the action is moderated by the use of ethereal solutions, yellow crystals are formed, consisting of the compound $C^{12}H^{11}N^2Br^2$, or $C^{12}H^{10}N^2.HBr.Br^2$, already described (p. 149) (Werigo, *Zeitschr. f. Chem.* [2] vi. 387).

Phosphorus pentachloride rapidly converts azoxybenzene into azobenzene, but in ethereal solution a product is formed, apparently similar to that which is obtained with the pentabromide (Werigo, *Ann. Ch. Pharm.* clxv. 203).

Sodium-amalgam does not simply reduce azoxybenzene to azobenzene, but converts it into hydrazobenzene, and azoxy-compounds generally into the corresponding hydrazo-compounds (1st Suppl. 270).

Dibromazoxybenzene, $C^{12}H^8Br^2N^2O$. Sodium-amalgam, which converts nitrobenzene into azobenzene, according to the equation $2C^{12}H^5NO^2 - O^2 = C^{12}H^{10}N^2$, does not act in a precisely similar manner on monobromonitrobenzene, so as to produce dibromazobenzene, but takes away only 3 atoms of oxygen instead of 4, producing dibromazoxybenzene: $2C^{12}H^4BrNO^2 - O^2 = C^{12}H^8Br^2N^2O$. This substance is yellow, crystalline, easily soluble in hot alcohol and hot benzene, melts at 175° (Werigo, *Ann. Ch. Pharm.* clxv. 198). Hofmann & Goyger (*Deut. Chem. Ges. Ber.* v. 916) by treating an ethereal solution of bromonitrobenzene (melting at 126°) with sodium, obtained a black substance which, when decomposed by methyl iodide or hydrochloric acid, yielded dibromazoxybenzene, crystallising from alcohol in leaflets, and melting at 172° .

Trinitro-dibromazoxybenzene, $C^{12}H^8Br^2(NO^2)^3N^2O$, is formed, together with nitrated dibromazobenzenes, by the action of fuming nitric acid on dibromazobenzene. It is crystalline, very slightly soluble in alcohol, melts at 174° , solidifying to a resinous mass on cooling, and decomposes at a higher temperature (*ibid.* 191).

Dichlorazoxybenzene, $C^{12}H^8Cl^2N^2O$, is formed by heating solid chloronitrobenzene with alcoholic potash. A violent reaction takes place, and the mixture on cooling solidifies to a mass of long, hair-like crystals of dichlorazoxybenzene, melting at 155° – 156° , insoluble in water, and slightly soluble in alcohol, from which it is deposited in pale yellow needles having a silky lustre.

The liquid modification of chloronitrobenzene, treated with alcoholic potash, yielded also a small quantity of dichlorazoxybenzene; but this was probably due to the presence of a small quantity of the solid modification, inasmuch as the greater part of the fluid chloronitrobenzene remained unacted upon, even in presence of an excess of potash.

Dichlorazoxybenzene dropped into warm fuming *nitric acid* is dissolved, and the solution, on addition of water, or on cooling, deposits dichloronitrazoxybenzene, $C^{12}H^7Cl^2(NO^2)^2N^2O$, as a bright yellow substance, melting at 134° , insoluble in water, and sparingly soluble in alcohol, from which it is deposited in felt-like flocks, consisting of small needles. Its crystals have a beautiful silky lustre, and are difficult to powder. It is apparently reduced by ammonium sulphide, but the product has not been isolated.

Dichlorazoxybenzene added to fuming sulphuric acid, dissolves with slight evolution of heat, the solution at the same time acquiring a metallic reflex, like that of the aniline colours. On cooling, a crystalline substance is deposited, which, when boiled with alcohol and animal charcoal, yields long, reddish-yellow needles of dichlorazobenzene, melting at 183° , insoluble in water, and sparingly soluble in alcohol. Other products appear to be formed at the same time.

If solid chloronitrobenzene be heated with alcoholic potash, and, after the conversion into dichlorazoxybenzene, the mixture be distilled in a retort, a stage is reached at which a violent reaction takes place, resulting in the formation of chloraniline, which passes over in oily drops, and of dichlorazobenzene, which sublimes in yellowish-red crusts, melting at 183° , and identical with that above described. Dichlorazobenzene treated with ammonium sulphide yields white needles, the nature of which has not yet been determined (K. Heumann, *Deut. Chem. Ges. Ber.* v. 910).

When chloronitrobenzene (melting at 83°) is dissolved in anhydrous ether, and small fragments of sodium are added, the metal is gradually transformed into a black friable substance, which becomes warm and turns yellow on exposure to the air. This substance dissolves in water with red colour, and when heated to 100° with ether and methyl iodide, yields a yellow crystalline mass, which, on distillation with water, gives a distillate containing methyl iodide and chloronitrobenzene, melting at 83° , and the residue, when crystallised from alcohol, yields dichlorazoxybenzene. The black substance, treated with concentrated hydrochloric acid, yields a yellow crystalline mass similar to that obtained by the action of methyl iodide, and likewise yielding dichlorazoxybenzene.

When the black substance is suspended in ether and treated with benzoyl chloride, an energetic action takes place, the black colour changes to yellow, and the product, distilled with water, gives a distillate containing nitrochlorobenzene. The residue on crystallisation from alcohol yields a substance which has the composition $C^{12}H^{10}Cl^2N^2O^2$, crystallises in long prisms, melts at 125° , is insoluble in water, and moderately soluble in alcohol or ether. This substance may be regarded as hydro-dichlorazoxybenzene, $C^{12}H^{10}Cl^2N^2O$, in which two hydrogen-atoms are replaced by benzoyl:—

The black substance may be regarded as containing the corresponding sodium compound:—

Dichlorazoxybenzene treated with ammonium sulphide yields, not the corresponding hydro-compound $C^{12}H^{10}Cl^2N^2O$, as might have been expected, but hydrodichlorazobenzene, $C^{12}H^{10}Cl^2N^2$ or $C^6H^5Cl-N=N-NH-C^6H^5Cl$, a compound formed from dichlorazoxybenzene by substitution of H^2 for O . This substance crystallises from alcohol in fine colourless crystals, melting at 122° . Its alcoholic solution boiled in the air for a long time, or heated to the boiling point with animal charcoal, turns yellow, and deposits crystals of dichlorazobenzene.

Sodium has no action on an ethereal solution of fluid chloronitrobenzene (Hofmann a. Geyger, *Deut. Chem. Ges. Ber.* v. 915).

Oxyazobenzene, $C^{12}H^{10}N^2O$ or $C^6H^5-N=N-OC^6H^5$. This compound, isomeric with azoxybenzene, is formed by the action of potassium phenate in aqueous solution on nitrate of diazobenzene:—

The reaction takes place without evolution of gas, and the oxyazobenzene gradually separates in a brown resinous mass, which soon solidifies in the crystalline form. It agrees in all its properties with the phenol-diazobenzene (azodiphenylamic acid $C^6H^5O.C^6H^5N^2$, iv. 433), which Griess obtained, together with phenol-didiazobenzene $C^6H^5O.2C^6H^5N^2$, by heating an aqueous solution of diazobenzene nitrate with barium carbonate (Kekulé a. Heideggh, *Zeitschr. f. Chem.* [2] vi. 384). According to Tschervinsky (*Deut. Chem. Ges. Ber.* vi. 560), it crystallises in brick-rod prisms, melting at 150° (according to Griess at 148°), dissolves at boiling heat in dilute alcohol and in toluene, slightly in boiling water. Its ammoniacal solution gives with silver nitrate a gelatinous precipitate which becomes crystalline on standing. Nitric acid converts it into picric acid.

Benzoylazobenzene, $C^{12}H^{10}(C^6H^5O)N^2O$, is easily soluble in toluene, sparingly in ether, still less in alcohol, crystallises in tables, nodules, or tetrahedrons, melts at 136° (Tschervinsky).

When oxyazobenzene is heated to 100° with phosphorus pentachloride, hydrochloric acid is given off; and a body is formed which crystallises from alcohol in long orange-red needles having the composition $C^{12}H^{10}N^2O^2$. This body is probably oxy-azoxybenzene,

It is converted by sodium-amalgam into a body which crystallises in yellowish needles: probably the corresponding hydrazo-compound (Kekulé a. Heideggh, *loc. cit.*).

BENZENE-SULPHONIC ACIDS.—*Benzene-disulphonic* or *Disulphobenzenic acid*, $C^6H^4(SO^3H)^2$. The potassium salt of this acid mixed with potassium cyanide and subjected to dry distillation, yields, together with a large quantity of ammonia, a liquid consisting of benzene, benzonitril, and paradicyanobenzene, $C^6H^4(CN)^2$ (1 : 4); a liquid which does not boil at 195° , solidifies on cooling, and when boiled with an alkali yields terephthalic acid: hence benzene-disulphonic acid, prepared as above is, for the most part, a para-compound. (Wislicenus a. Brunner, *Deut. Chem. Ges. Ber.* iv. 984).

Amidobenzene-sulphonic acid, $C^6H^4(NH^2).SO^3H$.—This mixture of isomeric acids, obtained by the action of sulphuric acid on phenol, gives with aniline (amidobenzene), a crystalline product soluble in water and in alcohol. This, when freed from excess of sulphuric acid and cautiously heated, gives off phenol, aniline and sulphurous oxide, and leaves an amidobenzene-sulphonic acid isomeric with Laurent's sulphanic acid, and apparently identical with the sulphanic acid of Gerhardt, Hofmann, Buckton, and Schmitt (v. 477). Pratesi (*Deut. Chem. Ges. Ber.* v. 970).

Amidobenzene-sulphonic acid in aqueous solution is not acted upon by cupric chloride alone; but if, whilst the liquid is boiling, ammonium chloride and a small quantity of ammonia be added, it becomes immediately of a dark red colour. On removing the copper by sulphuretted hydrogen, the colouring matter is reduced, and the liquid becomes brown. On allowing it to remain in contact with air, it is again oxidised, the surface becomes once more red, and on shaking, or on removing the sulphuretted hydrogen by warming, the original colour returns. On evaporation, the colouring matter is obtained. By the addition of a sufficient quantity of copper chloride, amidobenzene-sulphonic acid is completely decomposed. The colouring matter is easily dissolved by water and alcohol, which it colours intensely red; it is completely insoluble in ether and in benzene. It is destroyed by tin chlorino and nitric acid; concentrated sulphuric acid dissolves it with brown coloration; on diluting the solution, the characteristic red colour reappears (H. Rose, *Deut. Chem. Ges. Ber.* v. 41).

Azobenzene-sulphonic acid, $C^{12}H^9N^2SO^3$.—This acid, discovered by Griess (*Ann. Ch. Pharm.* cxxxi. 89; *eliv.* 208), and further examined by Skandarow (*Zeitschr. f. Chem.* [2] vi. 643), is produced by heating azobenzene with fuming sulphuric acid to 130° . The liquid, diluted with a moderate quantity of water, deposits the sulpho-acid, which when re-crystallised from a larger quantity of water, forms shining orange-yellow laminae. Its salts are mostly crystallisable. The potassium salt $C^{12}H^9KN^2SO^3 + 2H^2O$ crystallises in shining orange-yellow tables; the silver salt $C^{12}H^9AgN^2SO^3$ also in tables. The barium salt $Ba(C^{12}H^9N^2SO^3)^2$ is sparingly soluble in water.

The acid fused at a gentle heat with potassium hydrate yields the compound $C^{12}H^9N^2O$, identical with phenol-diazobenzene or azodiphenylamic acid (iv. 433); and by treating this compound with ammonium sulphide, a base is produced, probably $C^{12}H^{12}N^2O$.

By saturating an ammoniacal solution of azobenzene-sulphonic acid with hydrogen sulphide, evaporating and precipitating with hydrochloric acid, benzidine-sulphonic or hydrazobenzene-sulphonic acid, $C^{12}H^{12}N^2SO^3$, is obtained. This acid dissolves sparingly in hot water and crystallises therefrom in yellow needles or laminae. Its barium salt $Ba(C^{12}H^{12}N^2SO^3)^2$ crystallises in light yellow shining laminae. The acid does not dissolve in ammonia or other alkalis, but is resolved thereby into benzidine and sulphuric acid.

Azobenzene-sulphonic Chloride, $C^{12}H^9N^2SO^3Cl$, is formed by treating potassium azobenzene-sulphonate dried at 165° with phosphorus pentachloride. The action commences at ordinary temperatures, but must be completed by heating for a few hours in the water-bath, after which the product may be mixed with water, and the precipitated solid chloride dried and crystallised from pure ether. It forms loosely-coherent orange-yellow nodules, insoluble in water, and slowly resolved by boiling with water into hydrochloric and azobenzene-sulphonic acid. It dissolves in alcohol, and is decomposed thereby, without however yielding an ether. It is also decomposed by ammonia and by boiling potash (Skandarow).

Azobenzene-sulphamide, $C^{12}H^9N^2SO^3NH^2$, is prepared by treating the chloride with strong ammonia. The reaction begins spontaneously, and is attended with rise of temperature. The product is heated in the water-bath to expel the excess of ammonia; the sal-ammoniac formed in the reaction is dissolved out by cold water; and the amide, after drying, is recrystallised from boiling alcohol. It is an orange-yellow powder, insoluble in water, slightly soluble in boiling alcohol, insoluble in caustic alkali; gives off ammonia when boiled with potash (Skandarow).

Dibromobenzene-sulphonic acid, $C^6H^2Br^2N^2SO^3 + 3H^2O$. When a warm solution of dibromobenzene in fuming sulphuric acid is digested for some time, and then poured into boiling water, the liquid becomes filled with yellow crystals of the brominated sulpho-acid, provided a certain quantity is present; if more or less than this particular quantity of water has been taken, the acid remains in solution. It thus resembles azobenzene-sulphonic acid in being soluble both in water and in strong sulphuric acid, as well as in the mode of its production. It is monobasic, and dissolves easily in water, alcohol, and ether, the solutions having an acid reaction. A hot concentrated aqueous solution gelatinises when suddenly cooled, but gradually becomes filled with crystals. It occurs in three forms, appearing under the microscope as very slightly coloured needles, broad yellow plates, and reddish crystals pointed at both ends.

The *potassium salt* resembles the free acid in appearance, but is less soluble in water and still less in alcohol. From its hot alcoholic solution it separates on cooling in orange-yellow needles. The *silver salt* is a yellow, amorphous powder, very slightly soluble in water and in alcohol (Werigo).

Oxyazobenzene-sulphonic acid, $C^{12}H^8N^2O.SO^3H$, obtained by heating oxyazobenzene in the water-bath with 3 or 4 parts of fuming sulphuric acid, and purified by separation from its barium salt, crystallises in well-defined octohedral combinations, and is easily soluble in water. The sparingly soluble *barium salt* $Ba(C^{12}H^8N^2O.SO^3)^2 + 2H^2O$ crystallises in gold-yellow laminae. The easily soluble *copper salt* and the *magnesium salt* contain $6H^2O$; the *potassium salt* is anhydrous (Tschirvinsky, *Deut. Chem. Ges. Ber.* vi. 560).

Bromobenzene-sulphonic acid, $C^6H^4Br.SO^3H$.—According to A. Ross-Garrick, the acid formed by the action of bromine on benzene-sulphonic acid is isomeric, not identical, with that which Couper obtained by dissolving bromobenzene in sulphuric acid, differing from the latter, partly by the forms of its salts, but more especially in apparently yielding hydroquinone when fused with potash, whereas Couper's acid yields resorcin. According to Genz, on the other hand, the isobromobenzene-sulphonic acid prepared by the action of bromine on benzene-sulphonic acid yields resorcin as well as hydroquinone by fusion with potash (*1st Suppl.* 274).

To throw further light on this question, the behaviour of isobromobenzene-sulphonic acid with potassium hydrate has been re-examined by A. Wölz (*Zeitschr. f. Chem.* [2] vii. 449; *Ann. Ch. Pharm.* clxviii. 88), who obtained an oily product, exactly as described by Garrick, only partially soluble in water; the aqueous solution left on spontaneous evaporation a dark-coloured crystalline residue, from which, by sublimation, pure resorcin was obtained. Pure hydroquinone was ascertained to give no trace of its isomerides when similarly sublimed, nor was it altered by fusion with potassium hydrate, so that the resorcin cannot have been a product of the conversion of hydroquinone.

Further, potassium isobromobenzene-sulphonate was distilled with potassium cyanide, whereby a liquid and a solid product were obtained: the former gave benzoic, the latter terephthalic acid on treatment with alkali. The results obtained with potassium hydrate and with potassium cyanide are, therefore, in complete accordance, and necessitate a re-examination of the two series of salts.

Bromobenzene-sulphochloride, $C^6H^4BrSO^2Cl$, is produced by dissolving bromobenzene with gentle heat in fuming sulphuric acid, neutralising the solution with lime, separating the calcium salt of the bromobenzene-sulphonic acid from the gypsum by extraction with boiling water, converting it into the corresponding sodium salt, and heating the latter in the dry state with the calculated quantity of phosphorus pentachloride in a capacious flask till the entire mass becomes liquid. After cooling, the sulphochloride is washed with water and dissolved in ether free from alcohol, from which it crystallises with great facility, forming large shining prismatic crystals belonging to the triclinic system, and exhibiting the combination $P \infty . \frac{P}{2} . OP$. It

melts at $75-76^\circ$ (Hübner u. Alsborg, *Zeitschr. f. Chem.* [2] vi. 389).

Bromobenzene-sulphydrate, C^6H^4BrSH , is formed by heating the sulphochloride with tin and concentrated hydrochloric acid, the liquid then turning blue. It volatilises with vapour of water, dissolves easily in hot, slowly in cold alcohol, and crystallises in white laminae resembling naphthalene, and melting at 75° . The alcoholic solution forms with *lead acetate* a bright yellow precipitate; with *mercuric chloride* a heavy white precipitate, both insoluble in water and in alcohol; with *cupric acetate* and *silver nitrate* it forms dirty yellow precipitates (Hübner u. Alsborg).

Dibromobenzene-sulphonic acid, $C^6H^2Br^2.SO^3H$, is obtained by dissolving dibromobenzene in Nordhausen sulphuric acid, diluting with water, neutralising with

lime, decomposing the resulting calcium salt with sulphuric acid, and dissolving out the sulpho-acid with alcohol; or, better, by neutralising with lead carbonate and decomposing the lead salt with hydrogen sulphide.

The sulpho-acid crystallises in silky needles, which gradually change into compact plates. It contains 2 mol. water of crystallisation, and melts at about 117° , becoming brown at the same time.

Its *calcium salt* $(C^6H^3Br^2SO^3)^2Ca + 4H^2O$ forms long colourless needles, very soluble in water; the *silver salt* $C^6H^3Br^2SO^3Ag + 3H^2O$ transparent needles, also very soluble. The *lead salt* $(C^6H^3Br^2SO^3)^2Pb + 3H^2O$ crystallises from a saturated solution in fine, long, six-sided prisms, which change after some time into largo, compact, rhombic tables. The *barium salt* $(C^6H^3Br^2SO^3)^2Ba + 2H^2O$, the *sodium salt* $C^6H^3Br^2SO^3Na + 1\frac{1}{2}H^2O$, and the *potassium salt* $C^6H^3Br^2SO^3K + H^2O$, are very soluble in water; the first crystallises in four-sided tables, the other two in needles (R. Douglas Williams, *Zeitschr. f. Chem.* [2] vii. 302. Hübner a. Williams, *Ann. Ch. Pharm.* clxvii. 117).

This acid has also been prepared in the same manner as above by A. Wölz (*ibid.* 353; further, *Ann. Ch. Pharm.* clxviii. 81), whose results agree for the most part with those of Williams. He finds, however, that the crystallised acid contains 3 mol. water of crystallisation, only 2 of which are given off at 100° , the remainder at about 120° , at which temperature the acid undergoes further decomposition. According to Wölz, also, the *calcium salt* contains 9 mol. water instead of 4, as found by Williams; the *barium salt* dried over sulphuric acid is anhydrous; the *copper salt* $(C^6H^3Br^2SO^3)^2Cu$ forms long shining laminae, apparently containing $14H^2O$; the *ammonium salt* $C^6H^3Br^2SO^3(NH^4)$ crystallises, from a concentrated solution, in shining needles, and by slow evaporation in compact plates. Wölz believes that his dibromobenzene-sulphonic acid is identical with that of Williams, and isomeric with that which Schmitt obtained some years ago by decomposing dibromodiazobenzene-sulphonic acid with boiling alcohol (*Ann. Ch. Pharm.* cxx. 158).

Dibromonitrobenzene-sulphonic acid, $C^6H^2Br^2(NO^2).SO^3H$, is obtained as a viscous mass on boiling dibromonitrobenzene with fuming nitric acid. The *potassium salt* $C^6H^2Br^2NO^2SO^3K + 2\frac{1}{2}H^2O$ forms small needles, soluble in alcohol and water; the *barium salt* $(C^6H^2Br^2NO^2SO^3)^2Ba + 2\frac{1}{2}H^2O$ groups of small needles. The *copper salt* $(C^6H^2Br^2NO^2SO^3)^2Cu + H^2O$ is very soluble in water, alcohol, and ether; on evaporating the latter solution, it remains as a syrup, in which crystalline nodules gradually appear. The *lead salt* $(C^6H^2Br^2NO^2SO^3)^2Pb + H^2O$ forms very small, reddish needles, sparingly soluble in water. The *strontium salt* is very soluble, and crystallises in microscopic needles (Hübner a. Williams, *Ann. Ch. Pharm.* clxvii. 121).

BENZHYDROXAMIC ACIDS. (Lossen, *Ann. Ch. Pharm.* clxii. 347).—The successive replacement of the 3 atoms of hydrogen in hydroxylamine NH^3O by benzoyl, gives rise to two acids, namely, benzhydroxamic, $NH^2(C^6H^5O)O$, and dibenzhydroxamic, $NH(C^6H^5O^2)O$, while the replacement of the third atom in like manner produces a neutral body $N(C^6H^5O^2)O$, called tribenzhydroxylamine.

Preparation of Benzhydroxamic and Dibenzhydroxamic Acid.—Benzoyl chloride poured into an aqueous solution of hydroxylamine or its hydrochloride supersaturated with soda, is almost entirely converted into benz- and dibenz-hydroxamic acid. The two acids being produced simultaneously,

1 part of hydroxylamine salt is dissolved in 8 to 10 parts of water with sufficient soda to take up all the chlorine set free by the reaction, and 3 parts benzoyl chloride are added gradually with constant agitation, keeping the mixture cold. The sparingly soluble dibenzhydroxamic acid which separates should be recrystallised from alcohol, and the benzhydroxamic acid, which remains for the most part in solution, may be obtained by precipitating with baryta-water, decomposing with sulphuric acid, purifying the product by crystallisation from a small quantity of warm alcohol, and washing the crystals with ether. The hydroxylamine solution for this preparation may be obtained by digesting tin for a week in the cold with nitric acid, hydrochloric acid and water, and precipitating the tin with soda (1st Suppl. 723).

Benzhydroxamic Acid, $NH^2(C^6H^5O)O$.—The pure acid crystallises in colourless rhombic plates, exhibiting the forms ∞P , $\infty \bar{P}$, \bar{P} , P , and cleaving perfectly

parallel to $\infty P \infty$. Ratio of axes $a : b : c = 0.325563 : 1 : 0.321707$. The crystals are strongly double-refractive, and have the plane of the optic axes parallel to bc (Klein, *Ann. Ch. Pharm.* clxvi. 180). The acid dissolves in 44.5 parts of water at 6° , much more easily in warm water, very easily in alcohol, sparingly in ether and in carbon sulphide, and not at all in benzene. The impure acid forms warty masses. It has an acid reaction, and melts at 124.5° . The acid and its salts are decomposed more or less violently at a high temperature. Heated with dilute hydrochloric or sulphuric acid, it splits up into benzoic acid and a salt of hydroxylamine.

Benzhydroxamic acid is monobasic, but has a tendency to form acid salts. The acid potassium salt $\text{NH}(\text{C}_6\text{H}_5\text{O})\text{OK} \cdot \text{NH}_2(\text{C}_6\text{H}_5\text{O})\text{O}$, and the acid sodium salt $\text{NH}(\text{C}_6\text{H}_5\text{O})\text{ONa} \cdot \text{NH}_2(\text{C}_6\text{H}_5\text{O})\text{O} + 3\text{H}_2\text{O}$, form rhombic prisms or plates, moderately soluble in warm water, little soluble in alcohol. The sodium salt effloresces in dry air. An alcoholic solution of the free acid treated with potash gives a precipitate of the acid salt, redissolved by further addition, but reappearing in crystals as the solution evaporates in air.

The neutral barium salt is obtained in microscopic needles when the acid potassium salt, neutralised with ammonia, is treated with barium chloride. If the ammonia be omitted, a variable mixture of neutral and acid barium salt is precipitated. The latter crystallises in small prisms, together with the free acid, when the neutral salt is decomposed with an insufficient quantity of sulphuric acid, and the filtrate allowed to evaporate. It is nearly insoluble in water and alcohol. The calcium and zinc salts are neutral: the former is an amorphous, the latter a crystalline precipitate.

Solutions of the acid sodium salt give white precipitates with manganous chloride, cadmium sulphate, alum and lead nitrate, nearly white with cupric sulphate, green with chrome alum, whitish green with nickel sulphate, peach-coloured with cobalt nitrate, yellow with mercuric chloride, all soluble in excess; white with silver nitrate, rapidly blackening, and insoluble in excess. Ferric chloride gives a dark red precipitate, soluble with intense red colour in excess, or in dilute sulphuric or hydrochloric acid. The latter when concentrated destroys the colour, but it appears again on dilution.

Dibenzhydroxamic Acid, $\text{NH}(\text{C}_6\text{H}_5\text{O})_2\text{O}$, crystallises by cooling in needles or prisms, by spontaneous evaporation of the alcoholic solution in shining rhombic crystals, which, according to Klein, exhibit the faces $0P$, $\infty P \infty$, ∞P , $2P \infty$, $P \infty$, $2P \infty$, and cleave perfectly parallel to ∞P ; they exert strong double refraction, and have the plane of the optic axes parallel to bc . The acid dissolves with difficulty in water, cold alcohol, ether, or carbon sulphide, more easily in hot alcohol, not at all in benzene. It has an acid reaction, melts at 145° , decomposes violently at a higher temperature, with formation, among other products, of benzanilide. With acids it splits up like benzhydroxamic acid; with alkalis it gives a benzoate and a benzhydroxamate. The latter, by slaking with benzoyl chloride and water, may be reconverted into dibenzhydroxamic acid.

The acid is monobasic and forms neutral salts. The potassium salt $\text{N}(\text{C}_6\text{H}_5\text{O})_2\text{OK}$ crystallises from alcohol in pearly, very thin plates, or microscopic six-sided tables, decomposing with violence by heat, and leaving a benzoate and a sparingly soluble indifferent body. The aqueous solution decomposes on standing, without, however, producing benzhydroxamic acid. The sodium salt is rather more soluble in alcohol than the potassium salt, and forms sharp-pointed prisms.

A fresh solution of potassium dibenzhydroxamate gives white precipitates with manganous chloride, with lead, silver, and cobalt nitrates, and with zinc and cadmium sulphates; blue-green with chrome alum; apple-green with nickel sulphate; and with ferric chloride a reddish-yellow precipitate but no coloration. It is distinguished from benzhydroxamate and oxalhydroxamate by giving no precipitate with salts of the alkaline earths.

Tribenzhydroxylamine, $\text{N}(\text{C}_6\text{H}_5\text{O})_3\text{O}$, is among the products of the action of a solution of benzoyl chloride in a hydrocarbon boiling at 110° , on dry hydroxylamine hydrochloride. It is also formed by heating potassium dibenzhydroxamate to 100° with benzoyl chloride in excess, afterwards removing the benzoyl chloride with ether and the potassium chloride with water, and recrystallising the residue from alcohol. It is insoluble in water, ether, and benzene, nearly insoluble in cold, but easily soluble in boiling alcohol, from which it crystallises in groups of small shining prisms. These crystals (fig. 5), are monoclinic, having the axes $a : b : c = 1.15835 : 1 : 0.334900$, and the angle of the inclined axes $bc = 83^\circ 21' 20''$. Angle $-P : -P = 149^\circ 24'$; $\infty P : \infty P = 96^\circ 36'$; $-P : \infty P = 118^\circ 14'$. Observed forms:—

The plane of the optic axes coincides with the clinodiagonal principal section, and the two principal directions of vibration are so situated in this plane that one runs nearly

parallel to $P\infty$, the other nearly at right angles to it (Klein, *loc. cit.*). Tribenzhydroxylamine melts at 140° , and decomposes at 190° . Its alcoholic solution treated with potash splits up into benzoate and dibenzhydroxamate.

FIG. 5.

Tribenzhydroxylamine admits probably of only one rational formula; but benzhydroxamic and dibenzhydroxamic acid admit each of two: the first may be either $\text{NH}(\text{C}^6\text{H}_5\text{O})(\text{HO})$ or $\text{NH}^+(\text{OC}^6\text{H}_5\text{O})$, the second $\text{N}(\text{C}^6\text{H}_5\text{O})(\text{HO})$ or $\text{NH}(\text{C}^6\text{H}_5\text{O})(\text{OC}^6\text{H}_5\text{O})$.

BENZHYDRYL-BENZOIC ACID.

See BENZOYL-BENZOIC ACID.

BENZIDINE, $\text{C}^{12}\text{H}^{10}\text{N}^2 = \text{C}^{12}\text{H}^8(\text{NH})^2$.

—The cyanide of this base, $\text{C}^{12}\text{H}^{10}\text{N}^4 \cdot 2\text{CN}$, is formed when benzidine, prepared from azobenzene, decolorised by boiling with animal charcoal, and purified by several recrystallisations from alcohol, is dissolved in alcohol, and cyanogen gas is passed into the solution till the liquid smells strongly of it. The liquid, if then left to itself for two days, deposits benzidine cyanide as a red mass, the quantity of which gradually increases. This compound appears amorphous under the microscope; it is insoluble in water, slightly soluble in alcohol, ether, and benzene, somewhat more freely in light petroleum oil, but even in this liquid it is not sufficiently soluble to admit of purification by solution and separation. It is resolved by acids into benzidine and oxalic acid (Wittenstein, *Deut. Chem. Ges. Ber.* iii. 723).

Nitrobenzidines.—Benzidine treated with nitric acid yields only oxidation-products, no nitro-compounds. To obtain the latter, benzidine must first be converted into acetobenzidine, which is easily effected by boiling benzidine with glacial acetic acid for two hours.

Acetobenzidine, $\text{C}^{12}\text{H}^8(\text{NH} \cdot \text{C}^6\text{H}_5\text{O})^2$, is insoluble in water, and crystallises from hot alcohol in white needles. It is a very stable compound, not so easily decomposed by stronger acids as acetanilide.

Cold nitric acid converts it into **dinitracetobenzidine**, $\text{C}^{12}\text{H}^8(\text{NO}_2)^2(\text{NH} \cdot \text{C}^6\text{H}_5\text{O})^2$, a yellow crystalline powder which, when boiled with caustic potash, yields **dinitrobenzidine**, $\text{C}^{12}\text{H}^8(\text{NO}_2)^2(\text{NH})^2$, a light red crystalline powder, insoluble in water, but soluble in hot alcohol, from which solution it separates after some time in larger crystals having a beetle-green lustre. The **hydrochloride** forms shining dark yellow plates, and is a very unstable body, being readily decomposed by water as well as by heat.

Dinitrobenzidine does not appear to be convertible into amidobenzidine by the action of reducing agents. By acting on the dinitro-compound with tin and hydrochloric acid, the nitrogen of the nitro-group is separated in the form of ammonia, and benzidine is formed, whilst by heating it with ammonium sulphide only indefinite brown substances are obtained.

On digesting benzidine with carbon sulphide, the compound $\text{C}^{12}\text{H}^8 \left\{ \begin{smallmatrix} \text{NH} \\ \text{NH} \end{smallmatrix} \right\} \text{CS}$ is obtained, a body quite insoluble in all common solvents. Besides this substance, another, having the same composition, but soluble in alcohol, is formed in smaller quantity, to which perhaps the above formula should be given, whilst the insoluble body might be a polymeride (Strakosch, *Deut. Chem. Ges. Ber.* v. 236).

Benzidine-disulphonic acid or **Hydrazobenzene-sulphonic acid**, $\text{C}^{12}\text{H}^{10}\text{N}^2\text{SO}_3$, is formed by the action of ammonium sulphide on azobenzene-sulphonic acid (see page 152).

Base homologous with Benzidine, $\text{C}^{14}\text{H}^{10}\text{N}^2$ (Petrie, *Zeitschr. f. Chem.* [2] vi. 265). This base is obtained as a hydrochloride or sulphate when strong hydrochloric or sulphuric acid is added by drops to an alcoholic solution of hydrazotoluene prepared from azotoluene by the action of sodium-analgam; hydrazotoluene prepared with ammonium sulphide does not yield it. The aqueous solution of the hydrochloride treated with ammonia deposits the base in colourless transparent laminae having a silvery lustre. These crystals are easily soluble in boiling water, soluble also in alcohol and in ether, melt at 128° – 129° , and decompose at a higher temperature.

The **hydrochloride**, $\text{C}^{14}\text{H}^{10}\text{N}^2 \cdot 2\text{HCl}$, crystallises in colourless laminae, which dissolve

easily in water, but separate from the solution on addition of strong hydrochloric acid. It is insoluble in alcohol and ether. The aqueous solution forms a yellow crystalline precipitate with platinum chloride. There are two *sulphates*, which resemble one another in external characters, but differ in solubility, the one being soluble, the other insoluble in hot water and in alcohol. The insoluble salt, which has the composition $C^{11}H^{10}N_2 \cdot 2HCl$, is a white pulverulent mass, partially decomposed by water, the liquid gradually turning reddish.

BENZILE, $C^{11}H^{10}O^2$.—This compound distilled with soda-lime yields, together with benzene, considerable quantities of benzophenone or diphenyl ketone, $C^{14}H^{10}O^2 = CO + CO(C^6H^5)^2$. Heated with potassium sulphhydrate, to 120° , it is converted into benzoin and toluylene oxide or deoxybenzoin:

(Jena, *Ann. Ch. Pharm.* clv. 77).

Benzile tetrachloride, $C^{11}H^{10}O^2Cl^4$, treated with zinc in alcoholic solution yields two isomeric compounds, $C^{11}H^{10}Cl^4$, the first of which forms white rhombic plates, melting at 153° , and dissolving in 10 parts of boiling alcohol, whereas the second crystallises in long needles or six-sided prisms, which melt at 63° and dissolve in any quantity of boiling alcohol; 10 parts of the tetrachloride yield 2.2 to 2.4 parts of the first and 6 to 5.2 parts of the second compound. Both these compounds dissolve without decomposition in ether and acetic acid. They are not attacked by zinc, or by alcoholic potash at 130° ; sodium-amalgam, on the other hand, converts them into toluene (Zinin, *Zeitschr. f. Chem.* [2] vii. 284).

Dinitrobenzile, $C^{11}H^8(NO^2)^2O^2$.—Benzile treated with boiling fuming nitric acid, yields two isomeric *dinitrobenziles*, one crystallising in octohedrons which melt at 131° and dissolve in 41 parts of boiling and 137 parts of cold alcohol; the second crystallising in plates, which melt at 147° and dissolve in 52.5 parts of boiling and 230 parts of cold alcohol (Sagmenny, *Deut. Chem. Ges. Ber.* v. 1100).

BENZILIC ACID, $C^{11}H^{12}O^3$ (Jena, *Ann. Ch. Pharm.* clv. 77).—This acid is formed by heating benzile with water, or better with alcoholic potash:

Benzile dissolves in alcoholic potash with deep violet colour, and its conversion into benzoic acid takes place sometimes at ordinary temperatures, the liquid becoming heated to the boiling point of the alcohol, sometimes only after heating over a gas flame. After the reaction is ended, the liquid must be heated till it becomes light yellow, then mixed with water and precipitated with hydrochloric acid. If the benzoic acid is only slightly contaminated with benzoic acid, it may be completely purified by one or two crystallisations from hot water. If a larger quantity of benzoic acid is present, it is best to digest the precipitate with a quantity of sodium carbonate not sufficient to dissolve it completely; the benzoic acid is then chiefly dissolved, and may be precipitated from the filtrate by hydrochloric acid and recrystallised from hot water.

Benzilic acid was originally obtained by oxidation of benzoin, $C^{11}H^{12}O^2$ (i. 515), and is commonly said to be formed from that substance also by the action of alcoholic potash; according to Jena, however, this takes place only when the benzoin is contaminated with benzile; and according to Limpricht & Schwanert (*Deut. Chem. Ges. Ber.* iv. 336), the products obtained by heating benzoin with alcoholic potash are different, according as the reaction takes place in an open flask or in sealed tubes. In the former case the benzoin is partly converted by the oxidising action of the air, into benzile—the formation of which is rendered evident by the deep violet colour which the liquid assumes from the beginning of the action,—and the benzile is then converted into benzoic acid as above. When, on the other hand, the reaction takes place in sealed tubes, no benzoic acid is obtained, or only a trace—and the liquid exhibits the violet coloration above mentioned only at the commencement of the reaction, a small quantity of benzile being then formed by the oxidising action of the air in the tube.

Benzilic acid crystallises in small monoclinic needles, which have a white colour and satiny lustre, but assume a fine reddish colour at 110° , melt at 150° ,* the liquid

* It is commonly stated that benzoic acid melts at 120° ; this, however, is the melting point of benzoic acid, which is often formed in considerable quantity simultaneously with benzoic acid, by the action of alcoholic potash on benzile, and when contaminated with traces of benzoic acid, exhibits the red coloration characteristic of the latter when heated or acted upon by sulphuric acid.

becoming deep red at a higher temperature; the same colour is produced by treatment with strong sulphuric acid, but disappears on addition of water. It has a bitter taste; dissolves easily in alcohol, ether and hot water, very sparingly in cold water.

Barium Benzilate, $\text{Ba}(\text{C}^{11}\text{H}^{11}\text{O}^3)^2 + 6\text{H}^2\text{O}$, obtained by dissolving the acid in baryta-water, decolorising with animal charcoal and evaporating, forms white crusts. The silver salt obtained by precipitation is white, but becomes dark coloured, gradually at ordinary temperatures, more quickly when heated. *Ethyl benzilate* is precipitated on adding water to the alcoholic solution of benzilic acid mixed with hydrochloric acid, as a yellow oil, which has an odour of peppermint, does not crystallise, and is decomposed by distillation.

Benzilic acid heated for several hours to 180° is converted into a deep red liquid, which solidifies on cooling to an amorphous mass easily soluble in alcohol. On evaporating the alcoholic solution thus obtained, several compounds crystallise out, among which are dibenzilic acid $\text{C}^{28}\text{H}^{20}\text{O}^3 = 2\text{C}^{14}\text{H}^{10}\text{O}^3 - \text{H}^2\text{O}$, and benzophenone $\text{C}^{18}\text{H}^{10}\text{O}$. A similar decomposition appears to take place when benzilic acid is heated to 150° with hydrochloric acid. By dry distillation benzilic acid yields a red-brown empyreumatic oil, which may be distilled with aqueous vapour, but carbonises when heated alone to 270 – 280° . Benzilic acid is not altered by heating to 150° for three hours with alcoholic potash.

By oxidising substances, chromic acid for example, benzilic acid is converted into carbon dioxide, water, and benzophenone:

Benzophenone is likewise formed by the dry distillation of silver benzilate, or by prolonged boiling of that salt with water.

Barium benzilate distilled with $\frac{1}{10}$ th of its weight of *soda-lime* is resolved into carbon dioxide and benzhydrol: $\text{C}^{14}\text{H}^{12}\text{O}^3 = \text{CO}^2 + \text{C}^{14}\text{H}^{12}\text{O}$.

Deoxybenzyllic Acid, $\text{C}^{14}\text{H}^{12}\text{O}^2$.—Benzilic acid is not acted upon by sodium-amalgam or by zinc and hydrochloric acid; but when heated to 150° with concentrated *hydriodic acid*, it is reduced to deoxybenzyllic acid. On digesting the product with water, dissolving the residue in aqueous sodium carbonate, and acidulating with hydrochloric acid, the deoxybenzyllic acid is precipitated, and may be purified by crystallisation from hot water or from alcohol, separating from the former in needles resembling those of benzilic acid, from the latter in large laminæ. It is sparingly soluble in cold water, but dissolves easily in hot water, also in alcohol and ether; melts at 146° , and when more strongly heated yields a small sublimate, but does not turn red, like benzilic acid. Heated with strong sulphuric acid, it assumes a greenish-yellow colour. By oxidation with chromic acid it yields the same products as benzilic acid. Its silver salt $\text{AgC}^{14}\text{H}^{11}\text{O}^2 + 2\text{H}^2\text{O}$ obtained by precipitation from a neutralised solution, forms small needles blackening on exposure to light. The barium-salt $\text{Ba}(\text{C}^{14}\text{H}^{11}\text{O}^2)^2 + 2\text{H}^2\text{O}$ is easily soluble in water, and crystallises in tufts of satiny needles, melting above 300° . This salt distilled with a small quantity of soda-lime yields diphenyl-methane, $\text{C}^{18}\text{H}^{12}$ or $\text{CH}_2\left\{\begin{smallmatrix} \text{C}^6\text{H}^5 \\ \text{C}^6\text{H}^5 \end{smallmatrix}\right.$:

The diphenyl-methane passes over as an oil, crystallises at low temperatures, and when purified by solution in alcohol, decoloration with animal charcoal, evaporation, and recrystallisation in a freezing mixture, forms monoclinic prisms, having a very fragrant odour, like that of oranges, melting at 26.4° , soluble in ether and in alcohol. The ethereal solution gives a precipitate after a while with bromine (Jena).

Benzilic acid is regarded by Städeler and by Lämpricht a. Schwanert, as *diphenylglycollic acid* $\text{C}(\text{OH})(\text{C}^6\text{H}^5)^2\text{CO}^2\text{H}$, and deoxybenzyllic acid as *diphenyl-acetic acid* $\text{CH}(\text{C}^6\text{H}^5)^2\text{CO}^2\text{H}$ (see Benzoin).

Ethyl-benzilic acid, $\text{C}^{18}\text{H}^{16}\text{O}^3 = \text{C}^{14}\text{H}^{11}(\text{C}^6\text{H}^5)\text{O}^3$.—A body having this composition is formed, together with several other products, when benzoïn is heated with sodium-alcohol to 160° in sealed tubes (4 grams of benzoïn with 1 gram of sodium dissolved in 20 c. c. spirit of 92 p. c., for two or three hours). On evaporating off the alcohol, mixing the slightly yellowish residue with water, filtering after 12 hours, and treating the filtrate with hydrochloric acid, ethyl-benzilic acid is precipitated, together with a little benzoic acid and a very small quantity of benzilic acid. These two acids may be removed by cold solution of sodium carbonate, which leaves the ethyl-benzilic acid undissolved; and, on washing with water, dissolving the residue in alcohol or ether, and evaporating, ethyl-benzilic acid remains as a light-yellow uncrystallisable mass, having the consistence of turpentine.

Ethyl-benzilic acid distils apparently unaltered, leaving only a small residue. Heated with strong sulphuric acid, it turns first red-brown, then dark brown, but not red like benzilic acid. It is insoluble in water, but dissolves easily in alcohol and ether, the alcoholic solution having an acid reaction. It does not dissolve in cold solution of sodium carbonate or in ammonia, and is nearly insoluble in aqueous potash, but dissolves very easily on addition of a little alcohol. Boiled with baryta-water, it partly dissolves, and is reprecipitated by hydrochloric acid, while another portion is converted into a viscid adhesive resin probably a barium-compound. The alcoholic solution of ethyl-benzilic acid gives a precipitate with neutral lead acetate and a little ammonia, none with silver nitrate, even on careful addition of ammonia. The alcoholic solution, mixed with a small quantity of soda-ley, forms with silver nitrate a white precipitate, which, after drying, turns brown even at a gentle heat. Ethyl-benzilic acid is not altered by heating to 160° for three hours with alcoholic potash, or by digestion in alcoholic solution with sodium-amalgam. Heated to 170° with hydriodic acid, it yields a brown mass insoluble in alcohol and in sodium carbonate. Bromine acts but feebly on it even with the aid of heat, forming resinous products.

It will be seen from the preceding description, that the acid properties of this compound are by no means well defined; indeed, it is doubtful whether the name ethyl-benzilic acid can be appropriately applied to it. (Jena a. Limpricht, *Ann. Ch. Pharm.* clv. 100).

Respecting the constitution of benzilic acid and its derivatives, see Benzoin.

BENZIMIDE. Laurent's benzimide, $C^{12}H^{11}N^2O^2$, produced by the action of hydrocyanic acid on bitter almond-oil, is resolved by heating with water to 160 – 180° into benzoic aldehyde and the imide of formo-benzilic (mandelic) acid (Zinin, *Deut. Chem. Ges. Ber.* iii. 552):

BENZOIC ACID, $C^7H^5O^2$.—This acid is formed by fusing a dry mixture of sodium formate and potassium phenylsulphite:

By dissolving the fused mass in water, distilling after acidulation, neutralising the distillate with sodium carbonate, boiling it with animal charcoal to remove sulphur-compounds, then concentrating by evaporation, and acidulating with hydrochloric acid, benzoic acid is separated, and may be obtained perfectly pure by recrystallisation from water and sublimation (V. Meyer, *Deut. Chem. Ges. Ber.* iii. 112).

Löwe (*J. pr. Chem.* cviii. 257) finds that when gum benzoin is dissolved in alcohol of 95 p. c. and the filtered solution is mixed with alcoholic soda, it deposits after 48 hours a red-brown substance, the aqueous solution of which gives with hydrochloric acid an amorphous precipitate, which, when heated, yields an abundant sublimate of benzoic acid. Hence Löwe infers that the greater part of the benzoic acid does not exist in the resin ready formed—since, in that case, it would have gone down in the soda-precipitate and would have been precipitated in the crystalline form on addition of hydrochloric acid to the aqueous solution of that precipitate—but is produced by the action of heat on a substance previously existing in the resin. The acid filtrate did indeed yield on evaporation a small quantity of benzoic acid, which probably existed in the resin in the free state. The formation of benzoic acid from the resin by heat does not depend on the action of the air, for Löwe found that the same quantity of the acid product is obtained by heating the gum benzoin with an equal weight of sulphuric acid (free from nitric acid), to 170° . The mixture, contained in a leaden dish, is placed in a shallow vessel of iron or copper covered with the usual paper cover, and having fixed to its side a vertical glass tube within which a thermometer is placed. The heat must be applied slowly, as otherwise the mass is apt to froth over.

According to Guichard (*Null. Soc. Chim.* [2] xix. 359), benzoic acid may be advantageously extracted from gum benzoin by means of carbon sulphide. Having left a quantity of benzoin macerating for some time with carbon sulphide, he found it covered with colourless crystals of benzoic acid, and the liquid on evaporation yielded a further crop of nearly pure crystals.

The following determinations of the melting points of mixtures of benzoic and cinnamic acids are given by J. Kachler (*Zeitschr. f. Chem.* [2] vi. 60):—

Benzoic Acid	Cinnamic Acid	Melting Point	Benzoic Acid	Cinnamic Acid	Melting Point
100 p.c.	0	123.3°	40	60	98.7°
99	1	118.2	30	70	108.2
90	10	111.5	20	80	118.0
80	20	106.4	10	90	126.6
70	30	101.4	1	99	131.8
60	40	87.1	0	100	133.3
50	50	81.3			

Hence it appears that the lowest melting point is exhibited by a mixture of the two acids in equal proportions.

Reactions.—1. When *bromine* is added by drops to a mixture of 1 mol. benzoic acid and 1 mol. *phosphorus trichloride*, a violent action takes place, hydrobromic acid being given off, and the mass gradually becoming liquid. The product when subsequently distilled, yields benzoyl chloride and oxychlorobromide of phosphorus:

Phosphorus pentachloride acts in a similar manner (Wichelhaus, *Deut. Chem. Ges. Ber.* i. 77).

According to Gauthier et. Michaelis (*Jenaische Zeitschrift*, vi. 242), the action of bromine and phosphorus trichloride on benzoic acid takes place in a different manner, namely, as represented by the equation:

When 40 grams of benzoic acid, 45.2 PCl^3 , and 52.4 bromine were made to act on one another as described by Wichelhaus, and the mass afterwards fractionated, it separated into a portion boiling at 110°–115° and another passing over at 150°–190°, whereas nothing was obtained having a boiling point of 135°–137° (oxychlorobromide of phosphorus.) From the higher-boiling portion, by cooling and addition of a crystal of phosphorus oxybromide, a portion was obtained in the crystalline state, having the properties and composition of the oxybromide. The greater part of the latter, however, remained dissolved in the benzoyl chloride,

2. When benzoic acid is fused with *potassium hydrate* at 360° for about half-an-hour, paraoxybenzoic acid is formed, together with a yellow amorphous body, $\text{C}^{10}\text{H}^7\text{O}^2$, and brown resinous bodies. A small quantity of a crystalline acid, $\text{C}^{14}\text{H}^{12}\text{O}^2$, easily soluble in alcohol and ether, and giving a violet-red colour with ferric chloride, is likewise produced by the further action of the fused potash on the paraoxybenzoic acid.

3. When benzoic acid is fused with an equal weight of *potassium sulphocyanate*, the reaction commences at 150°, and is terminated at 170°. Carbon oxysulphide, sulphuretted hydrogen, and carbon sulphide are evolved, and a residue is left, consisting principally of benzamide, which can easily be purified by crystallisation. The yield is large, amounting to 81 p.c. of the benzoic acid taken, so that this method can be advantageously employed for the preparation of benzamide.

When potassium sulphocyanate is distilled with two molecules of benzoic acid, scarcely anything but benzonitril is formed (as previously shown by Letts), so that it would seem that the potassium benzoate formed during the reaction abstracts water from the benzamide, forming benzonitril. Benzamide distilled with potassium benzoate yields benzonitril. Ammonium benzoate, on the contrary, has no action on benzamide (Kekulé, *Deut. Chem. Ges. Ber.* vi. 110).

Metallic Benzoates.—Several of these salts have been examined by Sestini, Ciognani et. Zavatti (*Bull. Soc. Chim.* [2] xiii. 488). The *potassium salt* $\text{K}^2\text{C}^6\text{H}^5\text{O}^2 + 3\text{H}^2\text{O}$ is obtained by spontaneous evaporation of its solution, in irregular whitish laminae, which effloresce and fall to powder on exposure to the air. By evaporation under a bell jar over sulphuric acid, colourless anhydrous needles are obtained.

Sodium Benzoate, $\text{NaC}^6\text{H}^5\text{O}^2 + \text{H}^2\text{O}$, forms small efflorescent nodules made up of microscopic prisms.

The *magnesium salt* $\text{Mg}(\text{C}^6\text{H}^5\text{O}^2) + \text{H}^2\text{O}$ is obtained by spontaneous evaporation over sulphuric acid, in spherical masses composed of small oblique prisms, or by evaporating the solution till a crystalline film forms on the surface, as a white laminated mass.

The *zinc salt*, $\text{Zn}(\text{C}^7\text{H}^5\text{O}^2)^2$ crystallises in oblique prisms when its concentrated solution is left to cool, and in shining laminae united in arborescent masses when left to evaporate over sulphuric acid. It is more soluble in cold than in hot water: consequently a solution saturated in the cold becomes turbid when heated, and deposits part of the salt in the anhydrous state.

The *nickel salt* $\text{Ni}(\text{C}^7\text{H}^5\text{O}^2)^2 + 3\text{H}_2\text{O}$ crystallises by spontaneous evaporation in light green crusts. It is efflorescent, slightly soluble in cold, more soluble in hot water.

The *cobalt salt* $\text{Co}(\text{C}^7\text{H}^5\text{O}^2)^2 + 2\text{H}_2\text{O}$ forms delicate, shining, longitudinally striated laminae, which are colourless when viewed separately, but appear peach-blossom-coloured in mass. When heated it gives off its water and acquires a fine blue-violet colour.

The *copper salt* $\text{Cu}(\text{C}^7\text{H}^5\text{O}^2)^2 + 2\text{H}_2\text{O}$ is a light blue precipitate, slightly soluble in cold, abundantly in hot water, and crystallising therefrom in thin, light blue, rhomboidal laminae united in spherical groups; when heated it gives off its water and becomes deep blue.

Tin salts. Benzoates yield insoluble precipitates both with stannous and with stannic chloride. The stannous precipitate is reddish and appears to have the composition $\text{Sn}(\text{C}^7\text{H}^5\text{O}^2)^2 + \text{H}_2\text{O}$. The white precipitate obtained with stannic chloride appears to be a molecular compound of stannic hydrate with benzoic acid, $\text{SnH}^4\text{O}^4 \cdot \text{C}^7\text{H}^5\text{O}^2 + 9\text{H}_2\text{O}$.

The *aluminium salt*, $\text{Al}^3 \left\{ \begin{array}{l} (\text{C}^7\text{H}^5\text{O}^2)^2 \\ (\text{OH})^2 \end{array} \right\} + \text{H}_2\text{O}$, forms white, easily soluble crystals, grouped in dendritic forms.

The ferrous and ferric salts were not obtained in the crystalline form.

Silver benzoate, treated with bromine, yields benzoic acid and a resinous body (Dunze, *Zeitschr. f. Chem.* [2] vii. 119). With *liquid phosgene* it forms benzoyl chloride:

A small quantity of a chlorinated oil, probably $\text{C}^7\text{H}^5\text{Cl}^2$, is formed at the same time (V. Meyer, *Zeitschr. f. Chem.* [2] vi. 496).

Ethyl Benzoate, $\text{C}^2\text{H}^5\text{C}^7\text{H}^5\text{O}^2$.—This ether, treated with sodium ethylate, yields sodium benzoate and ethyl oxide, according to the equation:

besides formic acid, and two oily bodies, one of which has the composition $\text{C}^{20}\text{H}^{20}\text{O}^3$ (or perhaps $\text{C}^{20}\text{H}^{20}\text{O}^2$), and the other $\text{C}^{27}\text{H}^{26}\text{O}$. Their formation may perhaps be represented by the equation:

The production of formic acid may be due to the action of the liberated oxygen on the benzoic ether (Geuther, *Jenaische Zeitschrift*, vii. 126).

Bromobenzoic acids.—Parabromobenzoic or bromodracrylic acid, obtained by oxidising bromotoluene with chromic acid, melts at 251° ; metabromobenzoic acid, produced by the action of bromine on benzoic acid, melts at 153° (*1st Suppl.* pp. 309, 310). The ortho-modification, or bromo-salicylic acid, does not appear, to have been obtained. V. v. Richter indeed states that it is formed, together with the meta-acid, by the action of bromine on benzoic acid; but this statement is contradicted by Hübner a. Petermann (*Ann. Ch. Pharm.* cxlix. 131), who found that only one brominated acid (the meta-acid) is formed in this way; also by Hübner a. Friedburg (*ibid.* elviii. 19), who obtained in this same manner a mixture of metabromobenzoic with unaltered benzoic acid. Such mixtures often melt at temperatures lower than the melting points of either of their constituents; thus a mixture of 2 parts benzoic with 1 part bromobenzoic acid melts at about 190° , and a mixture of 1 part benzoic with 5 parts bromobenzoic acid at about 115° . This circumstance has probably given rise to the supposition that two brominated acids are formed by the action of bromine on benzoic acid. Peligot, by treating silver benzoate with bromine, obtained a brominated acid melting at 100° (i. 534), and Angerstein (*Ann. Ch. Pharm.* elviii. 1) has shown that the product thus obtained is a mixture of bromobenzoic with benzoic acid; further that the bromobenzoic acid separated from it, agrees with metabenzoic acid in its melting point (153°), in the characters of its barium salt, which crystallises in small smooth needles, and in those of its nitro-acid.

Metabromobenzoic acid then is formed by the action of bromine on benzoic acid, on silver benzoate, and on benzamide (*1st Suppl.* 315), whence it appears that the three groups COOH , COOAg , CONH^2 , have the same influence on the bromine-atom, causing it to stand to the group COOH , &c. in the position 1 : 3. Moreover, it is known that the

presence of the group CH^3 gives rise to the formation of a para-compound, bromo-toluene $\text{C}^6\text{H}_4\text{CH}^3$ being converted by oxidation into para-oxybenzoic acid; hence it appeared possible that the presence of the group CN might cause the formation of orthobromobenzoic acid. On heating benzonitrile, $\text{C}^6\text{H}_5\text{CN}$, with bromine in closed tubes, a reddish-brown thick liquid was obtained, which was dissolved in alcohol, and the solution diluted with water; microscopic crystals gradually separated out, which were scarcely attacked by caustic potash solution at 120° . From the alkaline liquid a small quantity of an acid was obtained, melting at 230° – 235° , which was probably parabromobenzoic acid. Other experiments to prepare the missing or orthobromobenzoic acid, likewise gave only negative results. As Henry has shown, this acid is not formed, as chlorosalicylic acid (orthochlorobenzoic acid) is, by treating salicylic acid with phosphorus pentabromide, and decomposing the product with water. Friedburg found, like Henry, that only bromosalicylic acid is thereby formed. He tried further to prepare diazo-orthoamidobenzoic acid, in order to convert it by the action of hydrobromic acid into metabromobenzoic acid, but did not succeed in obtaining the diazo-compound, which appears to be a most unstable body. On mixing a solution of the sulphate of ortho-amidobenzoic acid (anthranilic acid) with potassium nitrate in the cold, and adding hydrobromic acid, nitrogen is evolved, but no orthobromobenzoic acid is formed; the solution containing only salicylic and nitro-salicylic acids, which shows that the diazo-compound is decomposed by the water before the hydrobromic acid can act upon it (Friedburg, *Ann. Ch. Pharm.* clviii. 29).

Friedburg further confirms the results of Hübner, Ohly, and Philipp, that by treating pure meta-bromobenzoic acid with strong nitric acid, two isomeric bromonitrobenzoic acids are formed, viz. *α*-bromonitrobenzoic acid, which melts at 250° , and the *β*-acid melting at 140° (1st Suppl. 315, 316).

Potassium bromobenzoate fused with sodium formate yields isophthalic acid, together with benzoic acid. The formation of isophthalic acid is represented by the equation:

(Ador a. Meyer, *Deut. Chem. Ges. Ber.* iv. 359).

Dibromobenzoic acid, $\text{C}^6\text{H}^2\text{Br}^2\text{O}^2$ (Hübner n. Angerstein, *loc. cit.*). This acid is best obtained by enclosing 5 grams of benzoic acid and 13.1 grams of bromine in tubes, half filled with water and heating them to 200° – 230° , until the colour has nearly disappeared. The resulting mixture of mono-, di-, and tri-bromobenzoic acid is boiled with water and barium carbonate, and the solution concentrated. Tribromobenzoate then crystallises out first, and afterwards impure dibromobenzoate; whilst the salt of the mono-bromobenzoic acid remains in the mother-liquor. The complete separation of the three acids is very difficult, and can only be effected by employing large quantities of material.

Barium dibromobenzoate, $\text{Ba}(\text{C}^6\text{H}^2\text{Br}^2\text{COO})_2 + 2\text{H}_2\text{O}$, crystallises in fine, short, transparent needles. The calcium salt forms shining plates; the sodium salt is very soluble, and does not crystallise well; the silver salt forms a white, and the copper salt a light green precipitate. Pure dibromobenzoic acid is sparingly soluble in water, readily in ether and alcohol, and crystallises in tufts of slender needles, melting at 223° – 227° , and subliming without decomposition.

Silver monobromobenzoate treated with bromine does not yield dibromobenzoic acid, the product consisting of silver bromide, monobromobenzoic acid, and a few drops of a volatile oil, which attacks the eyes powerfully.

Dibromonitro-benzoic acid, $\text{C}^6\text{H}^2\text{Br}^2\text{NO}^2\text{COOH}$. To prepare the compound, impure dibromobenzoic acid is dissolved in hot concentrated nitric acid. The solution is evaporated on the water-bath, and the residue dissolved in sodium carbonate. As the sodium salt of the acid crystallises exceedingly well, it is easily obtained by recrystallising the mixture of the sodium salts, rejecting the first crystals and the last mother-liquors. The middle portion yields, on further crystallisation, the pure salt $\text{NaC}^6\text{H}^2\text{Br}^2(\text{NO}^2)\text{COO} + 3\text{H}_2\text{O}$, which separates from a hot concentrated solution in large shining leaflets, and from a diluted solution in long fine needles. When heated it deflagrates, leaving a bulky, carbonaceous mass behind.

Barium dibromonitrobenzoate, $\text{Ba}(\text{C}^6\text{H}^2\text{Br}^2\text{NO}^2\text{COO})_2 + 2\text{H}_2\text{O}$, forms fine silky needles. The strontium salt crystallises in very long and fine silky needles. The lead and silver salts are white precipitates, and the copper salt forms a light green precipitate. The acid crystallises from water in white needles, which melt at 182° , and deflagrate on further heating.

Dibromamido-benzoic acid, $\text{C}^6\text{H}^2\text{Br}^2(\text{NH}^2)\text{COOH}$, is obtained by boiling dibromonitro-benzoic acid for a short time with tin and strong hydrochloric acid. On adding water to the cold solution, the amido-acid, which does not combine with hydrochloric acid, is

precipitated; it crystallises from boiling water in microscopic needles, and from dilute alcohol in distinct needles: it melts at 196°, and decomposes on stronger heating. By sodium-amalgam it is converted into *ortho*-amido-benzoic (anthranilic) acid. The mother-liquor from the preparation of this compound contains *metamido-benzoic acid*.

The relative positions of the radicles in the above-described brominated derivatives

of benzoic acid may be represented as follow, regarding bromo-benzoic

acid as a meta-compound, and supposing that the carboxyl is combined with carbon No. 1 of the benzene nucleus:—

Bromochlorobenzoic acids (Claus a. Pfeiffer, *Deut. Chem. Ges. Ber.* v. 656).—The three chlorobenzoic acids are not all converted with equal ease into the corresponding bromochlorobenzoic acids by the action of bromine on their aqueous, alcoholic, or ethereal solutions. Chlorosalylic acid is scarcely altered even after heating with bromine in sealed tubes, whereas chlorobenzoic acid is acted upon with comparative readiness. They may all be easily brominated, however, by the action of bromine on a hot solution of the silver salt.

Bromochlorosalylic acid crystallises in fine, small, glistening needles, melting at 151°, and soluble in 380 parts of water at 21°. Like chlorosalylic acid, it melts under boiling water, but is more soluble than that acid. Its salts are also more soluble than the corresponding chlorosalylates.

Bromochlorobenzoic acid also crystallises in fine, white, felted needles, but is less soluble than the above (1080 parts of water at 21° dissolve 1 part of the acid), and does not melt under boiling water. Its barium salt crystallises with two molecules of water; that of the above-mentioned isomeric acid contains three.

In the preparation of chlorobenzoic acid by the action of potassium chlorate and hydrochloric acid on benzoic acid, somewhat considerable quantities of dichlorobenzoic acid are formed. The properties of the acid thus obtained differ in several respects from those described as characteristic of dichlorobenzoic acid by Otto, and by Beilstein and Kuhlberg.

The two acids above described appear to be converted into dioxy-benzoic acids by fusion with potassium hydrate. This appears to succeed if the temperature be carefully regulated, but if the heating be carried too far, chlorobromosalylic acid yields considerable quantities of salicylic acid.

Chlorobenzoic acids.—Parachlorobenzoic or chlorodraeylic acid heated in a sealed tube to 200° with antimony pentachloride is converted into dichlorobenzoic acid boiling at 201°, and identical in every respect with that which is obtained by the action of chloride of lime on benzoic acid, &c. &c. (*1st Suppl.* 312).

In this acid, therefore, the two chlorine-atoms occupy the para- and meta- positions, that is to say, its formula is $C^HClHHCLO^2H$. *Ortho*-chlorobenzoic (chlorosalylic) acid similarly treated would probably yield an isomeric dichlorobenzoic acid (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] vi. 417).

Another modification of dichlorobenzoic acid is obtained, together with the monochlorinated acid, by the action of potassium chlorate and hydrochloric acid on benzoic acid in diffused daylight. It crystallises in soft, silky, interlaced needles, melting at 158°, and subliming without decomposition. Its barium salt $Ba(C^H^2Cl^2O^2)^2 + 3H^2O$ forms long, thin lustrous needles, which dissolve in 12.5 parts water at 28°. The calcium salt $Ca(C^H^2Cl^2O^2)^2 + 2H^2O$ crystallises in slender radiated needles (Claus, *Deut. Chem. Ges. Ber.* 721).

Otto, by boiling dichlorhippuric acid with strong hydrochloric acid, obtained a dichlorobenzoic acid, melting at 196°–197°; its calcium and barium salts have, however,

the same form and composition as those of the acid obtained by Claus (*Ann. Ch. Pharm.* cxxii. 129; cxxiii. 216).

Trichlorobenzoic acid, $C^6H^3Cl^3.CO^2H$. A trichlorobenzoic acid, isomeric with that produced from trichlorotoluene-trichloride (1st *Suppl.* 312), is obtained by heating chrysanic (amido-dinitrobenzoic) acid with concentrated hydrochloric acid for nine hours to 200° – 210° . On opening the tubes, torrents of nitrogen and carbon dioxide escape, and the residue contains ammonium chloride and some nitro-products. This reaction, which may be represented by the equation:

affords the first example of the replacement of amido- and nitro-groups by chlorine.

The trichlorobenzoic acid thus obtained, crystallises from dilute alcohol in fine needles, melting at 203° , but subliming at a lower temperature; it is almost insoluble in cold, and sparingly soluble in boiling water. Its *silver salt* $AgC^6H^3Cl^3O^2$ is a white precipitate crystallising from boiling water in microscopic needles. The *barium salt* $Ba(C^6H^3Cl^3O^2)^2 + 4H^2O$ crystallises from a hot solution in small prisms. The *calcium salt* $Ca(C^6H^3Cl^3O^2)^2 + 6H^2O$ is but slightly soluble in cold water, and crystallises from a hot solution in small shining needles. The *ethyl ether* is insoluble in water, and crystallises from alcohol in slender needles melting at 86° .

The *chloride*, $C^6H^3Cl^3.CO^2Cl$, obtained by the action of phosphorus pentachloride on the acid, is readily soluble in ether, benzene, and carbon sulphide, and forms hard prisms, melting at 36° , and having a faint but pungent odour. The *amide*, $C^6H^3Cl^3.CONH^2$, produced by heating the chloride with ammonia, is readily soluble in alcohol and ether, and crystallises in small needles melting at 176° (Salkowski, *Ann. Ch. Pharm.* clxiii. 33).

Fluobenzoic acid, $C^6H^5FO^2$ (Schmitt a. Gehren, *J. pr. Chem* [2] i. 394). Hydrofluoric acid decomposes diazo-amidobenzoic acid in a manner similar to hydriodic and hydrochloric acids, producing fluobenzoic and hydrofluoro-amidobenzoic acids, with evolution of nitrogen:

The mixture of the two acids was gently heated in a platinum dish till it had become entirely fluid, and the evolution of nitrogen had ceased. On cooling, the crude fluobenzoic acid crystallised out, and was purified, first by treatment with animal charcoal and crystallisation from water, and finally by solution in ether, in order to separate the hydrofluoro-amidobenzoic acid which remained undissolved. Fluobenzoic acid crystallises in colourless rhombic prisms very similar to benzoic acid. It volatilises readily at 100° , melts at 182° , and solidifies at 170° . It dissolves with difficulty in cold water, but easily in hot water, alcohol and ether. It has a strong acid reaction, expels carbonic acid from the alkaline carbonates, and does not etch glass. It is soluble without decomposition in concentrated sulphuric acid and with nitric acid it forms nitrofluoro-benzoic acid.

With the metals, fluobenzoic acid forms neutral salts which crystallise well from their aqueous solutions. The *silver salt*, prepared by precipitating the ammonium salt with silver nitrate, and recrystallising, forms yellow plates having the composition $AgC^6H^5FIO^2$. The *calcium salt* $Ca(C^6H^5FIO^2)^2 + 3H^2O$, obtained by neutralising the acid with calcium carbonate, crystallises in large prisms. The *barium salt* $Ba(C^6H^5FIO^2)^2 + 4H^2O$ was prepared in a manner similar to the calcium salt. *Ethyl fluobenzoate* was obtained by saturating an alcoholic solution of the acid with dry hydrochloric acid; it crystallises, and may be volatilised without decomposition. Calcium fluobenzoate distilled with 4.3 times its weight of calcium hydrate is decomposed, with formation of fluobenzene C^6H^5F (p. 142).

Iodobenzoic acid.—The iodobenzoic acid which Griess obtained by the action of hydriodic acid on sulphate of diazosallylic acid (from anthranilic acid) crystallises in long white needles, which may be readily sublimed. It dissolves somewhat in hot, very sparingly in cold water, very easily in cold ether and alcohol; melts at 132° . This is doubtless the ortho-acid. Another modification which Griess obtained by the action of hydriodic acid on diazobenzo-amidobenzoic acid melts at 185° , and this is most probably the meta-acid, inasmuch as Körner has obtained the para-acid (iododraeylic acid) and found it to melt at 260° (Griess, *Deut. Chem. Ges. Ber.* iv. 188; *Chem. Soc. J.* [2] ix. 702). See also 1st *Suppl.* p. 313.

Nitrobenzoic acids.—Ortho-nitrobenzoic acid (not hitherto known) is produced by oxidising ortho-nitrocinnamic acid with chromic acid. That the nitrobenzoic acid thus obtained is really the ortho-acid is proved by its conversion into

ortho-amidobenzoic or anthranilic acid by reduction with tin and hydrochloric acid, and conversion of the latter into salicylic acid by the action of nitrous acid.

Crude nitro-cinnamic acid (which likewise contains the para-acid), may be used for the preparation, inasmuch as the para-nitrobenzoic acid formed at the same time is much less soluble than the ortho-acid, and therefore easily separated from it.

Orthonitrobenzoic acid crystallises from water in small needles readily soluble in cold alcohol and ether. It melts at 141° , the same temperature at which metanitrobenzoic acid melts, but differs from the latter by being more soluble in water (100 parts of water dissolving at 16.5° , 0.61 parts of the ortho-acid and only 0.235 of the meta-acid); the barium and zinc salts of the former are also more soluble than the salts of the meta-acid. The barium salt $\text{Ba}[\text{C}_6\text{H}_4(\text{NO}_2)\text{O}]^2 + 3\text{H}_2\text{O}$ forms radiated crystalline groups. The calcium salt $\text{Ca}[\text{C}_6\text{H}_4(\text{NO}_2)\text{O}]^2 + 2\text{H}_2\text{O}$ is very soluble in water, and crystallises in small thin needles. The lead salt $\text{Pb}[\text{C}_6\text{H}_4(\text{NO}_2)\text{O}]^2 + \text{H}_2\text{O}$ crystallises in small shining prisms, sparingly soluble in cold water. The zinc salt is obtained in a syrup which gradually crystallises. The ethylic ether melts at 30° . The amide $\text{C}_6\text{H}_4(\text{NO}_2).\text{CONH}^2$ crystallises in short needles (Beilstein a. Kuhlberg, *Ann. Ch. Pharm.* clxiii. 134).

Dinitrobenzoic acid, $\text{C}_6\text{H}_3(\text{NO}_2)^2.\text{CO}^2\text{H}$ (Tiemann a. Judson, *Deut. Chem. Ges. Ber.* iii. 223. Murctow, *Zeitschr. f. Chem.* [2] vi. 641).—1. From *Dinitrotoluene*. When pure dinitrotoluene is heated for some time with fuming nitric acid, especially at 100° under pressure, the unaltered dinitrotoluene then removed by precipitation with water, and the filtrate evaporated, crystals of dinitrobenzoic acid are obtained, which may be purified from small quantities of adhering dinitrotoluene by solution in aqueous sodium carbonate. The acid precipitated from the solution by dilute nitric acid may be recrystallised from boiling water, in which it first melts, then dissolves and separates in long prisms on cooling. In the dry state it melts at 179° . It sublimes without decomposition and forms well crystallised salts. The lead, barium, and silver salts are soluble in water, and may be recrystallised therefrom (Tiemann a. Judson).

2. From *Mononitrobenzoic acid*.—When pure nitrobenzoic acid melting at 127° is continuously heated with a mixture of fuming nitric and fuming sulphuric acid, and the cooled mixture is diluted with water, dinitrobenzoic acid separates after a while in shining crystals, an additional quantity of which may be obtained by partially neutralising the excess of nitric and sulphuric acids present with sodium carbonate, or by shaking the acid liquid with ether (Tiemann a. Judson). Murctow boils 100 grams of nitrobenzoic acid with 300 grams of fuming nitric acid, sp. gr. 1.48—1.49, and 600 grams of oil of vitriol, as long as red fumes are given off (four or five hours), and then leaves it to cool, whereupon the pure dinitro-acid crystallises out; this may be drained on asbestos, and the rest of the dissolved acid precipitated by water, in which, in fact, it is less soluble than in weak nitric acid. To purify it from adhering mono-nitrobenzoic acid, it may be combined with ammonia, precipitated with silver nitrate, and crystallised from water; the less soluble silver dinitrobenzoate then crystallises out first, in needles; or the acid may be combined with baryta, whereupon needles of the mononitrated salt separate first; if they are mixed with nodules, the quantity of water added has not been sufficient. The solution is to be precipitated with hydrochloric acid, and the precipitate recrystallised from water; 35 grams of nitrobenzoic acid yield by this process 15 grams of the dinitro-acid.

Cahours, who discovered dinitrobenzoic acid, prepared it by heating benzoic acid with a mixture of nitric and sulphuric acids (*1st Suppl.* 557). According to Murctow, this process yields only the mono-nitrated acid. As, however, this acid is converted by the same treatment into the dinitro-acid, it is difficult to understand how some quantity of the latter can fail to be produced when benzoic acid is subjected to the prolonged action of a mixture of sulphuric and nitric acids.

Dinitrobenzoic acid prepared as just described is nearly insoluble in cold, somewhat soluble in boiling water (1 part in 53 according to Murctow) and crystallises therefrom on cooling in shining laminae, which melt when dry at 202° , but begin to sublime at a lower temperature (Tiemann a. Judson). According to Murctow, it crystallises from water in square plates, which gradually become larger, but remain so thin that they exhibit the finest interference colours. It dissolves in alcohol more freely than in water, and separates in large, transparent, well-defined prisms, melting at 204° — 205° .

Dinitrobenzoic acid forms dark red solutions with alkalis and with baryta-water. It dissolves in a small quantity of strong aqueous ammonia, and the solution deposits crystals which dissolve in a larger quantity of ammonia, like those of the mononitrated acid. With excess of ammonia, a red solution is formed which becomes colourless on boiling, and then deposits crystals of ammonium dinitrobenzoate. The barium salt

$\text{Ba}\{\text{C}^6\text{H}^4(\text{NO}^2)_2\text{O}^2\}^2 + 5\text{H}_2\text{O}$ crystallises from water in pale yellow nodules; acetates when heated. The silver salt is yellowish when recently precipitated, but crystallises from water in nearly colourless needles. It is permanent in the air and detonates when heated (Muretow).

The differences of melting point and crystalline form of the dinitrobenzoic acids prepared from dinitrotoluene and from mononitrobenzoic acid, show that they are isomeric, not identical.

Dinitrobenzoic acid heated in alkaline solution with sodium-amalgam, is converted into a black humus-like body, having the composition of diazoxybenzoic acid, $\text{C}^6\text{H}^3\text{N}^2\text{O}^3$ (Meyer a. Michler, p. 168).

Trinitrobenzoic acid, $\text{C}^6\text{H}^2(\text{NO}^2)_3\text{CO}^2\text{H}$, is obtained by digesting trinitrotoluene with fuming nitric acid at 100° in sealed tubes; the transformation, however, is not complete, even when the action is continued for a fortnight. The unaltered trinitrotoluene having been precipitated by water and the liquid filtered, the filtrate on evaporation deposits trinitrobenzoic acid in large well-defined prismatic crystals which may be further purified in the manner above described for the dinitro-acid. Pure trinitrobenzoic acid melts at 190° when dry, and sublimes without decomposition. Its ammonium salt is crystallisable. The silver salt crystallises in reddish laminae, slightly soluble in water. When the free acid is heated with an excess of alkali, especially of ammonia, it first turns red and then decomposes (Tiemann a. Judson).

Reduction-derivatives of the Nitrobenzoic Acids.

Amidobenzoic acids, $\text{C}^6\text{H}^5(\text{NH}^2)\text{O}^2 = \text{C}^6\text{H}^4(\text{NH}^2)\text{COOH}$.—*Meta-amidobenzoic acid*. When this acid is treated with carbon bisulphide in alcoholic solution, hydrogen sulphide is evolved and dicarboxyl-sulphocarbonyl $\text{N}^2 \left\{ \begin{array}{l} \text{OS}^2 \\ \text{C}^6\text{H}^4 \\ \text{H}^2 \end{array} \right.$ COOH^2 , is separated in white needles (Merz a. Weith, *Zeitschr. f. Chem.* [2] vii. 46).

Carboxamidobenzoic and Uramidobenzoic acids (Griess, *J. pr. Chem.* [2]. iv. 292; v. 369).—When amidobenzoic acid and urea are melted together at a moderate heat, uramidobenzoic or oxybenzuramic acid, $\text{C}^6\text{H}^4\text{N}^2\text{O}^3$ (1st *Suppl.* 318) is formed:

and this acid, if kept at the temperature of 20° , is gradually resolved into urea and carboxamidobenzoic acid, $\text{C}^6\text{H}^5\text{N}^2\text{O}^3$:

This method of preparation consequently yields a mixture of the two acids, the relative quantities depending on the time and temperature.

By heating amidobenzoic ether with urea, the ethers of both the above acids are obtained; and from this mixture uramidobenzoic ether may readily be extracted by hot water. It melts at 176° ; carbamidobenzoic ether at 162° .

Uramidobenzoic ether is easily prepared by adding hydrochloric solution of amidobenzoic ether to aqueous solution of potassium cyanate. This ether is identical with the one obtained by the method given above; and the carboxamidobenzoic ether obtained from it by the action of heat, is identical with that mentioned above. These two ethers may also be obtained by the action of cyanic acid upon alcoholic solution of amidobenzoic acid. A compound is thus formed having the composition $\text{C}^6\text{H}^4\text{N}^2\text{O}^3$. By evaporation in a vacuum over sulphuric acid, it loses 3 mols. of water, becoming $\text{C}^6\text{H}^3\text{N}^2\text{O}^4$, a compound isomeric with uramidobenzoic ether, into which it is converted by the application of heat.

Carbamidodracrylic and Uramidodracrylic acids are obtained in like manner by fusing a mixture of urea and amidodracrylic acid.

Uramidodracrylic acid crystallises in anhydrous, white plates, difficultly soluble even in boiling water. It is obtained with these properties, however, only when very small quantities of material are operated upon; if more than 3 grams of the two substances are fused together, the product crystallises in minute round forms which, under the microscope, have a certain resemblance to yeast-cells. All attempts to obtain the two modifications similarly crystallised have been unsuccessful; both, however, are exactly the same products of decomposition. The latter modification is also obtained by the action of potassium cyanate on amidodracrylic hydrochloride.

Carboxamidodracrylic acid, $\left. \begin{array}{l} \text{C}^6\text{H}^5\text{H} \\ (\text{CO}) \\ \text{C}^6\text{H}^5\text{H} \end{array} \right\} \text{NO}^2$, crystallises in minute needles, insoluble in all neutral solvents.

Ortho-amidobenzoic acid or *Anthranilic acid*, fused with urea, yields, not a uramido-acid, but cyananthranilic acid, $C^6H^4(CN)NO^2$ (1st Suppl. 320):

(Griess, *loc. cit.*).

Triamidobenzoic acid, $C^6H^2(NH^2)^3O^2 = C^6H^2(NH^2)^3.CO^2H$, is produced by the action of tin and hydrochloric acid on chrysanilic (dinitro-amidobenzoic) acid. It crystallises from a hot aqueous solution in fine shining needles, which in the pure state are almost colourless, but generally have a chocolate colour. It is sparingly soluble in cold water and nearly insoluble in alcohol and ether; the solution has an acid reaction. It is resolved by heat into carbon dioxide and triamidobenzene, $C^6H^2(NH^2)^3$, (p. 147).

Triamidobenzoic acid combines with other acids as well as with bases. The hydrochloride $C^6H^2(NH^2)^3.CO^2.2HCl$ is obtained by treating the liquid, after reduction, with hydrogen sulphide. It is very readily soluble in water, and crystallises in silver-grey needles; the aqueous solution undergoes decomposition on exposure to the air, with separation of brown amorphous flakes. With platinic chloride it gives, not a double salt, but a black residue; but it combines with stannous chloride, forming the compound, $C^6H^2(NH^2)^3.CO^2.2HCl.SnCl^2 + 3\frac{1}{2}H^2O$, which is obtained on evaporating the product of reduction, and forms monoclinic crystals. The sulphate $C^6H^2(NH^2)^3.CO^2.H^2SO^4 + H^2O$ forms hard brownish crystals, sparingly soluble in boiling water. The nitrate $C^6H^2(NH^2)^3.CO^2.2HNO^3$ crystallises in small rhombic six-sided brown plates, and is moderately soluble in cold water. The oxalate is obtained in fasciculated needles on mixing the hot concentrated solutions of the two acids.

The triamidobenzoates of the alkali-metals and magnesium have not been obtained in crystals. *Calcium triamidobenzoate* $Ca(C^6H^2(NH^2)^3.CO^2)^2$ is obtained by neutralising the acid with calcium carbonate, and forms brown, hard crystalline crusts. *Zinc triamidobenzoate* $Zn[C^6H^2(NH^2)^3.CO^2]^2 + 6H^2O$, forms hard, light-brown shining crystals.

The aqueous solution of triamidobenzoic acid does not dissolve lead oxide, but on evaporating it with lead acetate, small shining prisms separate out, which, when once formed, are quite insoluble in water. The solution of the free acid is precipitated by copper, silver, and mercuric salts; ferric chloride produces a brown precipitate, the solution containing ferrous chloride (Salkowski, *Ann. Ch. Pharm.* clxiii. 12).

Ethyl-amidobenzoic acid (Griess, *Deut. Chem. Ges. Ber.* v. 1038).—When potassium amidobenzoate is treated with ethyl iodide, a mixture of ethyl- and diethyl-amidobenzoic acids is produced, which may be separated by crystallising their hydrochlorides from hot dilute hydrochloric acid.

Ethyl-amidobenzoic acid, $C^6H^{11}NO^2 = C^6H^4(NH.CO^2H)^2O^2$, isomeric with the ethyl amidobenzoate, $C^6H^4NO^2.CO^2H$, which Cahours obtained by reducing ethyl nitrobenzoate with ammonium sulphide, crystallises in small white or greyish prisms, slightly soluble in hot, very sparingly in cold water, but soluble in any quantity of alcohol or ether. The solutions are tasteless, but have an acid reaction. The acid melts at 112° , and volatilises without decomposition at a higher temperature. Like amidobenzoic acid, it unites both with bases and with mineral acids, not, however, with acetic acid. The hydrochloride, $C^6H^{11}NO^2.HCl$, crystallises in small four- or six-sided plates, also in needles, especially from dilute hydrochloric acid. It is moderately soluble in cold, freely in hot water, almost insoluble in cold hydrochloric acid. It forms a double salt with platinic chloride.

Barium ethylamidobenzoate, $Ba(C^6H^{11}NO^2)^2 + 2H^2O$, crystallises from water and from alcohol in small indistinct very soluble plates.

Nitroso-ethylamidobenzoic acid, $C^6H^4(N \begin{Bmatrix} C^6H^4 \\ NO \end{Bmatrix})O^2$, is formed when nitrous acid is passed into a moderately strong solution of hydrochloride of ethylamidobenzoic acid, or when potassium nitrite is added to it, and separates as a crystalline precipitate. It is sparingly soluble in boiling water, and crystallises therefrom almost completely, in yellowish-white, long, narrow plates. It is almost tasteless, but has a strong acid reaction; dissolves freely in cold alcohol and ether; and combines with bases, but not with acids. The silver salt forms small yellowish-white six-sided plates, and is but slightly soluble in boiling water.

Diethyl-amidobenzoic acid, $C^{12}H^{19}NO^2 = C^6H^4(C^2H^5.CO^2H)^2O^2$, crystallises in perfectly white prisms very much like the crystals of ethyl-amidobenzoic acid, and, like the latter, has no taste, but an acid reaction; it melts at 90° and can be distilled without decomposition. The hydrochloride $C^{12}H^{19}NO^2.HCl + H^2O$ forms shining four-sided plates, which are freely soluble in cold water and in hydrochloric acid, and give off their water at 130° .

Diallyl-amidobenzoic acid, $C^3H^3(C^2H^3)^2NO^2$, is formed, as sole product, by the action of allyl iodide on potassium amidobenzoate. It crystallises in small, soft, white, plates, melting at 90° , sparingly soluble in boiling water, but dissolving in all proportions of alcohol or ether. The *hydrochloride* $C^3H^3(C^2H^3)^2NO^2.HCl + H^2O$ forms large white prisms, very sparingly soluble in cold dilute hydrochloric acid; it combines with platonic chlorido.

Diazobenzoic acid, $C^3H^3N^2O^2$ (Griess, *J. pr. Chem.* [2] i. 102). When the gold salt of this acid, $C^3H^3N^2O^2.HClAuCl^3$, suspended in alcohol, is decomposed by hydrogen sulphide, gold sulphide is precipitated, nitrogen gas is evolved, and three organic acids are formed, namely, benzoic, chlorobenzoic, and a sulphuretted acid. To obtain the latter, the filtrate from the gold sulphide is freed from alcohol by evaporation, and the residue is repeatedly boiled with a large quantity of water which does not dissolve the sulphuretted acid. On dissolving the residue in hot dilute baryta-water, evaporating, and extracting several times with hot water, the barium salt of the sulphuretted acid remains behind; it may be decomposed with ammonium carbonate, and the acid precipitated from the resulting ammonium salt by hydrochloric acid. This sulphuretted acid is nearly insoluble in water even at the boiling heat, also in cold alcohol. From a solution in boiling alcohol it separates on cooling in white needles, melting at 242° . It gives by analysis numbers which may be represented approximately either by $C^3H^3SO^2$ or by $C^3H^3S^2O^3$, but Griess prefers the latter.

Compounds of Diazobenzoic acid with Oxybenzoic acid (Griess, *loc. cit.*).—1. An acid, $C^4H^4N^2O^3 = C^3H^3O^2.C^3H^3N^2O^2$, isomeric with azoxybenzoic acid (1st Suppl. 322), is formed, together with a brown amorphous acid and a large quantity of oxybenzoic acid, when an aqueous solution of the nitrate of diazobenzoic acid is left in contact for several days with barium or calcium carbonate. Hydrochloric acid added to the filtrate throws down a mixture of the three acids just mentioned, and on treating this mixture with cold alcohol, the acid $C^4H^4N^2O^3$ remains undissolved. It dissolves with great difficulty in cold alcohol, but very easily in boiling alcohol and ether; water takes up only traces of it. From the hot alcoholic solution it separates in golden-yellow needles. When heated it swells up strongly and leaves a difficultly combustible cinder. Its *silver salt* $C^4H^4Ag^2N^2O^3$ is a yellow gummy precipitate.

2. An acid having the composition $C^4H^4N^2O^3 = C^3H^3O^2.2C^3H^3N^2O^2$ is obtained by the action of sodium carbonate on an aqueous solution of the nitrate of diazobenzoic acid for 24 hours at ordinary temperatures, and is precipitated from the resulting solution by hydrochloric acid, together with a small quantity of a brown amorphous acid, probably having the composition $C^3H^3N^2O^3$; this latter may be removed by cold alcohol in which the acid $C^4H^4N^2O^3$ is but very slightly soluble. This acid crystallises from hot alcohol in brown-red grains or short thick needles. Its ammoniacal solution, which has a deep blood-red colour, gives with silver nitrate a brown-red precipitate, having the composition $C^4H^4Ag^2N^2O^3$.

The formation of the two acids just described may be represented by the equations:

Diazoxybenzoic acid, $C^3H^3N^2O^3 = C^3H^3 \begin{array}{c} \diagup N \diagdown \\ | \\ COOH \end{array} O$. This acid is formed by

the action of 5 p.c. sodium-amalgam on dinitrobenzoic acid dissolved in caustic soda. The resulting black liquid neutralised with hydrochloric acid deposits a black flocculent precipitate, which when dry forms a black velvety powder, insoluble in water, alcohol, ether, benzene and acetic acid. The salts are black and amorphous, like the acid itself. The analyses of the zinc, silver, and barium salts lead to the formula of the acid above given. The acid bears a remarkable resemblance to the so-called humous or ulmous substances, which are regarded by some chemists as nitrogenous (Meyer u. Michler, *Deut. Chem. Ges. Ber.* vi. 746).

BENZOIC CHLORIDE or **BENZOYL CHLORIDE**, C^3H^3COCl , is strongly acted upon by sulphuric acid, with rapid evolution of hydrochloric acid, the liquid becoming sensibly warm. When an excess of sulphuric acid is used, a compound is formed which crystallises out in prisms. As soon as it is brought in contact with water, much benzoic acid separates. The crystals placed on a porous plate, a vacuum become opaque, amorphous, and completely soluble in water, with separation of benzoic acid. On adding the sulphuric acid to an excess of benzoic chloride, heating, and distilling off the excess in a current of carbonic acid, a hard, hygroscopic mass remains, which, like the preceding product, is completely

soluble in water, and consists of sulphobenzoic acid, which in this way is easily obtained in large quantity (Oppenheim, *Zeitschr. f. Chem.* [2] vii. 21).

An alcoholic solution of potassium sulphhydrate produces, by its action on benzoyl chloride, not thiobenzoic as might be expected, but principally a body indifferent to alkalis, and crystallisable from alcohol in pale red needles; this substance appears, from its properties and composition, to be identical with the benzoyl sulphide of Liebig and Wöhler (*A. Woddlgo, J. pr. Chem.* [2] iv. 50).

BENZOIC PEROXIDE or **BENZOYL PEROXIDE** (C^6H^5O) $_2$ O.—For the preparation of this compound, Sperlich a. Lippmann (*Wien. Akad. Ber.* [2 Abth.] lxxii. 613), recommend the use of commercial barium peroxide, the quantity of active oxygen in which they determine by titration with iodine and sodium thiosulphate. The peroxide is triturated in a mortar with benzoyl chloride, and when the reaction is over, the product is exhausted with water, washed with dilute solution of sodium carbonate, pressed, dissolved in ether, and left to crystallise.

When an ethereal solution of benzoyl peroxide is heated to 100° with *amylene*, the ether and unaltered amylene then distilled off, and the solid residue washed with solution of sodium carbonate, a heavy oil is left which remains undecomposed even in rarefied air, and has the composition of amylene in which 1 atom of hydrogen is replaced by benzoyl peroxide:

BENZOÏN. $C^{14}H^{12}O^3$ (Jena a. Limpricht, *Ann. Ch. Pharm.* clv. 89; Limpricht a. Schwanert, *Deut. Chem. Ges. Ber.* iv. 335).—This compound distilled over heated *zinc-dust* is partly or wholly deoxygenised, yielding deoxybenzoïn or toluylene oxide, $C^{14}H^{12}O$, toluylene $C^{14}H^{12}$ (melting at 120°), and an oily compound isomeric with the latter, boiling at about 260°.

Decomposition of Benzoïn by Alcoholic Potash.—The products of this reaction vary according to the proportions of the reacting substances, the temperature and duration of the action, and the presence or absence of air.

1. When benzoïn is heated to 100° in a sealed tube for 12 hours with a small quantity of *alcoholic potash*, and the contents of the tube, after evaporation of the alcohol, are treated with water, a precipitate is formed consisting of hydrobenzoïn or toluylonic alcohol, $C^{14}H^{12}O^2$, and the aqueous solution treated with hydrochloric acid gives a precipitate of benzoic acid, with traces of benzilic acid.

2. When 4 grams of benzoïn are heated for two or three hours in a sealed tube to 150° with 1 gram of *sodium* dissolved in 20 c.c. alcohol of 9·2 p.c. the product treated with water as above, the liquid filtered off after twelve hours, and the undissolved portion taken up with alcohol, a solution is obtained which deposits first hydrobenzoïn, then ethyl-benzoïn, $C^{14}H^{14}(C^2H^5)O^2$, and lastly a compound $C^{18}H^{24}O^4$, which, on account of its great solubility, is difficult to separate from the last mother-liquors.

The aqueous solution mixed with hydrochloric acid gives a precipitate of ethyl-benzilic acid (p. 158).

The hydrobenzoïn obtained in the manner just mentioned is the orthorhombic modification, which forms large well-defined crystals, melting at 132°.

According to Zinin (*Deut. Chem. Ges. Ber.* vi. 1207) benzoïn is partly decomposed by boiling, or when its vapour is passed through a red-hot tube, yielding benzoic aldehyde, benzil, deoxybenzoïn, and water.

Ethyl-benzoïn, $C^{14}H^{14}(C^2H^5)O^2$, may be freed from hydrobenzoïn by repeated crystallisation. It crystallises in well-defined glassy prisms, often united in concentric groups, which dissolve easily in alcohol and ether, and melt at 95°. It is not altered by prolonged digestion of its alcoholic solution with sodium-amalgam. When it is heated with *nitric acid* of sp. gr. 1·4, and the product treated with water, a resin gradually separates, the alcoholic solution of which yields on evaporation, crystals, apparently of benzoïn, melting at 137°, and afterwards an uncrystallisable oil, which, when purified by repeated solution in cold alcohol and evaporation, and dried at 70°, exhibits the composition $C^{14}H^{14}O^3$, and may therefore be regarded as an isomeride of Zinin's acetyl-benzoïn $C^{14}H^{14}(C^2H^3O)O^3$. *Bromine* acts violently on ethyl-benzoïn, forming partly crystalline, partly oily products.

The compound $C^{14}H^{14}O^3$ crystallises, after several days' standing at a low temperature, from the oily mother-liquor which remains after the hydrobenzoïn and ethyl-benzoïn have been removed from the precipitate formed by water; the crystals are purified by draining, pressure between paper, and recrystallisation from alcohol. It dissolves in all proportions of ether and alcohol, and separates therefrom at a low winter temperature, sometimes in well-defined crystals: it melts at 181°. Distilled

with dilute sulphuric acid, it gives off an oil which gradually solidifies, and leaves a soft yellow residue convertible, by agitation with ether and alcohol in succession, into crystals, consisting partly of a substance soluble in hot alcohol, and separating therefrom in transparent crystals melting at 108° , partly of a white crystalline powder melting at 190° , and soluble only in large quantities of alcohol. The latter has not been analysed; the former has the composition $C^{22}H^{22}O$, showing that sulphuric acid acts on the compound $C^{22}H^{22}O^2$, in the same manner as on the other members of the benzoïn group, viz. as a dehydrant.

3. When benzoïn (4 parts) was heated with sodium ethylate (1 part sodium in 20 parts alcohol of 92 p. c.) to 170° , a gas, probably hydrogen, escaped on opening the tubes, and the products were somewhat different from those obtained in the experiments described under (2), toluylene C^4H^{12} being obtained instead of toluylenic alcohol $C^4H^{14}O^2$, (this alcohol being converted by the sodium ethylate at the high temperature of the reaction into toluylene hydrate $C^4H^{14}O$, benzoic acid and hydrogen, and the hydrate being then resolved into water and toluylene). The precipitate, formed by water in this case, likewise contains the compound $C^{22}H^{22}O^2$; and the precipitate formed by hydrochloric acid in the aqueous solution consists of ethyl-benzilic acid, together with benzoic and very little benzilic acid.

When benzoïn is heated for three hours to 160° , with very-concentrated alcoholic potash, strong pressure shows itself on opening the tubes; water throws down toluylene and the compound $C^{22}H^{22}O^2$; and hydrochloric acid added to the filtrate precipitates a large quantity of benzoic acid, with a little ethyl-benzilic, and traces of benzilic acid.

The formation of the compounds above described may be explained as follows:

The nascent hydrogen produced in this last reaction converts part of the benzoïn into toluylenic alcohol, $C^4H^{14}O^2$, which by the action of the alcoholic potash at high temperatures is resolved, as above mentioned into toluylene hydrate, $C^4H^{14}O$, benzoic acid and hydrogen, and the toluylene hydrate is in some cases further resolved into toluylene and water. The compound $C^{22}H^{22}O^2$ is probably formed from benzoïn by the action of nascent hydrogen in the manner shown by the equation:

(Jena a. Limpricht).

4. When benzoïn is heated with alcoholic potash in an open flask, the alcohol being replaced as it evaporates, and the product is treated with water and hydrochloric acid, a resinous precipitate is formed, and the liquid after a while deposits crystals of benzoic acid containing a trace of benzilic acid. The resin freed from benzoic acid by digestion with sodium carbonate, dissolves easily in hot alcohol, forming a solution which deposits, first nodular crusts of small white crystals consisting of dibenzoïn $C^{22}H^{22}O^2 = 2$ mols. benzoïn - H^2O , and afterwards a soft white mass the constitution of which has not been distinctly made out (Jena a. Limpricht).

According to more recent experiments by Limpricht a. Schwanert, the precipitate formed on adding water to the product obtained by several hours' digestion of benzoïn with alcoholic potash in an open vessel, consists of hydrobenzoïn (orthorhombic) and benzile (in sealed tubes no benzile is formed); and the liquid filtered from this precipitate and mixed with hydrochloric acid deposits benzoic acid, benzilic acid and ethyl-dibenzoïn, $C^{22}H^{22}O^3 = C^{22}H^{21}(C^2H^5)O^2$, (formerly regarded by Jena as isomeric with benzoïn, and designated as *tolane alcohol*). On boiling the precipitate formed by hydrochloric acid with water, the benzoic and benzilic acids dissolve, and ethyl-dibenzoïn remains as a resinous mass, which dissolves in alcohol and separates therefrom in crystals melting at 200° . Heated with acetyl-chloride, it is converted into acetyl-ethyl-dibenzoïn, $C^{22}H^{20}(C^2H^5O)(C^2H^5)O^2$.

It appears from the observations above described that the action of alcoholic potash on benzoïn gives rise to the formation of three compounds derived from two molecules of benzoïn, viz. dibenzoïn, $C^{22}H^{22}O^2$, ethyl-dibenzoïn, $C^{22}H^{22}O^3$, and the compound $C^{22}H^{22}O^2$.

A fourth compound, similarly derived, is oxylopidene, which Zinin obtained by the action of hydrochloric acid upon benzoïn. Dilute sulphuric acid produces the same effect:

Oxylepidene is closely allied to the compound $C^{12}H^{22}O^2$, and would undoubtedly be obtained from it by the action of acids. When a mixture of oxylepidene and benzoïn is heated with water to 150° , these bodies are converted into lepidene, $C^{12}H^{20}O$, and benzilo, respectively. This would account for the results obtained by Zinin, who found the two latter to be the chief products of the action of hydrochloric acid on benzoïn. (Limpricht a. Schwanert.)

Hydrobenzoïn. $C^{14}H^{14}O^2$.—It was stated in the *First Supplement*, p. 333, that the products thus designated obtained from different sources, exhibit considerable differences of melting point; and it now appears from the experiments of Ammann (*Zeitschr. f. Chem.* [2] vii. 83; *Ann. Chem. Pharm.* clxviii. 69), that there are two modifications of hydrobenzoïn, both of which are formed by the action of sodium-amalgam on benzoic aldehyde in aqueous or alcoholic solution. One of these is identical with Zinin's hydrobenzoïn, obtained by treating benzoic aldehyde with zinc and hydrochloric acid (iii. 185); the other, named isohydrobenzoïn, is the principal product of the action of sodium-amalgam on bitter-almond oil in presence of warm water; both isomerides are obtained if an alcoholic solution be used, the proportion of hydrobenzoïn rising with the strength of the alcohol employed. Their separation is very difficult, and can only be effected by repeated crystallisation from alcohol, in which isohydrobenzoïn is somewhat the more soluble.

Hydrobenzoïn crystallises from water and alcohol in anhydrous silky scales, soluble in 80 parts water at 100° and 400 parts water at 15° , easily soluble in alcohol, fusible at $132^\circ\cdot5$.

Isohydrobenzoïn crystallises from water in glistening hydrated needles, from alcohol in well-defined hexagonal crystals. It dissolves in 80 parts water at 100° and 526 parts at 15° , is easily soluble in alcohol, and melts at $119^\circ\cdot5$. It is unaltered by eight days' digestion in alcoholic solution with sodium-amalgam, and therefore seems to be not convertible into benzyl alcohol.

Action of Acetyl Chloride.—After 24 hours' digestion with acetyl chloride and expulsion of the excess by a current of air, both substances yielded products corresponding with the formula $C^{14}H^{12}(OC^2H^3O)^2$; the isohydrobenzoïn derivative is obtained with difficulty in crystals, which melt at 117° – 118° ; this substance seems to be identical with the acetic ether obtained by Limpricht and Schwanert from stilbene bromide (which melts at 105° – 120°).

Action of Nitric Acid.—Zinin found that hydrobenzoïn is easily converted into benzoïn by nitric acid. Isohydrobenzoïn dissolves readily in this acid; the product of the reaction collects on the surface of the liquid in oily drops, which in contact with water pass into a tough yellow mass, which could not be made to yield any definite compound.

Action of Phosphoric Chloride.—The reaction with isohydrobenzoïn seems to be more energetic than with hydrobenzoïn. The product of the reaction was the same with both substances, was very sparingly soluble in alcohol, and crystallised from toluene in colourless needles, melting at 184° , and having the composition $C^{14}H^{12}Cl^2$.

Limpricht a. Schwanert (*Ann. Chem. Pharm.* clx. 177), by heating toluylene bromide $C^{14}H^{12}Br^2$ with an equivalent quantity of silver acetate mixed with glacial acetic acid for some hours in a flask with reversed condenser, obtain toluylene acetate $C^{14}H^{12}(C^2H^3O^2)^2$, which, when precipitated by water and heated with alcoholic potash for 24 hours, yields at least two isomeric compounds having the formula $C^{14}H^{12}(OH)^2$, separable by successive crystallisation from alcohol.

The least soluble of these, called toluylene alcohol, melts between 115° and 146° ; but all attempts to obtain from it a substance of constant melting point having failed, it appears most probably to consist of two mutually convertible isomerides: when heated with glacial acetic acid, acetic anhydride, or acetic chloride, it yields acetic ethers, which likewise do not exhibit any constant melting point. Nitric acid of sp. gr. 1·4 oxidises it to benzoïn, and bromine converts it chiefly into benzilo, according to the equation:

Alcoholic potash or soda at 180° – 200° decomposes toluylene alcohol, with evolution of inflammable gas, yielding toluylene and oily substances which, when heated, give

off vapours having an odour of geranium. Dilute sulphuric acid abstracts the elements of water, forming a crystalline compound $C^{14}H^{12}O$, which melts at 95° .

Isotolulylenic alcohol crystallises in slender needles from the mother-liquors of toluylene alcohol prepared as above described; it melts at 96° , and when heated to 160° for two hours with acetic anhydride, gives two isomeric acetic ethers, melting respectively at 135° and 96° . Dilute sulphuric acid (20 p.c.) gives a small quantity of a crystalline compound, $C^{14}H^{12}O$, melting at 95° , and probably identical with that obtained from toluylene alcohol; the principal product, however, is an oily isomeric of this crystalline compound. Nitric acid of sp. gr. 1.4 converts isotolulylenic alcohol into benzoïn.

Limpricht a. Schwanert give the name of stilbene alcohol to the modification hitherto called hydrobenzoïn, which Zinin obtained by the action of alcoholic potash on benzoïn, reserving the name hydrobenzoïn for the other modification obtained by the action of nascent hydrogen on benzoic aldehyde (Ammann's isohydrobenzoïn). They find that stilbene alcohol crystallises in large tabular prisms melting at 132° ; heated with glacial acetic acid to 170° for two hours it furnishes the mono- and di-acetic ethers, $C^{14}H^{12}O_2(C^2H^3O)$ and $C^{14}H^{12}O_2(C^2H^3O)_2$, melting respectively at 77° and 135° ; acetyl chloride and acetic anhydride give the diacetic ether melting at 135° . Bromine forms benzil and bromo-toluylene, just as with toluylene alcohol; alcoholic potash at 180° for some hours forms benzoic acid and toluylene hydrate, $C^{14}H^{14}O$; this latter is further split up into water and toluylene, $C^{14}H^{12}$. On heating stilbene alcohol with dilute sulphuric acid for half an hour, a crystalline compound, $C^{14}H^{14}O$, is produced, melting at 125° .

The general conclusion deduced by Limpricht a. Schwanert from these experiments is, that toluylene bromide gives at least two isomerides of the formula $C^{14}H^{14}O^2$; that benzoïn and alcoholic potash give another, with which the hydrobenzoïn of Ammann is probably identical, the isohydrobenzoïn of this chemist being probably a different isomeride. These isomerides differ in the melting point, &c., of the acetyl derivatives, and yield different bodies by the action of sulphuric acid; in some instances, however, both the toluylene and stilbene alcohols form the same products, e.g., by the action of bromine.

Ammann, on the other hand, infers from the description given by Limpricht a. Schwanert of their toluylene and isotolulylenic alcohols, that the substances so designated were not definite chemical compounds, but mere mixtures. Their melting points show that they could not be mixtures of hydrobenzoïn and isohydrobenzoïn.

Deoxybenzoïn or Toluylene Oxide. $C^{14}H^{12}O$ (Limpricht a. Schwanert, *Ann. Ch. Pharm.* clv. 59).—This compound, discovered by Zinin in 1860, was obtained by the action of zinc and hydrochloric acid on benzoïn and on benzil chloride (*1st Suppl.* 382). Limpricht a. Schwanert believed that they obtained the same compound by heating toluylene acetate with alcoholic potash, but they have since found that the compound thus obtained is not toluylene oxide $C^{14}H^{12}O$, but toluylene hydrate $C^{14}H^{14}O$.

Deoxybenzoïn is also produced when benzoïn is passed over heated zinc-dust, but the deoxidation sometimes goes further, producing toluylene $C^{14}H^{12}$, and an oil isomeric therewith; and, lastly, it is obtained by heating bromo-toluylene $C^{14}H^{11}Br$ with water for several hours to 180° – 190° in a sealed tube: this last appears to be the most convenient mode of preparation.

The tube after cooling is opened (strong pressure sometimes showing itself); the aqueous hydrobromic acid resulting from the action is decanted from the crystalline deoxybenzoïn; and the latter is purified by several recrystallisations from alcohol.

Deoxybenzoïn thus prepared agrees in its properties with that obtained by Zinin. It crystallises in plates sometimes of considerable size; dissolves easily in alcohol and ether, melts at 54° – 55° , and may be distilled without alteration.

According to Radziszewski, deoxybenzoïn is produced by heating a mixture of benzoate and phenylacetate of calcium, whence it appears to have the constitution of phenyl-benzyl ketone:

(*Deut. Chem. Ges. Ber.* vi. 489).

Deoxybenzoïn is converted, by abstraction of oxygen, into toluylene (stilbene), as when benzoïn vapour is passed over heated zinc-dust: heated to 180° for six hours with highly concentrated hydriodic acid (b. p. 127°), it likewise yields toluylene and afterwards dibenzyl $C^{14}H^{14}$.

By addition of *hydrogen*, deoxybenzoin is converted into the two compounds $C^{12}H^{12}O^2 = 2C^{11}H^{12}O + H^2$, and $C^{14}H^{14}O$ (toluylene hydrate) $= C^{14}H^{12}O + H^2$. To obtain the former of these compounds, the alcoholic solution of deoxybenzoin is heated for several hours in the water-bath with zinc-filings and hydrochloric acid, then filtered; the filtrate is mixed with water; and the precipitate, collected after twelve hours, is dissolved in alcohol. The resulting solution first deposits the compound $(C^{12}H^{12}O^2)$ in white shining needles melting at 156° , and afterwards unaltered deoxybenzoin, finally leaving a viscid mother-liquor. By digesting the alcoholic solution of deoxybenzoin with sodium-amalgam for twenty-four hours in a steam-bath, filtering, neutralising the filtrate with hydrochloric acid, evaporating off the alcohol, and mixing the remaining liquid with water, a precipitate is obtained, the alcoholic solution of which first deposits the compound $C^{12}H^{12}O^2$ in small quantity, and then toluylene hydrate $C^{14}H^{14}O$.

Toluylene hydrate is likewise formed by heating hydrobenzoin or deoxybenzoin with alcoholic potash or sodium ethylate:

and, lastly, as already observed, by heating toluylene acetate with alcoholic potash.

When, deoxybenzoin is heated in sealed tubes to 150° for three hours with *sodium ethylate*, (each tube containing 4 grams of deoxybenzoin and a solution of 1 gram of sodium in strong alcohol), and the contents of the tubes are mixed with water after the alcohol has been driven off by gentle heating, the liquid, after standing for some time, deposits the toluylene hydrate completely in crystals, and the filtered mother-liquor mixed with hydrochloric acid yields the compound $C^{12}H^{12}O^2$. If the temperature has not been allowed to rise above 150° , these two bodies are the only products obtained, and no pressure is exhibited on opening the tubes; but if the temperature has risen to 160° , slight pressure is perceptible, and if to 170° , a very strong pressure is exerted, and the toluylene hydrate is then for the most part resolved into toluylene and water.

Toluylene hydrate forms long, slender, glassy, brittle needles, often radiating from a common centre, very soluble in alcohol and ether, insoluble in water, melting at 62° , and distilling without decomposition. Nitric acid of sp. gr. 1.3 converts it into deoxybenzoin. When bromine is poured upon it, hydrobromic acid is evolved, and several compounds are formed, among which, only bromotolane $C^{14}H^{14}Br$, could be distinguished with certainty.

The hydrate heated with dilute sulphuric acid (1 part hydrogen sulphate to 4 parts water) is resolved into toluylene (melting at 120°) and water. The same decomposition takes place, as already observed, when toluylene hydrate is heated to 170° with alcoholic potash; but in that case, another reaction seems also to occur, inasmuch as on opening the tube, pressure is exerted, probably resulting from hydrogen.

Toluylene hydrate dissolves very easily in acetyl chloride, forming acetyl-toluylene hydrate $C^{14}H^{14}(C^2H^3O)O$, which, when the excess of acetyl chloride has been expelled by gentle heating, and the hydrochloric acid by leaving the product for a week in a vacuum, is obtained as a colourless viscid liquid. The acetylated compound dissolves easily in alcohol and ether, distils for the most part undecomposed, a small portion only being resolved into acetic acid and toluylene. Heated with alcoholic potash, it is quickly resolved into acetic acid and toluylene hydrate, part of which is converted into toluylene. By heating to 150° for four hours with excess of acetyl chloride, it is completely resolved into acetic acid and toluylene.

The compound $C^{14}H^{14}O^2$ is precipitated by hydrochloric acid as a resinous mass, which dissolves easily in alcohol, and either crystallises therefrom very quickly, or separates by gradual evaporation in the form of an oil, and remains in that state for weeks; it may then be made to crystallise by pouring alcohol upon it and stirring briskly. From a hot concentrated alcoholic solution it separates in tufts of long white needles; the crystals formed by slow transformation of the oil are often short transparent prisms. It melts at 100° (not in boiling water, but in an oil-bath heated to 102° - 103°); dissolves easily in ether and glacial acetic acid, with moderate facility in boiling, much less in cold alcohol; with yellow colour in warm strong sulphuric acid, and is reprecipitated by water. Sodium carbonate, ammonia, and caustic soda do not dissolve it, even when heated; but it dissolves in alcoholic potash, and is precipitated therefrom by hydrochloric acid, but not by water. The alcoholic solution is

not precipitated by neutral lead acetate, or silver nitrate, even on addition of ammonia; mixed with a very small quantity of potash, it gives with silver nitrate a brown precipitate of silver oxide. It is not attacked by sodium-amalgam, or when its solution in acetic acid is boiled with nitric acid. Bromine acts on the free compound and on the solution in acetic acid, forming crystalline and oily products. Heated to 180° with fuming hydrochloric acid, or boiled for two hours with dilute sulphuric acid, it forms a brown oil easily soluble in alcohol; water slowly added to the alcoholic solution throws down a brown resin, and the liquid decanted therefrom yields prismatic crystals which have likewise the composition $C^{10}H^{10}O^2$, but melt at 132° .

Bromodeoxybenzoin or *Bromotoluylene Oxide*, $C^{11}H^{11}BrO$, is formed by adding 1 mol. bromine to 1 mol. deoxybenzoin in ethereal solution. On distilling off the ether, a large quantity of hydrobromic acid is given off, and the oily residue solidifies after some time to a crystalline mass. The alcoholic solution of this product slowly deposits drops of oil, which on immersing the vessel in ice, are converted into white nodular crystals.

Bromodeoxybenzoin dissolves easily in ether and hot alcohol, melts at 50° , and turns yellow at 100° . When it is heated with water to 160° , or with alcoholic potash to 150° , or when its alcoholic solution is digested with sodium-amalgam or mixed with silver nitrate, the whole of the bromine is removed.

By completely precipitating the alcoholic solution with silver nitrate, removing the excess of silver with hydrochloric acid, neutralising the filtrate with sodium carbonate, evaporating, mixing the residue with water, dissolving the precipitate in alcohol, and leaving the alcoholic solution to evaporate, an oil is obtained having the composition of benzoin, $C^{11}H^{12}O^2$. Its formation is represented by the equation:

It does not appear, however, to be a definite compound, for after some days it deposits crystals of benzile in large quantity, leaving an oil which remains liquid for several months.

Bromodeoxybenzoin heated with water to 160° yields benzile, deoxybenzoin and hydrogen bromide:

The products obtained by heating it with alcoholic potash to 150° , or by digesting its alcoholic solution with sodium-amalgam, have not been examined.

Dibromodeoxybenzoin $C^{11}H^{10}Br^2O$, analogous to chlorobenzile $C^{11}H^{10}Cl^2O$, is the compound which Zinin obtained by dropping bromine into fused deoxybenzoin (1st Suppl. 332). It is likewise obtained by adding bromine in excess to the ethereal solution of the latter. It crystallises in hard perfectly white prisms; dissolves easily in ether and in hot alcohol, sparingly in cold alcohol; melts at 110° - 112° (at 87° according to Zinin) and turns brown at 200° . Silver nitrate added to the alcoholic solution removes all the bromine and forms benzile. Heated with water to 160° , it is completely resolved into hydrogen bromide and benzile: $C^{11}H^{10}Br^2O + H^2O = 2HBr + C^{11}H^{10}O^2$. On treating the alcoholic solution with hydrochloric acid and zinc, filtering after four hours, and adding water, a precipitate is obtained, the alcoholic solution of which deposits crystals of deoxybenzoin and hydrobenzoin.

Acetyl-deoxybenzoin or *Acetyl-toluylene Oxide*, $C^{11}H^{11}(C^2H^3O)O$ is obtained by heating bromotoluylene $C^{11}H^{11}Br$ (1st Suppl. 1107) to 130° - 140° with silver acetate and glacial acetic. On filtering after eight hours, distilling off the greater part of the acetic acid, and adding water, a brown syrup is precipitated which separates from alcohol in the same form and shows no tendency to crystallise. It is decomposed by distillation even in a vacuum, deoxybenzoin passing over, and a considerable resinous residue being left. The acetyl-compound is slowly decomposed by water at 200° , yielding deoxybenzoin and acetic acid:

Boiled with alcoholic potash, it yields potassium acetate and tolane:

Toluylene oxides isomeric with that above described are produced by the action of dilute sulphuric acid on the several modifications of the alcohol $C^{11}H^{12}O^2$, described by Limpricht & Schwanert (p. 172). The oxide $C^{11}H^{12}O$, obtained in this manner from toluylalcohol, melts at 98° , and the same modification is obtained from isobenzylalcohol.

alcohol, together with another which is an oily liquid. Stilbene alcohol (Zinin's hydrobenzoïn) yields an oxide melting at 125°.

Constitution of Benzoïn and its Derivatives.—The constitution of these compounds has been variously represented by different chemists, the main point of discussion being whether the two phenyl-atoms contained in them are attached to the same or to different carbon-atoms. Limpricht a. Schwanert, as well as Grimaux, in 1867, proposed for deoxybenzoïn, the formula $\begin{matrix} \text{CH.C}^6\text{H}_5 \\ \text{CH.C}^6\text{H}_5 \end{matrix} \text{O}$, which was afterwards adopted by Kekulé in 1869. Städelér, in the same year (*Ann. Ch. Pharm.* cli. 457), proposed for this compound the formula $\text{O} \begin{matrix} \diagup \text{C}^6\text{H}_5 \\ \diagdown \text{CH}^2 \end{matrix}$, in which the two phenyl-atoms are attached

to the same atom of carbon; and this formula has subsequently been adopted by Limpricht a. Schwanert (*ibid.* cli. 74), in preference to their own, mainly on account of the relation of deoxybenzoïn to benzoic acid, which they regard as *diphenyl-glycollic acid*, $\begin{matrix} \text{C}^6\text{H}_5 \\ | \\ \text{C}^6\text{H}_5 \end{matrix} \text{C}(\text{OH})_2$ (p. 158).

The formulae of the principal compounds of the series, according to this view, are as follow:—

But the formula thus assigned to stilbene is not consistent, either with its formation from the sulphides of benzyl (*1st Suppl.* 1107), or with its conversion into dibenzyl $\text{C}^6\text{H}_5\text{—CH}^2\text{—CH}^2\text{—C}^6\text{H}_5$, by heating with hydriodic acid. Both these reactions, indeed, lead to the formula $\text{C}^6\text{H}_5\text{—CH=CH—C}^6\text{H}_5$ for stilbene; thus its formation from benzyl sulphide is represented by the equation:

The formation of benzoïn or of hydrobenzoïn from bitter-almond oil is likewise inconsistent with Städelér's formula, inasmuch as, in so easy a transformation, it is difficult to imagine that two atoms of phenyl, originally belonging to two different molecules of bitter-almond oil, should attach themselves to the same atom of carbon.

To throw further light on this question Zincke (*Deut. Chem. Ges. Ber.* v. 836) has examined the products of oxidation of stilbene, benzoïn and benzile. Stilbene oxidised with chromic acid mixture, is converted into benzoic aldehyde and benzoic acid. The production of the former of these compounds from stilbene, regarded as $\text{C}^6\text{H}_5\text{—CH=CH—C}^6\text{H}_5$, is easily explained, the introduction of 2 at. oxygen splitting the molecule up into two molecules of benzoic aldehyde $\text{C}^6\text{H}_5\text{C}^6\text{H}_4\text{O}$, part of which is then further oxidised to benzoic acid. Benzoïn similarly treated is likewise oxidised to benzoic aldehyde and acid; also by potassium permanganate, whereas nitric acid and arsenic acid do not act upon it. Benzile is somewhat less readily oxidised than stilbene or benzoïn; but by continued heating with the oxidising mixture, it is finally converted into benzoic acid.

These results are likewise inconsistent with Städelér's formula, according to which the bodies above mentioned should be converted by oxidation into benzophenone or diphenyl ketone $\text{O}(\text{C}^6\text{H}_5)_2$.

The following formulae are regarded by Zincke as most in accordance with the known reactions and modes of formation of these bodies:—

On the other hand, the mode of formation of deoxybenzoin observed by Radziszewski (p. 173), leads to the inference that this body and its congeners should be represented by ketonic formula, thus:

Hydrobenzoin and isohydrobenzoin appear to be chemically identical, inasmuch as they yield the same chloride when treated with phosphorus pentachloride (Zincke.) The modifications of hydrobenzoin and deoxybenzoin described by Limpricht & Schwanert—supposing their existence to be established—are perhaps also merely physical modifications.

BENZOPHENONE or **DIPHENYL KETONE**, $\text{C}^{12}\text{H}^{10}\text{O} = \text{CO}(\text{C}^6\text{H}_5)_2$, may be produced by the action of benzoyl chloride on mercury-diphenyl (Otto, *J. pr. Chem.* [2] i. 144):

A new modification of benzophenone is obtained by the oxidation of diphenylmethane, $\text{CH}_2(\text{C}^6\text{H}_5)_2$. It is first obtained as an oily liquid, which, on standing in the cold, deposits large, transparent, apparently monoclinic crystals, having great resemblance to Iceland spar; they melt at 26° – 26.5° to a clear liquid which boils constantly at 300° . The same modification of benzophenone is obtained as a by-product in the preparation of methyl-phenyl ketone. After some time the transparent crystals change their appearance; they become milk-white, and this change is accelerated by touching or gently warming them. They then melt at 48° – 49° , being transformed into common rhombic benzophenone, which is the more stable form of the two (Zincke, *Deut. Chem. Ges. Ber.* iv. 576).

Benzophenone heated to 180° with excess of phosphorus pentachloride, forms diphenyl-dichloromethane $\text{C}(\text{C}^6\text{H}_5)_2\text{Cl}_2$, which, however, cannot be obtained pure, as it is decomposed by heat, and by the action of water. When freed by warming from phosphorus oxychloride, and then treated with finely divided silver, it yields tetraphenyl-ethylene $\text{C}(\text{C}^6\text{H}_5)_4$, which separates from solution in hot benzene in spicular crystals melting at 221° . (Behr, *Deut. Chem. Ges. Ber.* iii. 751).

BENZOPHENONE-SULPHONIC ACID, $\text{C}^{12}\text{H}^{10}\text{SO}_3 = \text{CO} \begin{Bmatrix} \text{C}^6\text{H}_4\text{SO}_3\text{H} \\ \text{C}^6\text{H}_4\text{SO}_3\text{H} \end{Bmatrix}$.

—Benzophenone dissolves without alteration in cold sulphuric acid and is reprecipitated by water; but if the liquid be warmed, and especially if fuming sulphuric acid be used, a sulphonic acid is formed which yields readily soluble potassium and sodium salts, and a sparingly soluble crystalline anhydrous barium salt, $\text{CO} \begin{Bmatrix} \text{C}^6\text{H}_4\text{SO}_3 \\ \text{C}^6\text{H}_4\text{SO}_3 \end{Bmatrix} \text{Ba}$; a small quantity of an uncrystallisable barium salt is also formed, apparently isomeric with the crystalline salt.

The potassium salt fused with potash yields a small quantity of phenol, a large quantity of paraoxybenzoic acid, and a small quantity of a more soluble acid. The principal reaction is represented by the equation:

The formation of paraoxybenzoic acid as the principal product shows that the two groups SO_3H are in the position 1 : 4 with respect to the group CO (Städcl, *Zellulose-Chem.* [2] vii. 553).

BENZOYL CHLORIDE. See BENZOIC CHLORIDE, (p. 169).

BENZOYL-BENZOIC ACID, $\text{C}^{14}\text{H}^{10}\text{O}_3 = \text{C}^6\text{H}_5-\text{CO}-\text{C}^6\text{H}_4-\text{CO}_2\text{H}$ (V. V.

BENZOYL-BENZOIC ACID—BENZYL ALCOHOL. 177

Richter, *Deut. Chem. Ges. Ber.* iv. 459).—Produced by oxidising benzyl-toluene ($\text{C}_6\text{H}_5\text{—CH}_2\text{—C}_6\text{H}_4\text{CH}_3$) with chromic acid, the hydrocarbon being first converted into methyl-benzophenone or tolyl-phenyl ketone $\text{C}_6\text{H}_5\text{—CO—C}_6\text{H}_4\text{CH}_3$, the greater part of which is then further oxidised to benzoyl-benzoic acid.

On adding an acid to a cold solution of one of its salts, the benzoyl-benzoic acid separates as a gelatinous precipitate; from a hot solution it is obtained in the form of small silky needles. It is sparingly soluble in cold water, in chloroform, benzene, and toluene, a little more in hot water; in ether, alcohol, and glacial acetic acid it dissolves readily, less easily in dilute alcohol. From hot dilute alcohol or chloroform it crystallises in thin plates having a satiny lustre; from dilute acetic acid it separates in thin long needles. It melts at $194^\circ\text{--}195^\circ$, and sublimes at a higher temperature in large needles very much like sublimed benzoic acid. The barium salt $\text{Ba}(\text{C}_6\text{H}_5\text{O})_2 + \text{H}_2\text{O}$ crystallises from a hot aqueous solution in ramified needles, which become anhydrous at $160^\circ\text{--}160^\circ$. On evaporating a saturated solution, the salt crystallises in anhydrous plates. The calcium salt $\text{Ca}(\text{C}_6\text{H}_5\text{O})_2 + 2\text{H}_2\text{O}$ crystallises in needles like the barium salt, but is more soluble. The silver salt $\text{AgC}_6\text{H}_5\text{O}$ is a white precipitate, soluble in large quantities of hot water.

Benzoyl-benzoic acid is at the same time a ketone. On boiling its alcoholic solution with zinc and hydrochloric acid, it takes up hydrogen, being converted into benzhydriyl-benzoic acid, $\text{C}_6\text{H}_5\text{—CHOH—C}_6\text{H}_4\text{—CO}_2\text{H}$, which is much more readily soluble in water and dilute alcohol than benzoylbenzoic acid. It crystallises in ramified needles, melts at $164^\circ\text{--}165^\circ$, and is decomposed at a higher temperature. By oxidising agents it is easily reconverted into benzoyl-benzoic acid. The barium salt $\text{Ba}(\text{C}_6\text{H}_5\text{O})_2$ forms long hard needles grouped in stars; the calcium salt $\text{Ca}(\text{C}_6\text{H}_5\text{O})_2 + 3\text{H}_2\text{O}$ crystallises in white needles resembling wavelite. The silver salt $\text{AgC}_6\text{H}_5\text{O}$ is a white precipitate sparingly soluble in boiling water.

Benzhydriylbenzoic acid has the same composition as benzoic acid, but these two acids are not identical.

When benzhydriyl-benzoic acid is heated with concentrated hydriodic acid to 150° for some hours, it is transformed into benzyl-benzoic acid, $\text{C}_6\text{H}_5\text{—CH}_2\text{—C}_6\text{H}_4\text{—CO}_2\text{H}$, which is also obtained, besides other products, by acting on the hydrocarbon with dilute nitric acid. This acid is sparingly soluble in cold water; from a hot solution it crystallises in microscopic needles; from dilute alcohol in larger needles or plates with a satiny lustre. It melts at $154^\circ\text{--}155^\circ$, and sublimes like benzoyl-benzoic acid.

The barium salt $\text{Ba}(\text{C}_6\text{H}_5\text{O})_2$ is sparingly soluble, and forms crystalline crusts. The calcium salt $\text{Ca}(\text{C}_6\text{H}_5\text{O})_2$ has similar properties, and the silver salt is a white precipitate. By oxidising agents it is reconverted into benzoylbenzoic acid. On subjecting the calcium salt to distillation, diphenylmethane is produced.

BENZOYL-SULPHONIC ACID. $\text{C}_6\text{H}_5\text{SO}_3\text{H} = \text{C}_6\text{H}_5\text{—CO—SO}_3\text{H}$.—This acid, isomeric with sulphobenzoic acid, is obtained by the action of sulphuric acid in excess on benzoyl chloride. It crystallises in prisms, and is decomposed by water, yielding a large quantity of benzoic acid. By keeping, and more quickly by heating, it is converted into sulphobenzoic acid, which may accordingly be conveniently prepared by heating benzoyl chloride with excess of sulphuric acid (Oppenheim, *Deut. Chem. Ges. Ber.* iii. 735).

BENZYL, or **DIBENZYL**, $\text{C}_6\text{H}_5\text{CH}_2$, passed in the state of vapour through red-hot tubes three feet long filled with pumice, is resolved into toluene and toluylene (stilbene), $2\text{C}_6\text{H}_5\text{CH}_2 = 2\text{C}_6\text{H}_5\text{CH}_3 + \text{C}_6\text{H}_5\text{CH=CH}_2$ (Otto & Dreher, *Ann. Ch. Pharm.* cliv. 176).

Stilbene is also formed in considerable quantity, together with another hydrocarbon not yet isolated, when dibenzyl vapour is passed over heated lead oxide (Behr & van Dorp, *Deut. Chem. Ges. Ber.* vi. 753).

BENZYL ALCOHOL. $\text{C}_6\text{H}_5\text{CH}_2\text{OH} = \text{C}_6\text{H}_5\text{CH}_2\text{OH}$.—Kachler (*J. pr. Chem.* cvii. 307) prepares this alcohol from Peru balsam by the following process:—This balsam, which consists essentially of benzyl cinnamate, together with cinnamic acid and resins, is shaken with twice its volume of concentrated alcoholic potash (whereupon potassium benzoate separates), then with warm water, and the separated oil is heated with four times its volume of aqueous potash of sp. gr. 1.3, till the layers previously separated have dissolved to a clear liquid. The crystals which separate on cooling are pressed, and the liquid is diluted and boiled, whereupon the benzyl alcohol passes over.

Benzyl alcohol may also be obtained from liquid storax. By saponifying the crude styracine (chiefly cinnyl cinnamate) obtained from this resin, a product is obtained which begins to boil a little above 100° , and yields by fractional distillation benzyl

alcohol, boiling at 205°–207°, xylol alcohol $C^8H^{10}O$ boiling at 217°, and other products (Laubenheimer, *Ann. Ch. Pharm.* clxiv. 289). See STORAX.

Action of Cyanogen Chloride on Benzyl Alcohol.—When gaseous cyanogen chloride liquefied by cooling, is mixed in tubes drawn out in the middle (for convenience of sealing) and immersed in a freezing mixture with benzylic alcohol, in the proportion of $CNCl$ to $2C^6H^5O$, and the tubes, after being sealed, are exposed for an hour or two to the temperature of the air, the contents become hot and acquire a yellowish colour, and, on subsequent cooling, solidify to a crystalline mass, mixed in the lower parts with a small quantity of white amorphous substance. If the tubes be then opened (after again immersing them in the freezing mixture to prevent loss from projection) and the contents, liquefied by gentle warming, are poured into a flask and distilled under a pressure of about 10 mm., first in the water-bath and finally in a bath of salt water, benzyl chloride passes over, and the residue solidifies to a crystalline mass containing benzyl carbamate, which may be purified by repeated crystallisation from ether till it dissolves completely therein, and finally by crystallisation from boiling water. The matter insoluble in ether (the white amorphous substance above mentioned), consists of sal-ammoniac, and an organic substance insoluble in water, alcohol, and ether, slightly soluble in carbon sulphide.

If an excess of cyanogen chloride be added, the reaction takes place in the same way, the excess partly remaining unaltered, and being partly converted into solid cyanogen chloride; a small quantity of hydrochloric acid is also frequently evolved.

The principal and final action of gaseous cyanogen chloride on benzyl alcohol may therefore be represented by the following equation:—

The same products are obtained with solid cyanogen chloride. When this substance is triturated in a mortar with benzyl alcohol, added drop by drop till the proportion amounts to $C^8N^2Cl^2$ to $6C^6H^5O$, the reaction commences with evolution of heat, a small quantity of hydrochloric acid being given off before the whole of the benzyl alcohol has been added; and on placing the mortar, after the reaction is terminated, in a steam-bath, decanting the liquid portion of the contents into a flask, and distilling as above, benzyl chloride passes over and benzyl carbamate remains behind. The solid residue in the mortar yields to ether another portion of the carbamate, and the portion insoluble in ether contains sal-ammoniac, together with a white substance slightly soluble in boiling water, crystallising therefrom in gelatinous flocks, and very similar in appearance to the substance which Habich obtained in preparing cyanuric acid by heating urea.

Solid cyanogen chloride heated with benzyl alcohol to higher temperatures (180°–200°) yields, in addition to benzyl chloride and sal-ammoniac, two crystalline substances and scarcely a trace of benzylic carbamate. By repeated crystallisation from alcohol and ether, these two bodies are obtained, the one in slender, flexible, dazzling-white needles, melting at about 153°, and having nearly the composition of benzyl cyanate or cyanurate; the other in hard yellowish prisms, melting at about 143°, and containing about 75–76 p.c. carbon, 6.1 hydrogen, and 11.2 nitrogen, a composition agreeing approximately with the formula $C^{12}H^{14}N^2O$. This latter substance, treated with potash, yields a liquid base resembling dibenzylamine in odour and appearance (Cannizzaro, *Gazzetta chimica italiana*, i. 33).

Action of Urea Nitrate. The products of this reaction vary according to the temperature. When the two substances are heated together in a water-bath, or to any temperature below 120°, the chief products are dibenzylurea, $CH^2(C^6H^5)^2N^2O$ —identical with that which Cannizzaro obtained by the action of potassium cyanate on benzyl chloride—and benzoic aldehyde; but when the temperature of the mixture is raised to 130°–140°, the chief product is benzyl carbamate, together with a small quantity of another substance insoluble in cold ether, soluble in very strong alcohol and in boiling ether, from which it separates in crystals melting at 151°–153°. This process cannot, however, be recommended for the preparation either of dibenzylurea or of benzyl carbamate, as the product in either case is but small in proportion to the quantity of benzyl alcohol consumed (Campisi e. Amato, *Gazzetta chimica italiana*, i. 39).

BENZYL CARBAMATE or BENZYL-URETHANE. $C^6H^5N^2O$ = $CO \begin{Bmatrix} NH^2 \\ OC^6H^5 \end{Bmatrix}$.—This compound, whether prepared with gaseous or with solid cyanogen

chloride, crystallises in beautiful transparent colourless laminae, melting at 86°, moderately soluble in warm water, from which it crystallises on cooling, more soluble in ether, extremely soluble in alcohol. When it is heated in a retort to 200°-230°, a very small portion sublimes unaltered, but the greater part is resolved into benzyl alcohol and cyanuric acid:

(Cannizzaro, *loc. cit.*)

BENZYL CHLORIDE. $\text{C}^2\text{H}^2\text{Cl} = \text{C}^2\text{H}^2.\text{CH}^2\text{Cl}$.—This compound, heated in a sealed tube with sodium thiosulphate, yields a thick brownish oil, which contains a large quantity of sulphur, smells faintly of bitter-almond oil, and when distilled, gives off hydrogen sulphide, small quantities of benzyl sulphhydrate, and toluene, but chiefly toluylene (stilbene). On raising it to a very high temperature, thionessal and tolyl-allyl sulphido distil over. Now as these products are formed by the decomposition of the sulphide and sulphhydrate of benzyl (1st Suppl. 1087), it may be inferred that these latter compounds are the primary products of the action of sodium thiosulphate on benzyl chloride (R. Otto, *Zeitschr. f. Chem.* vi. 26).

Benzyl chloride heated with ethylic chlorocarbonate and sodium-amalgam is converted into dibenzyl-carbonylic acid $\text{C}^2\text{H}^2\text{O}^2$. The reaction apparently takes place by two stages, two molecules of benzyl chloride uniting together, with elimi-

nation of HCl , to form chloro-dibenzyl $\begin{array}{c} \text{C}^2\text{H}^2.\text{CH}^2 \\ | \\ \text{C}^2\text{H}^2.\text{CHCl} \end{array}$, and this compound being converted by the joint action of the sodium and the chlorocarbonic ether into ethylic

dibenzylcarbonylate $\begin{array}{c} \text{C}^2\text{H}^2.\text{CH}^2 \\ | \\ \text{C}^2\text{H}^2.\text{CH}.\text{CO}^2(\text{C}^2\text{H}^2) \end{array}$ (Wurtz, *Compt. rend.* lxx. 350).

BENZYL CYANIDE, DERIVATIVES OF. (Czampilek, *Deut. Chem. Ges. Ber.* iii. 472). *Nitrobenzyl Cyanide*, $\text{C}^2\text{H}^2\text{NO}^2 = \text{C}^2\text{H}^2(\text{NO}^2).\text{CH}^2\text{CN}$.—This compound is produced by dropping benzyl cyanide (prepared by repeatedly distilling benzyl chloride with alcoholic potassium cyanide) into fuming nitric acid contained in a cooled vessel. On leaving the liquid to stand over-night, and then pouring it into water, the nitro-compound separates as an oily body, which soon solidifies in crystals; it may be purified by washing it, first with water, then on a filter with cold alcohol, and dissolving it in boiling alcohol, whence it crystallises on cooling in long needles, which turn red in an alcoholic solution of potash or soda, the colour being changed to green by acids.

Amidobenzyl Cyanide, $\text{C}^2\text{H}^2\text{N}^2 = \text{C}^2\text{H}^2(\text{NH}^2).\text{CH}^2\text{CN}$, is obtained as a hydrochloride by treating the nitro-cyanide with tin and hydrochloric acid, decomposing the resulting tin-compound with hydrogen sulphide, and concentrating the filtered liquid. The hydrochloride $\text{C}^2\text{H}^2\text{N}^2.\text{HCl}$ then separates in beautiful tablets, sparingly soluble in cold, more soluble in hot alcohol. The *platino-chloride* has the composition $2(\text{C}^2\text{H}^2\text{N}^2.\text{HCl}).\text{PtCl}_4$. The base $\text{C}^2\text{H}^2\text{N}^2$, obtained by decomposing the hydrochloride with soda-loy, agitating with ether, and evaporating, forms concentric groups of scaly crystals; from water it separates as an oil.

The corresponding *azo-compound* appears to be formed by treating nitrobenzyl cyanide dissolved in absolute alcohol with sodium-amalgam; the liquid turns red, and after a while acquires a fine blue colour.

BENZYL IODIDE, $\text{C}^2\text{H}^2.\text{CH}^2\text{I}$.—Produced by the prolonged action of hydriodic acid of sp. gr. 1.96 on benzyl chloride at ordinary temperatures; at 120°-140°, the product consists of toluene and oils boiling above 280°. The iodide forms colourless crystals, having at 25° a sp. gr. of 1.7336, compared with water at the same temperature; it melts at 24.1°, contracts in solidifying, does not volatilise without decomposition. It is soluble in ether, carbon sulphide, and alcohol (slightly at 0°), insoluble in water. Its vapour excites tears. By silver acetate at ordinary temperatures it is immediately converted into benzyl acetate, and with alcoholic ammonia it quickly yields crystals of tribenzylamine (melting at 92°), while the hydriodides of mono- and dibenzylamine remain in solution (Lieben, *Zeitschr. f. Chem.* [2] vi. 786).

BENZYL ISOCYANATE and ISOCYANURATE, $\text{N} \begin{Bmatrix} (\text{CO})^2 \\ \text{C}^2\text{H}^2 \end{Bmatrix}$ and $\text{N} \begin{Bmatrix} (\text{CO})^2 \\ (\text{C}^2\text{H}^2)^2 \end{Bmatrix}$ (Letts, *Chem. Soc. J.* [2] x. 446). These ethers are produced by the action of silver cyanate on benzyl chloride. On heating these substances together in a paraffin-bath, the isocyanate distils over as a colourless transparent liquid; and, on heating the

remainder over a naked flame, the isocyanurate passes over as a yellowish oily liquid, which solidifies, on cooling, to a hard crystalline mass.

The isocyanurate has an excessively pungent odour, and its vapour causes the eyes to smart painfully. It boils between 175° and 200° , but cannot be completely freed by distillation from benzyl chloride, which boils at 175° . Alcoholic ammonia converts the isocyanate into benzyl-urea.

The isocyanurate $N^*(CO)^2(C'H')^3$ is the chief product of the reaction above mentioned. It dissolves slowly in hot alcohol, and separates on cooling in beautiful light silky needles. It is insoluble in water; dissolves with difficulty in ether, more readily in alcohol; melts at 157° , and boils at a temperature above 320° . By repeated sublimation in a tube, it is converted into the isocyanate; when fused with caustic potash, it yields potassium carbonate and benzylamine:

The solid substance melting at about 153° , which Cannizzaro obtained, as above mentioned, among the products of the action of solid cyanogen chloride on benzyl alcohol, was perhaps also the isocyanurate.

BENZYL KETONES. See KETONES.

BENZYL OXYGEN-ETHERS. (Sintenis, *Deut. Chem. Ges. Ber.* iv. 909).

—These ethers treated with chlorine or bromine are decomposed, without formation of substitution-products. *Benzyl-methyl oxide* $C^6H^5.CH^2.OCH^3$ and *benzyl-ethyl oxide* $C^6H^5.CH^2.OCH^2H^3$, treated with dry chlorine in the cold, yield benzoic aldehyde, hydrochloric acid, and chloride of methyl or ethyl; and *chlorobenzyl-ethyl oxide* $C^6H^4Cl.OCH^2H^3$ is decomposed into chlorobenzoic aldehyde, C^6H^3ClO , and ethyl chloride. By the action of chlorine at the boiling heat, the methyl and ethyl ethers yield methyl or ethyl chloride and benzoyl chloride, and chlorobenzyl-ethyl oxide splits up into chlorobenzoyl chloride and ethyl chloride:

When benzyl-ethyl oxide is acted upon by chlorine in presence of iodine, the products are ethyl iodide and monochlorobenzoyl chloride, which by oxidation is converted into parachlorobenzoic acid.

Benzyl-phenyl oxide, $C^6H^5.CH^2.OCH^2C^6H^5$, prepared by heating an alcoholic solution of benzyl chloride with potassium phenate, is also decomposed by chlorine or bromine, which, when acting in the cold, yield trichlorophenol or tribromophenol and benzyl chloride or bromide. As a similar decomposition takes place when only one molecule of chlorine or bromine is used, it is obvious that, in the first stage of the reaction, a substituted ether is formed, which is further decomposed by the hydracid produced, just as the anisols are split up by the action of hydriodic acid; and indeed by heating benzyl-phenyl oxide with hydrochloric acid to 100° , benzyl chloride and phenol were formed.

To obtain substitution-products, it is therefore necessary to remove the acid as soon as it is formed, which is easily effected by adding mercuric oxide. By adding bromine to an alcoholic solution of the ether in which freshly precipitated mercuric oxide is suspended, benzyl-bromophenyl oxide $C^6H^5.CH^2.OCH^2C^6H^4Br$ is formed. This compound crystallises from alcohol in long white needles melting at 59° – 59.5° ; it is not acted upon by caustic soda-solution. By the action of chlorine under the same conditions, the chlorinated ether, $C^6H^5.CH^2.OCH^2C^6H^4Cl$, is obtained, which forms long needles melting at 71° – 71.5° .

BENZYL SULPHOCYANATE, $C^6H^5NS = S \begin{Bmatrix} CN \\ C^6H^5 \end{Bmatrix}$; metameric with benzyl-

sulphocarbimide $N \begin{Bmatrix} CS \\ C^6H^5 \end{Bmatrix}$ (1st Suppl. 1056), is formed by heating benzyl chloride with the equivalent quantity of potassium sulphocyanate in presence of alcohol in a retort with reversed condenser. When recrystallised from alcohol, it forms large transparent prisms, insoluble in water, slightly soluble in cold alcohol, easily in hot alcohol, easily soluble also in ether and in carbon sulphide. It has a pungent taste and smell, melts at 36° – 38° , and boils, with partial decomposition at 256° (benzyl-sulphocarbimide boils at 243°). It unites rapidly with dry gaseous hydrogen bromide, forming a crystallised compound, insoluble in ether and instantly decomposed by water.

Fuming nitric acid converts it into *nitrobenzyl sulphocyanate*, $S \begin{Bmatrix} CN \\ C^6H^4(NO^2) \end{Bmatrix}$. The same compound is formed by heating nitrobenzyl chloride $C^6H^4(NO^2)Cl$ with potassium sulphocyanate in the manner above described. It crystallises from alcohol

solution in small brittle needles, which volatilise at about 70° , but decompose when heated before they distil (L. Henry, *Zeitschr. f. Chem.* vi. 207).

BENZYL UREAS. (Cannizzaro, *Gazzetta chimica italiana*, ii. 41.—Letts, *Chem. Soc. J.* [2] x. 449). *Monobenzyl-urea* $\text{CH}_2(\text{C}^6\text{H}_5)\text{N}^{\text{H}}\text{O}$ and *Dibenzyl-urea* $\text{CH}_2(\text{C}^6\text{H}_5)_2\text{N}^{\text{H}}\text{O}$ are produced simultaneously when benzyl chloride and potassium cyanate in alcoholic solution are continuously heated in an apparatus with reversed condenser.

On distilling off the alcohol and treating the residue with boiling water, an oily substance separates, which, on cooling, solidifies to a crystalline mass containing dibenzyl-urea. The aqueous solution contains the potassium chloride formed in the reaction, the carbonate resulting from decomposition of the cyanate, and monobenzyl-urea; and on evaporating this solution to dryness over the water-bath, treating the residue with a large quantity of ether, and distilling off the ether, the monobenzyl-urea remains behind, and may be purified, by recrystallisation, either from water or from alcohol. The two benzyl-ureas may likewise be obtained with tolerable facility by heating urea, benzyl chloride, and alcohol together in an apparatus with reversed condenser, then distilling off the alcohol, and treating the residue with water. The dibenzyl-urea is contained in the oily insoluble portion of the product, while the monobenzyl-urea dissolves in the water, and may be separated and purified as above (Cannizzaro).

Monobenzyl-urea is also produced by the action of alcoholic ammonia on benzyl isocyanate, and dibenzyl-urea by heating the same compound to 100° with water in a sealed tube (Letts):

Monobenzyl-urea crystallises in long white needles moderately soluble in water and in alcohol, more soluble at high than at low temperatures, freely soluble in ether. It melts at 147° – 147.5° , but begins at the same time to give off ammonia, and after being once fused, melts at a lower temperature (Cannizzaro). According to Letts, it melts at 144° . Heated to about 200° , it slowly gives off ammonia, and yields a white sublimate, which crystallises from alcohol in white needles having the appearance, composition and melting point of dibenzyl-urea (Cannizzaro).

Dibenzyl-urea is insoluble in water, but dissolves very easily in alcohol, from which it crystallises in beautiful white needles, melting at 167° . Both dibenzyl- and monobenzyl-urea form crystalline platinumchlorides, but no solid compounds with nitric or hydrochloric acid (Letts).

Phenyl-benzyl-urea, $\text{CH}_2(\text{C}^6\text{H}_5)(\text{C}^6\text{H}_5)\text{N}^{\text{H}}\text{O}$.—A mixture of benzyl isocyanate and aniline becomes hot and solidifies on cooling to a brown crystalline mass of phenyl-benzyl-urea, which, when purified by recrystallisation from alcohol, forms white needles melting at 168° . This compound is insoluble in water, and in hydrochloric acid, and forms an insoluble platinum salt, but not a crystallisable nitrate. When heated, it gives off pungent fumes of benzyl isocyanate (Letts).

BENZYLAMINE, $\text{C}^6\text{H}_5\text{N} = \text{C}^6\text{H}_5\text{CH}_2\text{NH}_2$. (Strakosch, *Deut. Chem. Ges. Ber.* v. 692).—The decomposition of isocyanate or isocyanurate of benzyl (p. 180) with potash, affords the means of preparing this base more readily than by the former method of heating benzyl chloride with alcoholic ammonia (1st Suppl. 336). The product obtained by heating benzyl chloride with silver cyanate is distilled, and the distillate, consisting of a mixture of the isocyanate and isocyanurate, is digested with caustic potash and subjected to distillation. The product generally contains some di- and tri-benzylamine, owing to the presence of undecomposed benzyl chloride. To purify it, the distillate is treated with hot hydrochloric acid; tri-benzylamine hydrochloride then remains undissolved, while the dibenzylamine salt soon crystallises out. The solution is then decomposed by caustic potash, and the base dried over solid potash. Benzylamine boils constantly at 185° .

Derivatives of Benzylamine.

Cyanbenzylamine, $(\text{C}^6\text{H}_5\text{NH})_2(\text{CN})$, is produced by passing cyanogen-gas into a cold solution of benzylamine. When recrystallised from alcohol, it forms colourless, shining crystals melting at 140° . It is insoluble in water, but dissolves in alcohol and ether. The hydrochloride $(\text{C}^6\text{H}_5\text{NH})_2(\text{CN}) \cdot 2\text{HCl}$ crystallises in white silky needles soluble in water and alcohol, and forms a crystalline platinum compound. Cyanbenzylamine, heated for some time with hydrochloric acid, is converted into benzylloxamide, dibenzylloxamide, and, on continued heating, even into oxamide.

Dibenzylamide, $\text{CO.N(C}^6\text{H}_5\text{)}_2\text{H}$, may also be obtained by boiling benzylamine with oxalic ether. It crystallises from boiling alcohol in white silky scales, dissolving sparingly in hot alcohol, but not in water and ether; it melts at 216° .

Cyanbenzylamide, $\text{C}^6\text{H}_5\text{.NH.CN}$, is obtained by passing dry cyanogen chloride into a cold ethereal solution of anhydrous benzylamine. The saturated solution is filtered from the benzylamine hydrochloride, the ether evaporated, and the residue placed in a vacuum. When recrystallised from ether, it forms transparent plates melting at 33° ; it is readily soluble in alcohol and ether, but insoluble in water. It does not combine with hydrochloric acid; on boiling it with this acid or with water, it is converted into monobenzyl-urea:

Tribenzylmelamine or *Tricyantribenzyltriamine*, $(\text{C}^6\text{H}_5)_3(\text{NH})_3(\text{CN})_3$.—Cyanbenzylamide soon undergoes polymerisation, even when kept in closed vessels or in a vacuum; the crystals melt, forming a heavy liquid which after some time becomes viscid, and at last solidifies; this transformation takes place more quickly on a water-bath. On treating the product with hydrochloric acid, the hydrochloride, $(\text{C}^6\text{H}_5)_3(\text{NH})_3(\text{CN})_3.2\text{HCl}$, is formed, which is sparingly soluble in water, more freely in alcohol and ether, and crystallises in needles. The free base obtained by decomposing this salt, dissolves in water and alcohol, crystallises in laminae, melts at a much higher temperature than cyanbenzylamide, and forms a platino-chloride.

Dibenzylguanidine, $\text{C} \begin{Bmatrix} \text{NH.C}^6\text{H}_5 \\ \text{NH} \\ \text{NH.C}^6\text{H}_5 \end{Bmatrix}$.—The hydrochloride of this base is produced by boiling an alcoholic solution of cyanbenzylamide and benzylamine hydrochloride, and the free base is formed by the action of dry cyanogen chloride upon pure dry benzylamine. The hydrochloride crystallises in laminae, melting at 176° , and dissolving sparingly in water, more readily in alcohol; with platinic chloride it forms a crystalline double-salt. By adding soda-solution to a solution of the hydrochloride the base is precipitated as an oil which soon solidifies, and crystallises from alcohol in colourless laminae or plates, melting at 100° , and dissolving freely in water, alcohol, and ether.

Dibenzyl Sulpho-urea, $\text{CS} \begin{Bmatrix} \text{NH.C}^6\text{H}_5 \\ \text{NH.C}^6\text{H}_5 \end{Bmatrix}$.—An alcoholic solution of benzylamine is heated in a flask connected with a reversed condenser as long as hydrogen sulphide is given off. The product is evaporated and the residue crystallised repeatedly from alcohol. It forms large four-sided brilliant plates, melting at 114° , and dissolving in alcohol and ether, but not in water. On heating it with mercuric oxide, it is converted into dibenzyl-urea.

Benzylacetamide, $\text{C}^6\text{H}_5\text{.C}^6\text{H}_5\text{O.HN}$, is formed when anhydrous acetic acid and benzylamine are heated together for some hours. It forms radiate needles, melting at 30° , boiling above 250° , and having a pleasant odour like that of flowers. It is very freely soluble in alcohol and ether, and does not crystallise from these solutions. It is remarkably stable, not being acted upon by acids, and not deprived of its acetyl by treatment with potash. By nitric acid it is converted into nitrobenzylacetamide, which crystallises from ether in yellow deliquescent needles or laminae. From this compound, too, the acetyl-group cannot be removed without complete destruction.

Nitrobenzyl mercaptan, $\text{C}^6\text{H}_4(\text{NO}_2)\text{CH}_2\text{SH}$, is formed by treating nitrobenzyl chloride with alcoholic ammonium sulphide. It forms small colourless, shining, plates, melting at 140° , insoluble in water, but soluble in alcohol and ether. The same compound is formed by boiling nitrobenzyl chloride with potassium sulphhydrate. By the continued action of ammonium sulphide or ammonia on this mercaptan, nitrobenzyl disulphide, $\text{C}^6\text{H}_4(\text{NO}_2)\text{CH}_2\text{S}$, is produced, in yellow microscopic crystals, melting at 89° ; it is insoluble in water, but dissolves in alcohol and ether.

When nitrobenzyl chloride is heated with alcoholic ammonia in a sealed tube, a mixture of different bases is produced, including nitrotribenzylamine, the hydrochloride of which is insoluble in water and sparingly soluble in alcohol (Strakosch).

BENZYL-BENZENE, $\text{C}^{12}\text{H}_{12} = \text{C}^6\text{H}_4(\text{C}^6\text{H}_5) = \text{C}^6\text{H}_5\text{—CH=CH}^6\text{H}_5$. (Zincke, *Deut. Chem. Ges. Ber.* iv. 298; *Chem. Soc. J.* [2] ix. 508, 688).—This hydrocarbon, which has the constitution of diphenyl-methane, is formed, together with other

products, when benzyl chloride is heated with benzene and zinc-dust. It constitutes the lower-boiling portion of the distillate, and solidifies on cooling to a crystalline mass of prismatic needles melting at 21° – 25° ; by slow cooling, large fine tables are sometimes formed. It dissolves readily in strong nitric acid, forming a crystalline nitro-product, and is slowly oxidised by a boiling mixture of dilute sulphuric acid and potassium dichromate, yielding a small quantity of benzoic acid and benzophenone $\text{C}^6\text{H}_5\text{—CO—C}^6\text{H}_5$, identical with that obtained from calcium benzoate. These reactions indicate the constitution of the compound; it is probably identical with the *diphenylated marsh-gas* which Jena obtained by distilling barium diphenylacetate with soda-lime (*Ann. Ch. Pharm.* civ. 86).

By using toluene, xylene, &c., in place of benzene in the above reaction, homologues of benzyl-benzene, represented by the general formula, $\text{C}^6\text{H}_{2n-14}$, may be obtained. Reduced iron or finely divided copper may be used in place of zinc-dust; with copper, however, a higher temperature is required.

Benzyl-toluene, $\text{C}^{11}\text{H}^{14}$ or probably $\text{C}^6\text{H}_5\text{—CH}_2\text{—C}^6\text{H}_4\text{—CH}_3$ (Zincke, *Deut. Chem. Ges. Ber.* iv. 298; v. 683), isomeric with dibenzyl and ditolyl, is formed by heating a mixture of benzyl chloride and toluene with zinc-dust or reduced iron. It is a colourless oil, which boils at 277° , and when boiled with chromic acid mixture yields benzoyl-benzoic acid $\text{C}^{11}\text{H}^{10}\text{O}_3$ (p. 177).

Vapour of benzyl-toluene passed over heated lead oxide yields a considerable quantity of anthracene (Behr and van Drop, *Deut. Chem. Ges. Ber.* vi. 753).

Benzyl-toluene is violently acted upon by *bromine*, even when dissolved in carbon bisulphide, but it has not been found possible to isolate a definite compound from the product.

Nitrobenzyl-toluenes.—Concentrated nitric acid converts benzyl-toluene into dinitrobenzyltoluene $\text{C}^{11}\text{H}^{12}(\text{NO}_2)_2$, a large quantity of a resinous body being formed at the same time. The dinitro-compound crystallises from hot alcohol in slender white needles, or on slowly cooling in thin prisms, and by spontaneous evaporation of the solution it is obtained in brilliant prisms melting at 137° . If instead of concentrated nitric acid, an acid of sp. gr. 1.4 is used, the action begins only at the heat of the water-bath; nitrous fumes are evolved, and besides nitration, oxidation also takes place, the chief product having the composition $\text{C}^{11}\text{H}^{11}(\text{NO}_2)_3$, probably nitro-methylbenzophenone $\text{C}^6\text{H}_4(\text{NO}_2)\text{—CO—C}^6\text{H}_4\text{—CH}_3$. It crystallises from hot dilute alcohol in long flat needles, or silky plates, melting at 127° , and subliming without decomposition in shining plates. When treated with tin and hydrochloric acid, it yields an amido-compound, forming amorphous salts, from which it is precipitated by soda-solution as a light white powder (Zincke). Tetranitrobenzyltoluene, $\text{C}^{11}\text{H}^{10}(\text{NO}_2)_4$, is obtained, together with resinous bodies, by acting on the hydrocarbon with a mixture of highly concentrated nitric acid and concentrated sulphuric acid. It crystallises from hot benzene or chloroform in small but well-defined prisms, melting at 160° – 161° , and deflagrating at a higher temperature (Zincke).

Diamidobenzyltoluene $\text{C}^{11}\text{H}^{12}(\text{NH}_2)_2$, is formed by treating the dinitro-compound with tin and hydrochloric acid. The product of the reaction is a stannochloride, which crystallises in small very soluble needles. When decomposed by hydrogen sulphide, it yields the *hydrochloride* $\text{C}^{11}\text{H}^{12}(\text{NH}_2)_2 \cdot 2\text{HCl}$, which is very soluble in water and alcohol, and can be purified only by recrystallisation from hot dilute hydrochloric acid; it forms white needles or plates. The *sulphate* $\text{C}^{11}\text{H}^{12}(\text{NH}_2)_2 \cdot \text{H}_2\text{SO}_4$ is also very soluble, and crystallises from hot alcohol in long colourless needles. By decomposing the hydrochloride with potash, the free base is obtained as a white crystalline powder. It is freely soluble in alcohol and ether, and the solution darkens when exposed to the air.

Benzyltoluene-sulphuric acid.—Benzyltoluene dissolves in hot fuming sulphuric acid, with formation of at least two sulpho-acids; but only the disulpho-acid has been isolated, its potassium salt being almost insoluble in strong alcohol, and crystallising from hot dilute alcohol in white laminae or broad needles, having the composition $\text{C}^{11}\text{H}^{12}(\text{SO}_3\text{K})_2 + 3\frac{1}{2}\text{H}_2\text{O}$, and readily soluble in water. The *barium salt* $\text{C}^{11}\text{H}^{12}(\text{SO}_3)_2\text{Ba} + 8\frac{1}{2}\text{H}_2\text{O}$ separates from an aqueous solution on addition of alcohol in crystalline crusts, which redissolve in water but slowly. The *copper salt* $\text{C}^{11}\text{H}^{12}(\text{SO}_3)_2\text{Cu} + 4\frac{1}{2}\text{H}_2\text{O}$ crystallises from a hot concentrated solution in small bluish-green laminae, and from dilute alcohol in prisms. The *lead salt* is readily soluble in hot water, sparingly in cold, and forms colourless prisms. The *free acid* is easily soluble in water, alcohol, and ether, and forms a crystalline mass, consisting of long colourless needles melting at 38° (Zincke).

Benzyl-ethyl-benzene, $C^{10}H^{14} = C^6H^5-CH^2-C^6H^5-C^2H^5$, is formed, together with other bodies, by boiling a mixture of benzyl chloride, ethyl-benzene and zinc, as long as hydrochloric acid continues to escape, and separated from the product by fractional distillation. It is a colourless liquid, having a faint aromatic odour, and boiling at $294^\circ-295^\circ$. By oxidation it yields benzoic acid, together with a ketone (J. F. Walker, *Deut. Chem. Ges. Ber.* v. 686).

(E. Roth, *Ann. Ch. Pharm.* clv. 72; *Zeitschr. f. Chem.* [2] iv. 650, vi. 680).—Produced by the action of benzoic aldehyde on acetamide:

To prepare it, about equal parts of acetamide and commercial bitter-almond oil are heated for some hours in a retort having its neck directed upwards. Water, prussic acid, and small quantities of an oil which floats on water, then escape, and the residue in the retort solidifies, on cooling, to a yellowish crystalline mass, which may be freed from bitter-almond oil by treatment with ether, then several times recrystallised from hot water. From the first mother-liquors, ammonia throws down small quantities of a body which appears to be amarine.

Benzylene-diacetamide forms capillary, silky, very bulky crystals, which, when dried in the air, unite into a felted mass. It dissolves sparingly in cold water and in ether, easily in boiling water and in alcohol, melts when heated, and resolidifies in the cold. When its solution is heated with hydrochloric acid, it decomposes with separation of benzaldehyde. Strong potash-solution, on the other hand, does not act upon it, even on prolonged boiling; neither does sodium-amalgam in neutral or a alkaline solution. Benzylene-diacetamide is permanent at 200° , but decomposes at a higher temperature, yielding, as distillation-products, first, acetamide; then, at a considerably higher temperature, oily bodies which do not solidify on cooling, and finally, above the boiling point of mercury, a mixture, recrystallising on cooling; of lophine with an easily soluble base not yet examined.

BENZYLENE-DIBENZIMIDE, $C^{21}H^{18}N^2O^2$, is prepared by heating bitter-almond oil with benzamide for several hours, treating the product, which solidifies in the crystalline form, with ether, and recrystallising the residue from boiling alcohol. It forms long silky needles, insoluble in boiling water, slightly soluble in ether and cold alcohol, melting at 197° . It dissolves in dilute hydrochloric acid, but the solution, even when only moderately heated, gives up benzoic aldehyde, while benzamide remains dissolved (Roth).

BENZYLENE-DIBUTYRIMIDE, $C^{22}H^{22}N^2O^2$, was obtained by Strecker from bitter-almond oil and butyramide in the same manner as the acetyl-compound above described. It forms slender crystals, nearly insoluble in cold, sparingly soluble in boiling water, easily soluble in alcohol, moderately soluble in ether. In the preparation of this substance also, small quantities of a light oil are obtained as a secondary product (Roth).

BENZYL SULPHUROUS ACID, $C^7H^7.SO^2H$ (Böhler, *Zeitschr. f. Chem.* [2] iv. 449; Barbaglia, *Deut. Chem. Ges. Ber.* v. 270, 687).—Böhler obtained this acid by boiling benzyl chloride with a moderately strong solution of neutral potassium sulphite: $C^7H^7.Cl + K^2SO^3 = KCl + C^7H^7.SO^2K$. The benzyl chloride gradually dissolves, and the concentrated solution on cooling deposits the *potassium salt* $C^7H^7.SO^2K + H^2O$ in colourless orthorhombic prisms, which give off the whole of their water at $100^\circ-150^\circ$. The *barium salt* $(C^7H^7.SO^2)^2Ba + 2H^2O$ obtained by double decomposition, crystallises in colourless laminae, somewhat sparingly soluble in water. By digesting this salt with dilute sulphuric acid, and saturating the filtrate with lead hydrate, a *basio lead salt* $(C^7H^7.SO^2)^2Pb.PbH^2O$ is obtained in shining crystals; and, on passing carbonic acid gas into the aqueous solution of this salt, the *neutral lead salt* $(C^7H^7.SO^2)^2Pb$ separates in anhydrous crystalline laminae. The *ammonium salt*, the *calcium salt* $(C^7H^7.SO^2)Ca + 2H^2O$, and the *silver salt* $C^7H^7.SO^2Ag$, are crystalline. The *hydrogen salt*, or *free acid*, is obtained by decomposition of the lead or barium salt, in colourless extremely hygroscopic crystals (Böhler).

The *potassium salt*, distilled with cyanide of potassium, yields a volatile cyanide $C^7H^7.ON$, which, when boiled with potash, is converted into alpha-toluidine and $C^6H^5.CH^2CO^2H$; this cyanide, is therefore benzyl cyanide $C^7H^7.CH^2ON$, and the acid

$C^6H^5SO^3H$, from the potassium salt of which it is produced as above, is benzyl-sulphurous acid, $C^6H^5CH^2SO^3H$, and not either of the modifications of toluene-sulphonic acid $C^6H^5\left\{\begin{smallmatrix} OH^+ \\ SO^3H^+ \end{smallmatrix}\right.$ described in the *First Supplement*, p. 286 (Barbaglia).

When the potassium salt is heated with phosphorus pentachloride, sulphurous oxide is evolved, and the distillate contains benzyl chloride, together with phosphorus oxychloride and a little thionyl chloride $SOCl^2$, but no sulphuryl chloride or phosphorus sulphochloride. Hence the group SO^3K in the potassium salt must be united with the carbon of the group CH^2 through the medium of oxygen, and not through that of sulphur; if the formula of the salt were $C^6H^5CH^2S-O-O-O-K$, it would, when distilled with PCl^5 , yield benzyl sulphochloride $C^6H^5CH^2S-O-O-O-Cl$. Its constitution formula must therefore be,

either $C^6H^5CH^2-O-S-O-O-K$,

or $C^6H^5CH^2-O-O-S-O-K$.

With either of these formulae it is easily seen that the replacement of the oxygen-atom next to the benzyl, and of that next to the potassium, by an equivalent quantity of chlorine, will give rise to benzyl chloride and thionyl chloride:

$C^6H^5CH^2Cl$
Benzyl chloride.

$Cl-O-S-Cl$
Thionyl chloride.

ClK .

The occurrence of sulphurous oxide during the reaction is due to the fact that thionyl chloride easily gives up its two atoms of chlorine in exchange for an atom of oxygen, and will therefore act on the potassium salt, $C^6H^5SO^3K$, in a similar manner to the pentachloride of phosphorus. The question as to which of the two formulae above given is the true expression of the constitution of the benzyl sulphite, cannot be determined by the products which it gives with phosphorus pentachloride. That the sulphur-atom is not in immediate union with the potassium, in other words, that the formula of the salt is not $C^6H^5CH^2-O-O-S-K$, may be inferred from the non-occurrence of phosphorus sulpho-chloride, $PSCl^3$, as one of the products of the reaction.

The preceding results lead then to the conclusion, that the acid $C^6H^5SO^3H$, obtained by the action of benzyl chloride on potassium sulphite, is not a *sulphonic acid*, that is to say, an acid in which the group SO^3H is united to the carbon through the medium of its sulphur-atom, but an acid sulphurous ether, its proper name being benzyl-sulphurous acid. Further, it appears most probable that the constitution of the sulphites—neutral potassium sulphite, for example—should be represented, not by the formula

but rather by

These conclusions, require however, to be confirmed by the study of other sulphurous ethers prepared by the action of alcoholic chlorides on neutral sulphites (Barbaglia).

When the boiling of the benzyl chloride with potassium sulphite is continued for a long time, a large quantity of sulphurous oxide is evolved, but the layer of oil floating on the saline solution never disappears completely. When distilled with water, and afterwards alone, it yields, besides unaltered benzyl chloride, a considerable quantity of benzyl alcohol and benzoic aldehyde, together with benzyl oxide (Barbaglia). According to Vogt & Henninger (*Ann. Chem. Phys.* [4] xxv. 129) there is also formed a body $(C^6H^5)^2SO^2$, isomeric, if not identical, with Otto & Grubert's sulphotoluide (1st *Suppl.* 289): Vogt & Henninger, however, call it *benzyl sulphide*. It is insoluble in water, slightly soluble in alcohol, and crystallises in flattened needles melting at 150° . (Otto & Grubert's sulphotoluide crystallised from alcohol in small tabular prisms melting at 155° – 156°).

Benzyl-sulphurous acid, identical in properties and reactions with that above described, is obtained by the oxidising action of nitric acid on benzyl bisulphide $(C^6H^5)^2S^2$ (prepared by the action of bromine on an ethereal solution of benzyl sulphhydrate). Benzoic aldehyde is formed at the same time, together with a little benzoic acid; on distilling the product, these bodies pass over with the vapour of water; and on neutralising the residue with sodium carbonate, evaporating, treating the residue with alcohol, and leaving the solution to evaporate, potassium benzyl sulphite is deposited in yellowish laminae, which may be rendered colourless by repeated crystallisation, or by treatment with tin and hydrochloric acid, or with sodium-amalgam, whereby adhering nitro-compounds are destroyed.

Benzylsulphurous Chloride, $C^6H^5.CH^2.SO^2Cl$, formed by the action of phosphorus pentachloride on potassium benzylsulphite, crystallises in prisms melting at 92° , and decomposing at a higher temperature into sulphur dioxide and benzyl chloride. Concentrated ammonia converts it into the amide, $C^6H^5.CH^2.SO^2NH^2$, which crystallises from water in small prisms melting at 105° (Limpricht, *Deut. Chem. Ges. Ber.* vi. 534).

Chlorobenzylsulphurous acid, $C^6H^4Cl.CH^2.SO^2H$, is obtained as a potassium salt by boiling chlorobenzyl chloride $C^6H^4Cl.CH^2Cl$ (obtained by the action of chlorine on chlorotoluene) with potassium sulphite. The solution on cooling deposits the potassium salt, $C^6H^4Cl.CH^2.SO^2K$, in colourless needles, which, according to Böhler (*loc. cit.*) are anhydrous, but according to Vogt & Henninger (*Ann. Ch. Phys.* [4] xxv. 129) contain a molecule of water, which they give off at 180° ; they are soluble in water and in boiling alcohol. The **barium salt** $(C^6H^4Cl.CH^2.SO^2)^2Ba + H^2O$, obtained by double decomposition, forms colourless shining crystals. The **basic lead salt** $(C^6H^4Cl.CH^2.SO^2)^2Pb.PbH^2O^2$, prepared by decomposing the barium salt with sulphuric acid, and neutralising with lead hydrate, forms silvery crystalline scales (Böhler). According to Vogt & Henninger, these chlorobenzylsulphites, though they appear to be homogeneous, nevertheless consist of mixtures of two isomerides, for when fused with potash they yield both salicylic and paraoxybenzoic acid.

The action of potassium sulphite on chlorobenzyl chloride likewise gives rise to chlorosulphotoluide $(C^6H^4Cl)^2SO^2$ (called *chlorobenzyl sulphide* by Vogt & Henninger). This compound is insoluble in water, and after washing with water and with ether, and crystallisation from boiling alcohol, is obtained in colourless needles. The mother-liquor of these crystals contains two other bodies, melting at 149° and 185° respectively (Vogt & Henninger).

Benzylene Chloride $C^6H^5.CHCl^2$, metameric with chlorobenzyl chloride, yields, when boiled with potassium sulphite, only a small quantity of a sulpho-acid not yet examined, the chief product of the reaction being benzoic aldehyde (Böhler).

Nitrobenzylsulphurous acid, $C^6H^4(NO^2).CH^2.SO^2H$. The **barium salt** of this acid, obtained by dissolving barium benzylsulphite in fuming nitric acid, crystallises in shining colourless needles containing $[C^6H^4(NO^2).CH^2.SO^2]^2Ba + 2H^2O$. By decomposing it with sulphuric acid and neutralising the filtered solution with lead hydrate, a **basic lead salt** $[C^6H^4(NO^2).CH^2.SO^2]^2Pb.PbH^2O^2$ is obtained in colourless needles. The **neutral lead salt** $[C^6H^4(NO^2).CH^2.SO^2]^2Pb + H^2O$ forms beautiful needle-shaped crystals more soluble than the basic salt (Böhler).

BERAUNITE. This mineral, hitherto known only as a pseudomorph after vivianite, from the Hrbek iron mine, at St. Benigna in Bohemia, (i. 579), has lately been found implanted on brown hematite, in the Father Abraham mine at Scheibenberg in Saxony. It forms laminar and radiate groups, also separate laminae and rods running out in crystalline points, which indicate the form of gypsum. Colour, hyacinth-red to reddish-brown; lustre, nacreous to silky; streak-powder, yellow. Sp. gr. 2.983. Analysis gave 54.50 Fe^2O^3 , 28.65 P^2O^5 , and 16.55 water, agreeing nearly with the formula $5Fe^2O^3.3P^2O^5 + 14H^2O$ (Fronzel, *Jahrbuch f. Mineralogie*, 1873, 23).

BERYL. A specimen of this mineral from Elba, of sp. gr. 2.699–2.710, was found to contain:

SiO^2	Al^2O^3	Fe^2O^3	GIO	Ca^2O
70.00	26.33	0.40	3.31	0.88 = 100.92.

It differs from all the beryls hitherto analysed in containing a smaller percentage of glucina and a larger proportion of alumina, and by the presence of caesia (E. Bechi, *Jahrbuch f. Mineralogie*, 1872, 95).

BETAINE, $C^3H^{11}NO^2$. (Schoibler, *Zeitschr. f. Chem.* vi. 505; Liebreich, *ibid.* 508).—This base, obtained from beet-juice (1st Suppl. 340), is identical with that which is produced by the action of trimethylamine on monochloroacetic acid, that is to say, trimethyl-glycoccine $C^3H^2(CH^3)^3NO^2$ and therefore with oxyneurine:

When fused with potassium hydrate, it gives off a large quantity of pure trimethylamine.

Betaine is not poisonous. The crystals of the hydrochloride, according to measurements by P. Groth, are monoclinic; they are thick, tabular, 10 mm. long and broad, and cleave with moderate distinctness parallel to the clinopinacoid, ($\infty P\infty$). The tribasic phosphate and the oxalate have been obtained in fine crystals; the malate and tartrate only in syrupy or hygroscopic masses (Schoibler).

For preparing betaine from the juice or molasses of beet, Scheibler now recommends that the liquid be first mixed with a slight excess of basic lead acetate, to precipitate various acids and colouring matters, which would interfere with the purification of the betaine to be subsequently separated. The filtrate from the lead precipitate is mixed with excess of dilute sulphuric acid to remove the lead; and from the acid filtrate the betaine is obtained by means of sodium phosphotungstate in the manner formerly described.

Liebreich boils the diluted molasses for twelve hours with barium hydrate; filters after removing the excess of baryta with carbonic acid; evaporates; exhausts the remaining treacly mass with alcohol; mixes the concentrated alcoholic extract with an alcoholic solution of zinc chloride; purifies the resulting precipitate by recrystallisation from water; and precipitates its aqueous solution with baryta-water. The liquid filtered from the precipitated zinc oxide contains a corresponding quantity of barium chloride. The barium is precipitated with the exact quantity of dilute sulphuric acid required; and on evaporating the filtrate, the hydrochloride of betaine crystallises out.

The juice of the beet in the earlier stages of growth contains a larger proportion of betaine than that of older beet, the proportion, of the base decreasing as that of the sugar increases with the ripening of the plant. Young beets gathered on July 1 yielded a juice containing about $\frac{1}{4}$ p.c. betaine, whereas ripe beets from the same field taken up on October 1, yielded only $\frac{1}{10}$ p. c., of betaine (Scheibler).

Betaine of the Phosphorus series or Trimethyl-phosphorylglycine, $C_3H_7PO_2 = C_3H_7(CH_3)_3PO_2$. (A. II. Meyer, *Deut. Chem. Ges. Ber.* iv. 734; *Chem. Soc. J.* [2] ix. 1066). The hydrochloride of this base, $C_3H_7PO_2.HCl$, is produced by heating 1 mol. trimethylphosphine with 1 mol. chloroacetic acid to 100° in a sealed tube for five or six hours. It unites with platinum chloride, forming a platinumchloride $2(C_3H_7PO_2.HCl).PtCl_4$, and when treated with sulphuric acid, yields a sulphate from which the free base may be precipitated by baryta-water. The base is a very hygroscopic crystalline mass, neutral to vegetable colours, and forming crystalline salts with hydriodic and with nitric acid.

The homologous compound, *triethyl-phosphorylglycine*, $C^6H^{17}PO_2 = C^6H^{17}(C^2H^5)_3PO_2$, is obtained in like manner by the action of chloroacetic acid on triethylphosphine (Hofmann, *Proc. Roy. Soc.* xi. 525).

Aromatic Betaines, (Griess, *Deut. Chem. Ges. Ber.* vi. 585).—These bases, analogous in constitution to the betaine of the fatty series (trimethyl-glycine), are produced by the action of methyl iodide in presence of methyl alcohol and an alkali on amidated aromatic acids, three atoms of hydrogen being replaced by methyl.

*Benzbetaine**, $C^6H^{13}NO_2$, which has the composition of trimethyl-amidobenzoic acid, $C^6H^9(CH_3)_3NO_2$, is prepared by pouring methyl alcohol on amidobenzoic acid, adding three times as much strong potash-ley as is necessary to neutralise the acid, and then methyl iodide in the proportion of 3 mol. to 1 mol. of the amidobenzoic acid. The mixture is left to itself for three days, the methyl alcohol then distilled off, hydriodic acid added in excess, and the hydriodide of benzbetaine, which crystallises out, is decomposed by lead hydrate, which separates the base.

Benzbetaine crystallises in small white needles containing 1 mol. water of crystallisation, which is easily given off at 105° . It is insoluble in ether, very soluble even in cold alcohol, and deliquesces on exposure to the air. It is neutral to vegetable colours, and has a strong bitter taste.

The *hydriodide*, $C^6H^{13}NO_2.HI + H_2O$, crystallises in small short prisms, which dissolve very sparingly in cold, easily in hot water or alcohol, but are quite insoluble in ether. The *platinchloride*, $2(C^6H^{13}NO_2.HCl).PtCl_4 + 4H_2O$, crystallises in prisms sometimes of considerable size, slightly soluble in hot, very slightly in cold water.

When anhydrous benzbetaine is heated to its melting point, it is converted into the isomeric methylic ether of dimethyl-amidobenzoic acid, $C^6H^{11}\{N(CH_3)_2\}COOCH_3$, a yellowish liquid having an aromatic odour, boiling at 270° (uncorrected), heavier than water and insoluble therein, but dissolved by cold dilute acids, with formation of saline compounds. Its *sulphate*, $C^6H^{11}\{N(CH_3)_2\}COOH.H_2SO_4$, crystallises in very small prisms, easily soluble in cold water, sparingly soluble in dilute sulphuric acid.

* In Griess's memoir, this compound is called trimethyl-benzbetaine, and the corresponding anisic compound trimethyl-anisbetaine; but the prefix 'trimethyl' is surely superfluous: the base $C^6H^9(CH_3)_3NO_2$ is called betaine, not trimethyl-betaine, and by analogy, the base $C^6H^{13}(CH_3)_3NO_2$ should be called benzbetaine.

The *platinochloride*, $2 \left[C^H \cdot \left\{ \begin{smallmatrix} N(CH^3)^2 \\ COOCH^3 \end{smallmatrix} \right\} \cdot HCl \right] \cdot PtCl^4$, forms spindle-shaped laminae, very slightly soluble in cold water.

Anis betaine $C^H H^3 NO^2 = C^H \cdot N(CH^3)^2 O^2$, which has the composition of trimethyl-amidanisic acid, is produced in like manner by the action of methyl iodide on amidanistic acid. It crystallises from aqueous solution in large, generally very well-defined prisms, sometimes an inch long, having a vitreous lustre, and containing 5 mols. water of crystallisation. It is very easily soluble in hot, moderately soluble in cold water, less soluble in alcohol, and quite insoluble in ether. Like benzbetaine, it has a bitter taste and is neutral to vegetable colours. The *hydriodide*, $C^H H^3 NO^2 HI + H^2 O$, forms white shining needles, sometimes an inch long, moderately soluble in hot, very slightly in cold water, apparently less soluble in alcohol, and quite insoluble in ether.

The *platinochloride*, $2(C^H H^3 NO^2 \cdot HCl) \cdot PtCl^4$, crystallises in narrow yellow laminae, very slightly soluble in cold water.

By dry distillation, anisbetaine is transformed, like the preceding compound, into the methylic ether of dimethylamidanic acid, $C^H H^3 \left\{ \begin{smallmatrix} N(CH^3)^2 \\ OCH^3 \\ COOCH^3 \end{smallmatrix} \right\}$, which is a yellowish liquid, having a faint aromatic odour, insoluble in water, and boiling at 288° (uncorrected.)

SEYRICHITE. A native sulphide of nickel from the Westerwald. See NICKEL.

BILE. *Modification of Pettenkofer's test.* G. Strassburg, (*Pflüger's Archiv. f. Physiologie*, iv. 461), in testing icteric urine for bile-acids by Neukomm's improved form of Pettenkofer's test (1st Suppl. 341), obtained only a yellow, but never a cherry or violet colour, showing that the quantity of these acids in the urine, even in cases of intense jaundice, is very small. The following method was, however, found to give certain indications: A piece of filtering paper is dipped into the urine previously mixed with a little cane-sugar, and allowed to dry; a drop of pure sulphuric acid is then put upon it, and allowed partially to run off. In a quarter of a minute, a beautiful violet colour appears, best seen by transmitted light. By this means, 0.00003 gram of glycocholic acid can be detected. The great delicacy of the test is, perhaps, due to the absence of water, whereby the charring, which would otherwise occur and obscure the reaction, is prevented.

The spectrum yielded by the violet-red liquid obtained in treating sodium glycocholate with sugar and sulphuric acid for Pettenkofer's test, consists of three bands, one extending from midway between C and D to D, the second midway between D and E, and the third between E and F (Heynsius u. Campbell, *Pflüger's Archiv. f. Physiologie*, iv. 497).

Action of Bile on Starch.—According to v. Wittich (*Pflüger's Archiv. f. Physiologie*, vi. 181), fresh human bile possesses the power of converting starch into sugar, a property previously observed by Masse in the bile of the pig. Boiled starch mixed with 20 to 30 drops of human bile, and left for an hour at the ordinary temperature, exhibited a distinct sugar reaction with copper sulphate. The bile mixed with absolute alcohol as long as it exhibited turbidity, left, on filtration, a residue which, on being treated with glycerin, yielded an extract, exhibiting after 24 hours an energetic diastatic action. Still more active was the alcoholic precipitate of the extract dissolved in water.

BILE-PIGMENTS.—Bilirubin and other bile-pigments, treated with oxidising agents, yield a blue product, called bilicyanin, produced by moderate oxidation, and a brown substance called cholestin, resulting from more complete oxidation. These products have been studied by Maly (*Wien. Akad. Ber. [zweite Abth.]* lix. 597; *Jahresb.* 1869, 817) and by Heynsius u. Campbell (*Pflüger's Archiv. f. Physiologie*, iv. 497). Bilicyanin is best obtained by adding an alcoholic solution of bromine to bilirubin suspended in chloroform. If the liquid be left to evaporate as soon as it exhibits a pure blue colour, there remains a shining dark mass, which appears dark green when spread in a thin layer upon porcelain, but dissolves with splendid blue colour in alcohol; it is less soluble in ether, more freely in ether-alcohol. The blue alcoholic solution (containing a little hydrobromic acid), exhibits the following reactions: on gently heating it with weak nitric acid, the blue colour passes slowly through violet and purple-red to light brown; with caustic potash a dingy sap-green liquid is produced, becoming blue again on addition of hydrochloric acid; with ammonia, a dark indigo-blue liquid, which becomes bright blue on addition of hydrochloric acid.

solution of neutral lead acetate forms a dark green-blue precipitate; silver nitrate merely throws down a little silver bromide, and on adding ammonia to the filtrate, a black-brown precipitate is formed, which dissolves in a mixture of alcohol and acetic acid, with a violet colour, changing to fine blue. With hydrochloric acid and zinc, the blue solution slowly becomes dark green, then sap-green; hydrochloric acid alone does not alter the colour. Hydrogen sulphide forms a bright green solution, and then flocks of biliverdin, the liquid becoming nearly colourless. On mixing the liquid with a few drops of nitric acid, and pouring it upon sulphuric acid, so as to form a supernatant layer, the remainder of the bile-pigment is obtained with very fine colour. Ammonia and calcium chloride slowly form a precipitate of dark indigo-blue colour (Maly).

According to Heynsius and Campbell, bilicyanin prepared as above, is not a perfectly definite product, as it exhibits various degrees of solubility, and gives two, or perhaps three absorption-spectra in the yellow and green. It does not exist in natural bile-pigment till after oxidation by exposure to the air or otherwise. It exists in gall-stones and probably in urine, inasmuch as it reacts with hydrochloric acid somewhat like indican, and may have been mistaken for that substance in urine.

Choletelin, the end-product of the oxidation, is best obtained by passing nitrous vapours into alcohol in which bilirubin or bilihumin is suspended. If the alcoholic solution be then poured into water, nearly the whole of the colouring matter separates in flakes of the colour of ferric oxide, which in many cases soon become denser, and are easy to filter and wash; they dry up to a brown powder. Choletelin cannot be made to crystallise from any solvent. It dissolves very easily in the fixed alkalis and their carbonates, also in ammonia, forming brown solutions, from which it is precipitated in flocks by acids. It is soluble in alcohol, ether, and chloroform. The alcoholic solution is precipitated by water; with silver nitrate it gives a precipitate only on addition of ammonia. No perceptible reaction is produced by hydrogen sulphide, or by zinc and hydrochloric acid.

The quantity of bromine used in the formation of choletelin shows that it is formed from bilirubin by assumption of 3 atoms of oxygen. Its analysis gave numbers leading to the formula $C^{18}H^{18}N^2O^3$ (= bilirubin — C + 3O); but as neither carbonic nor formic acid appears to be produced at the same time, Maly is of opinion that its true formula is $C^{18}H^{18}N^2O^4$. Silver nitrate added to a solution of choletelin in a small quantity of dilute aqueous ammonia throws down red-brown flocks, which separate from a nearly colourless liquid: the second of three fractional precipitations yielded an amount of silver agreeing with that of the bibasic compound $C^{18}H^{18}Ag^2N^2O^4$. Choletelin is not much attacked by strong nitric acid, and in particular does not yield any picric acid. By dry distillation with soda-lime it yields a tarry distillate not containing either aniline or phenol (Maly).

Choletelin does not give Gmelin's pigment reaction (the change of colour from green to blue, violet, red, and yellow produced by treating bile-pigments with nitric acid containing nitrous acid). Its spectrum is more constant than that of bilicyanin, consisting of one broad absorption-band extending from *b* to a little beyond *F*, when in acid solution; in an alkaline solution the band is somewhat less refrangible. Choletelin may be detected by its spectroscopic characters in icteric urine, but is never found in normal urine or in gall-stones (Heynsius & Campbell).

Reducible Product of the Oxidation of Bile-pigments (Stokvis, *N. Rep. Pharm.* xxi. 123).—This substance is formed as a secondary product in most cases of the oxidation of biliary colouring matter whereby Gmelin's reaction is produced. It is colourless, or of a light yellow tint, and is soluble in water, alcohol, and dilute acids. It becomes of a beautiful rose-red colour when boiled with reducing agents in alkaline solutions. The red solution gives in the spectrum a tolerably broad absorption-band in the green. In concentrated solutions (thick strata) the band begins close on the line *D*, and extends to *δ*. In dilute solutions (thin strata) it occupies only two-thirds of the space between *D* and *E*, ending short of *E*. Shaking with air causes both the rose colour and the absorption-band to disappear. This by-product differs from the bile colouring matter and other oxidation-products of the same, in being insoluble in chloroform and ether, and in not forming insoluble compounds with neutral or basic lead acetate. It is precipitated however by ammonia and basic lead acetate.

This substance exists as such in the gall-stones both of man and of the ox. It can be obtained from them by simple boiling with distilled water, and extraction with dilute acids. It does not exist in fresh bile. It occurs in the urine of animals which have been starved for some days previously, in icteric urine, and in the urine of febrile diseases, such as small-pox, typhus, &c. It is not found in healthy urine. It seems to be present in the alimentary canal, although in direct experiments with different kinds of food little or none could be found. In alkaline solutions it soon loses its

characteristic properties. Its occurrence in any liquid of neutral or acid reaction affords an indication of the previous existence of bile-pigments therein. In applying the test, the liquid is to be precipitated with lead acetate, excess of lead removed by oxalic acid, and the filtrate concentrated and boiled with alkalis and a reducing agent. If no reduction takes place, and if the other tests for biliary colouring matter have given a negative result, their absence may be safely inferred.

Blue Colouring matter of Bile. E. Ritter (*N. Rep. Pharm.* xx. 569) describes a blue colouring matter, which appears to be a constituent of the bile itself, and not a product of oxidation, like the blue pigment above described, or those which Städeler and Jaffé have obtained by the action of nitric acid on the natural pigments of the bile. Ritter finds this substance in the bile of man, and in that of the ox, sheep, pig, dog, and cat. To prepare it, bile is shaken with chloroform, till a yellow solution is obtained, and the yellow chloroform solution is treated with sodium carbonate till the colour entirely disappears. On neutralisation with hydrochloric acid, two layers are formed, one of which contains the yellow chloroform solution, the other the blue colouring matter in a state of suspension. This colouring matter is insoluble in chloroform and acids. It dissolves in alkalis, forming a colourless or yellowish solution. When this solution is neutralised with acids and exposed to the air, a brown precipitate is formed, which becomes blue again, sometimes in a few days, sometimes only after a month. In this respect it differs from reduced indigo, which, when dissolved in alkalis, instantly turns blue on exposure to the air.

Conversion of Bilirubin into Urinary Colouring matter: Hydrobilirubin. When bilirubin is dissolved in dilute soda or potash-ley, and sodium-amalgam is added, air being excluded, no hydrogen is evolved, but the dark colour gradually lightens; after two or three days' action, the solution acquires a yellow or bright brown-yellow colour, and then gives off hydrogen. From this liquid hydrochloric acid separates a pigment, which seems to be a weak acid, yielding with alkalis brown-yellow soluble salts, and with heavy metals insoluble compounds which separate in red flakes; it is readily soluble in alcohol, slightly in water, readily in ammonia and fixed alkalis, also in ether, liquid hydrocarbons, glacial acetic acid, and chloroform. Its spectrum has a characteristic dark black absorption-band between the green and blue (Fraunhofer's lines *D* to *F*) more marked in acid solution than in alkaline. This product appears to be identical with the urobilin of Jaffé (*Virchow's Archiv.* xlvii), obtained from normal and febrile urine; it also agrees with the product from excrement obtained by Vaulair and Masius (*Centralbl. f. d. Med. Wissensch.* 1871, No. 24), and with the urinary colouring matter obtained by Scherer. It contains about 1.5 p. c. carbon less, and about as much per cent. hydrogen more than bilirubin, and may therefore be appropriately called hydrobilirubin. Its composition may be represented by the formula $C^{22}H^{16}N^2O^7$, and its formation from bilirubin by the equation:

Its formation in the intestine from the colouring matter of the bile is essentially the same process as that with sodium-amalgam, inasmuch as abundance of hydrogen is generated in the intestine and immediately exerts a hydrogenising action.

Biliverdin appears to be acted upon by sodium-amalgam in the same manner as bilirubin (*R. Maly, Ann. Ch. Pharm.* clxi. 368; clxiii. 77).

BISMUTH. A specimen of native bismuth from Peru, analysed by G. Barth, (*Vierteljahrsschrift pr. Pharm.* xviii. 580), was found to contain 98.372 p. c. bismuth, 4.670 antimony (with a little tin), and 2.058 copper (with a little iron), no sulphur or arsenic.

Fusion and Volatilisation.—According to A. von Riemsdyk (*Chem. News*, xx. 32), bismuth melts at 268.3°, and does not volatilise sensibly at temperatures considerably above its melting point. At a bright red heat, 2.3433 grams of bismuth lost in an hour 1 milligram in weight.

Detection of Bismuth in presence of Lead and Antimony.—Small quantities of bismuth in presence of lead or antimony, may be detected by the characteristic red coating which, as observed by v. Kobell, (p. 102), is produced when bismuth is heated on charcoal with a mixture of potassium iodide and sulphur. The same reaction may be obtained by heating the substance under examination with an equal weight of a mixture of 5 parts sulphur and 1 part potassium iodide in an open tube 4 inches long and not less than half an inch wide.

When pure lead oxide is thus treated, part of the sulphur sublimes and condenses above the assay, its heavy vapours also burning at the lower end of the tube. The

copious yellow fumes pass through the tube, and an abundant sublimate condenses, beginning about one-third of an inch above the assay, and becoming bright yellow when cold.

Lead oxide, with 1 p. c. of Bismuth trioxide, exhibits the same phenomena as above, but one-third of an inch above its lower edge the yellow sublimate is replaced by a broad and distinctly red ring of the bismuth sublimate.

Lead oxide, with $\frac{1}{2}$ p. c. of Bismuth trioxide, gives the same reaction as in the last experiment, but the bismuth sublimate is orange-red, but still so distinctly marked as to leave no doubt that even a smaller proportion of bismuth could be detected.

With 50 parts of Lead oxide, 50 parts of Antimony trioxide, and 1 part of Bismuth trioxide, the white antimonial sulphide entirely conceals the bismuth reaction. To obviate this, the mixture of the three oxides is mixed with an equal volume of sulphur, and treated with the blue flame for several minutes; and the resulting fused sulphides are removed to a flat coal, and treated alternately with the oxidising and reducing flames, until the antimonial fumes have nearly ceased, and an impure blue lead flame appears. The residue, powdered and treated as before in the open tube, yields a distinct bismuth sublimate, about one-third of an inch above the lower edge of the yellow sublimate.

Care must be taken not to confound with the bismuth sublimate, a sublimate of iodine, which may condense in the upper part of the tube, but at a greater distance from the assay (H. B. Cornwall, *Chem. News*, xxvi. 150).

Assay of Cupreous Bismuth ores.—The direct separation of bismuth from ores containing a large proportion of copper is attended with considerable difficulty, inasmuch as copper and bismuth behave in the same manner with nearly all metallurgic reagents. In presence of an alkaline flux, however, bismuth sulphide is instantly reduced by carbonaceous matter, while copper sulphide is unattacked. The application of this reaction is as follows:

If the metals exist already in the state of sulphides, it is only necessary to fuse them with the ordinary reducing mixture, to which a little sulphur has been added, to prevent any desulphuration of the copper by the alkali. The yield of bismuth is tolerably free from copper. In the treatment of oxidised ores, the operation is conducted in a similar manner, but a larger amount of sulphur is required, since the whole of the metals have to be sulphurised. The following proportions are recommended for the flux:—Sodium carbonate, 5 parts; salt, 2 parts; sulphur, 2 parts; charcoal, 1 part. Two or three parts of this flux are required for the reduction of three parts of ore.

In the extraction of bismuth by the sulphur-carbon process, there is a loss of about 8 p.c. of the bismuth contained in the ore. Although this loss is unavoidable, it is partly compensated by the elimination during the operation of a considerable quantity of arsenic, antimony, and lead, so that the crude metal obtained by this process is not so impure as the corresponding metal obtained by the direct reduction of the oxidised ore (Hugo Tamm, *Chem. News*, xxv. 85).

Refining of Crude Bismuth.—To separate arsenic, the bismuth is melted at a bright red heat, under a cover of borax, and strips of iron are plunged into the molten metal. The arsenic rapidly combines with the iron, forming an arsenide, which rises to the surface of the metal. When the iron is no longer attacked, the whole is allowed to cool, and the bismuth, while still fluid, decanted from the iron arsenide, which solidifies more rapidly.

Antimony is most easily separated by melting the alloy with a quantity of bismuth oxide equal to three times the weight of antimony contained in the metal. The bismuth oxide is instantly reduced to the metallic state, while the antimony is converted into oxide. The latter, in combination with a little bismuth oxide, floats on the surface of the pure metal, whence it can be easily removed.

Copper may be completely separated from bismuth by treating the alloy, at a low red heat, with potassium sulphocyanate. One part of a mixture of 8 parts of potassium cyanide and 3 parts of sulphur is thrown over 16 parts of the metal melted at a low temperature. As soon as the reaction takes place, the crucible is covered, and when all deflagration has ceased, the metal is well stirred with a clay stirrer, the flux allowed to set, and the fluid metal poured out. The bismuth will be found perfectly free from copper (Tamm, *ibid.* 100).

Electrolysis of Bismuth oxide.—The fused oxide is easily reduced by the current of 12 Bunsen's elements. If copper poles are used, the negative pole soon becomes covered with metallic bismuth; with platinum wires, an alloy of bismuth and platinum is formed, which melts and drops off. In the solid state the oxide does not conduct (P. Buckhard, *Zeitschr. f. Chem.* vi. 212).

Bismuth-salts of Organic Bases. Jörgensen (*J. pr. Chem.* [2] iii. 328) has prepared a series of well-crystallised double salts containing bismuth, and represented by the general formula $3R(C^2H^3)^4R'.2BiR^2$, in which $R=N, P, As$ or Sb ; $R'=I, Br, Cl$. The iodine-compounds are red, or brownish-red, the bromine-compounds yellow, or occasionally brownish-yellow, the chlorine-compounds colourless.

The iodine-derivatives are produced by precipitating a hot alcoholic solution of the periodide of an organic base with potassium-bismuth iodide or with hydrogen-bismuth iodide. Thus the tetrethylammonium-bismuth iodide, $3N(C^2H^3)^4I.2BiI^2$, is formed according to the equation:

The ethylphosphonium, ethylstibonium, and ethylarsonium compounds have a composition similar to that of the nitrogen salt, viz.:

The bromine and chlorine derivatives are prepared by precipitating the hot alcoholic solution of the periodide with a solution of bismuth hydrate in strong hydrobromic or hydrochloric acid respectively. The tetrethylammonium-bismuth bromide has the composition, $3N(C^2H^3)^4Br.2BiBr^2$; the chloride, $3N(C^2H^3)^4Cl.2BiCl^2$. Corresponding phosphorus, arsenic, and antimony compounds have also been obtained.

BISMUTHITE. This mineral, consisting of hydrated bismuth carbonate, occurs, together with Joscite, at San João (José) di Madureira in Brazil, in small stratified lumps, which appear to inclose a number of pseudomorphous prismatic crystals; the recently fractured surface exhibits, under the lens, the appearance of pyromorphite. The mineral is very soft, and has a specific gravity of 5.66. The powder is grass-green, and retains its colour when boiled with potash, but is immediately blackened by ammonium sulphide. Heated in a tube before the blowpipe, the mineral decrepitates, gives off a large quantity of water, and becomes brownish. On charcoal it melts very easily, and is reduced with intumescence. It dissolves in nitric acid, especially when heated, with evolution of carbonic anhydride. Fused on charcoal with sulphur, and then with potassium iodide, it yields a bright red deposit of bismuth iodide (v. Kobell, *Jahrbuch f. Mineralogie*, 1871, 939).

BISMUTHOFERRITE. A silicate of iron and bismuth from Schneeberg in Saxony, occurring both in crystals and in finely granular, compact, and earthy forms. Two specimens analysed by Frenzel were found to contain:

SiO^2	Fe^2O^2	Bi^2O^2
23.08	33.33	43.26 = 99.67
24.05	33.12	42.83 = 100

agreeing nearly with the formula $Bi^2O^2.2Fe^2O^2.4SiO^2$, or perhaps $Bi^2O^2.SiO^2 + 2Fe^2O^2.3SiO^2$, which requires 23.44 SiO^2 , 31.25 Fe^2O^2 , and 45.31 Bi^2O^2 (Frenzel, *Jahrbuch f. Mineralogie*, 1872, 1321; 1873, 478).

The massive green iron ore containing bismuth, found also at Schneeberg, and known as *hypochlorite*, is probably a mixture of bismuthoferrite with quartz and another body of yet undetermined constitution. See *HYPOCHLORITE*.

BITTER ALMOND OIL. This liquid is often adulterated with nitrobenzene. The adulteration cannot be detected with certainty by the density, for though nitrobenzene is much heavier than pure bitter-almond oil, it is possible that alcohol may also have been added, which will diminish the density. Neither can the formation of aniline from nitrobenzene by the action of nascent hydrogen be relied upon, since this reaction does not take place in presence of a large quantity of bitter-almond oil. A very delicate test of purity is, however, obtained by agitating the suspected oil with half its weight of caustic potash. If nitrobenzene is absent, only a yellowish colour is thereby produced, but in presence of nitrobenzene the yellow becomes first yellowish-red, then green; and on adding water, the mixture separates into two layers, the lower yellow and the upper green (Bourgoin, *Bull. Soc. Chim.* xvii. 243).

The quantity of nitrobenzene present may be approximately determined by shaking 5 to 10 grams of the essence in a wide-mouthed bottle with 20 to 40 c.c. of concentrated solution of acid sodium sulphite, which precipitates the benzoic aldehyde, then adding ether, filtering quickly, evaporating off the ether, and weighing the residue of nitrobenzene. The quantity of nitrobenzene thus formed is about 90 p.c. of the total quantity present in the bitter-almond oil (Bourgoin, *ibid.* xviii. 113).

BIURET. $C^2H^4N^2O^2$. This body, which Wiedemann obtained by the action of heat upon urea (*Ann.* 1800) has lately been further studied by Hofmann (*Ann. Chem.*

Ges. Ber. iv. 262). The transformation of urea into biuret takes place so easily that the reaction may be used as a test for urea, or as a lecture experiment. It is only necessary to heat half a gram or even less of urea until ammonia escapes, to obtain a considerable quantity of biuret, the presence of which is shown by dissolving the residue in water, and adding a few drops of a solution of copper sulphate and an excess of soda. If very little copper sulphate has been taken, the liquid assumes a pale red colour, but if an excess has been used, a deep violet colour appears.

To prepare large quantities of biuret, urea is heated, according to Wiedemann's direction, in an oil-bath to 150°-160° till the residue no longer dissolves completely in water. The product is now boiled out with water, and the biuret, which separates out on cooling, is obtained in a perfectly pure state by recrystallising it repeatedly from water and at last from dilute ammonia. From the insoluble residue a large quantity of cyanuric acid may be obtained; the mother-liquors of the biuret contain undecomposed urea, which may be employed in a second operation.

Biuret is not readily soluble in cold water, as Wiedemann states; 100 parts require at 0°, 8025 parts; at 15°, 6493 parts; and at 106° (the boiling point of the concentrated solution), 222 parts of water. Wiedemann obtained it only in granular crystals; but if biuret is completely freed from cyanuric acid by crystallising it from alcohol, it crystallises in fine long needles, and is identical and not isomeric with the body, called *isobiuret*, which Baeyer obtained by the action of ammonia upon tribromacetyl-urea (1st *Suppl.* 349).

Biuret is also formed by heating ethylic allophanate with aqueous ammonia in sealed tubes to 100°:

The melting point of biuret is stated differently by different authors; the reason of this is, that the melting point is also the temperature of decomposition, and varies according to the quantities taken or the mode of heating.

Ethylamino does not act upon ethylic allophanate; if the two substances are heated together in sealed tubes to 160°, the same decomposition takes place that would be produced by water alone, the products being urethane, carbon dioxide, and ammonia.

Diphenyl-biuret, $C^6H^5N^2O^2 = C^6H^5(C^6H^5)^2N^2O^2$.—This compound has been obtained in two modifications, distinguished as α and β . The former, which is slightly soluble in alcohol and crystallises therefrom in densely interwoven needles melting at 210°, is formed by heating ethylic allophanate with aniline to the boiling point:

The same body is formed directly when aniline is boiled for some time with biuret:

β -Diphenyl-biuret is formed by pouring an alcoholic solution of ammonia on finely powdered phenylic isodicyanate:

It is insoluble in water, slightly soluble in ether, more easily in alcohol. The boiling saturated alcoholic solution deposits well-formed prisms with truncated pyramidal summits, melting at 165°.

Triphenyl-biuret, $C^6H^5N^2O^2 = C^6H^5(C^6H^5)^3N^2O^2$ is formed by prolonged digestion of 1 mol. phenyl isodicyanate with 1 mol. aniline. The two bodies unite into a crystalline mass, from which, by recrystallisation from alcohol, prisms with terminal planes are obtained. This body closely resembles urea, but melts at 147°, instead of 285° (*Hofmann, Deut. Chem. Ges. Ber.* iv. 250).

BLACK CUMKIN. See NIGELLA.

BLACK SNAKE-ROOT. See CIMICIFUGA.

BLEACHING POWDER. A new method for estimating the available chlorine in bleaching powder is given by J. Horreschhoff (*Chem. News*, xxiii. 293). It is based upon the fact that when bleaching powder is made to act upon an excess of stannous chloride in strongly acid solution, stannic chloride is formed at the expense of the available chlorine in the former. The reaction is represented by the following equation:—

The excess of stannous chloride is afterwards estimated by means of a standard solution of potassium dichromate, and deducted from the amount originally employed:

2nd *Sup.*

The process is conducted in the following manner:—
 12·8738 grams of pure potassium dichromate are dissolved in water, and the solution diluted to 1 litre. 1·0 c.c. of this solution is equivalent to 0·01 milligram of chlorine. About 30 grams of stannous chloride are dissolved in water freely acidified with hydrochloric acid, and the solution is likewise diluted to 1 litre. To ascertain the strength of the stannous solution, 10 c.c. are taken with a pipette, diluted with distilled water and 5 c.c. of hydrochloric acid; a few drops of solution of potassium iodide and starch paste are added; and the standard solution of dichromate is run in from a burette, until a blue colour is produced by the liberation of iodine. If 20 c.c. of the standard dichromate solution are required, 1 c.c. of the stannous solution will equal 2 c.c. of the former, and also 0·02 milligram of chlorine.

Again, supposing the tin solutions to be of the above strength, 20 c.c. of the new standardised solution are measured as before, diluted with water, and 1 gram of bleaching powder well triturated with water is added, together with 10 or 12 c.c. of hydrochloric acid. The reaction is energetic and complete, and if a sufficient amount of hydrochloric acid is introduced, the solution will become perfectly clear.

A few drops of solutions of starch and potassium iodide are now added, and afterwards standard dichromate solution, until the deep blue colour of iodide of starch remains permanent. Supposing that 10 c.c. of the latter solution are consumed, then $10 \text{ c.c.} \div 2 = 5 \text{ c.c.}$; $20 \text{ c.c.} - 5 \text{ c.c.} = 15 \text{ c.c.}$ As 1 c.c. of the stannous solution equals 0·02 Cl. and 15 c.c. are required for 1 gram of bleaching powder, then $15 \times 0·02 \text{ Cl.} = 0·030 \text{ Cl.} = 30 \text{ per cent.}$

Herreshoff objects to Penot's well-known arsenic method, upon the ground that, in the first place, it is difficult to ascertain the purity of the arsenious acid employed; and secondly, that the solution of sodium arsenite will not remain with certainty unchanged for any length of time. In the present instance, although the tin solution alters slowly by keeping, it is nevertheless a matter of a few moments only to re-standardise it accurately by means of the dichromate solution.

The process, however, is not free from an objection which is sometimes urged against Bunsen's method, viz., that many specimens of bleaching powder contain chlorate, which, liberating chlorine on the addition of hydrochloric acid, will consume a certain volume of standard solution, and thus raise the percentage. Penot's method is not liable to this source of error.

Another method is given by Graeger (*Dingl. polyt. J.* cci. 167), depending on the use of ferrous sulphate.

To a dilute and strongly acidified solution of ferrous sulphate, the strength of which is exactly fixed by a $\frac{1}{10}$ th potassium permanganate solution, the bleaching powder solution is added with a pipette, the point of the latter being placed close on the bottom of the vessel, so that the bleaching powder solution forms the lower layer of liquid; the glass stopper is placed in the flask, and the latter, with its contents, is well shaken, and then allowed to stand for some minutes. When a sufficient quantity of ferrous sulphate is used, scarcely any smell of chlorine—in most cases, none at all—is perceived on opening the flask. The excess of the ferrous salt is now estimated with the $\frac{1}{10}$ th permanganate solution, the difference between this and the original amount of ferrous salt used representing the weight oxidised by the hypochlorous acid, from which the available chlorine in the powder is readily calculated. If 1 gram of bleaching powder be fixed as the constant weight to be taken, a sufficient excess of iron salt must be added to absorb all the oxygen yielded, and to leave not too large a residue to be estimated by the permanganate solution. 4 or 5 grams of ferrous sulphate is recommended as the weight to be used. The results are found to correspond exactly with those obtained by the use of Penot's solution of sodium arsenite. Graeger does not recommend the use of ammonio-ferrous sulphate as a substitute for ferrous sulphate, since it gives use to the formation of nitrogen chloride, as previously shown by Biltz.

Calvert (*Compt. rend.* lxxv. 411) analyses bleaching powder by exhausting a known weight of it with water, treating the filtrate with carbonic acid, and boiling to decompose bicarbonate. The precipitated calcium carbonate represents the quantity of hypochlorite, while the calcium chloride remains in solution, and may be determined by silver nitrate or by evaporation to dryness, and fusion. The average results give 1 part hypochlorite to 2 of chloride.

BLEGIOOLITE. This name is given to an iron colite belonging to the brown Jurassic formation of the Alps from the Glarnisch, in the Canton Glarus. It possesses a general interest, in so far as its formation by deposition from an ancient Jura Sea admits of chemical demonstration. When the iron-ore is exhausted with water, the resulting solution is found to contain the constituents of sea-water, viz., small but distinctly recognisable quantities of chlorine (bromine, iodine), magnesia, and alkalis. Specimens taken from the very middle of the compact mass contained these soluble

constituents, showing that they could not have been introduced by subsequent infiltration, but must have been derived from particles of sea-water mechanically enclosed in the mass as it was deposited. The quantity of chlorine found was 0.034 p.c. (A. Baltier, *Deut. Chem. Ges. Ber.* v. 983).

BLENDE, ZnS.—This mineral occurs at Unkel in rhombic dodecahedrons, sometimes of considerable size, and having their faces thickly covered with smaller blende crystals, all disposed parallel to one another, so that the reflected images from their dodecahedral faces coincide with those from the faces of the large crystal. The small crystals are very irregularly developed, but exhibit the face 303 in combination with ∞O , forming a four-faced accumulation of its octohedral summits, by which it is easy to recognise the situation of the faces of the crystal. The occurrence of 303, and of the subordinate faces $\infty O \infty$ and O , marks out the independent form of the small crystals, showing that the faces of the large crystal have not been corroded, but are covered with a layer of smaller crystals in regular order (A. v. Lasaulx, *Jahrbuch f. Mineralogie*, 1871, 937).

BLOOD. Inorganic Constituents.—Analyses of the inorganic constituents of dogs' blood have been made by Jarisch (*Ann. Ch. Pharm.* clxiii. 236). The blood was received direct from the vessel in carefully weighed and stoppered flasks surrounded by ice in order to avoid loss by evaporation. The weight was accurately determined after the blood had been allowed to thaw. The blood was then evaporated, and the mass, before complete incineration, digested with hot water in order to extract soluble chlorides, &c., and thus provide against loss of those constituents by strong heat. The solution was evaporated, incinerated to destroy organic matters, and redissolved in water. This solution was added to the fully incinerated mass, and the whole evaporated and dried. In this manner the inorganic constituents were obtained without loss. As, however, even after the most careful incineration, it is almost impossible to get rid of all the carbon, the results are always a little too high, but serious error is eliminated by comparison of the found with the calculated constituents.

The ash so obtained is partly soluble in water, and completely so in hydrochloric acid. The watery solution has an alkaline reaction.

The following Table contains the percentage results of four analyses of blood-ash, three of arterial and one of venous blood, compared with those formerly obtained by Verdeil:—

	Arterial Blood			Venous Blood	Verdeil	
	I	II	III	IV	A	B
Phosphoric anhydride	13.44	11.84	13.00	11.02	13.96	11.69
Sulphuric anhydride .	4.08	4.72	3.28	3.97	1.71	1.08
Chlorine .	30.55	33.73	30.08	30.48	30.25	30.94
Carbonic anhydride .	—	—	—	—	0.53	0.37
Potash .	4.43	3.54	3.66	3.70	15.16	19.16
Soda .	41.00	44.73	40.48	41.81	32.19	29.03
Lime .	1.01	1.61	1.25	1.13	1.10	0.70
Magnesia .	0.70	0.75	0.64	0.41	0.67	4.38
Ferric oxide .	9.14	6.68	7.56	10.08	12.75	8.65

Jarisch's results agree in many points with those of Verdeil; but he finds no carbonic acid, and his percentages of soda are much higher, and those of potash lower than in Verdeil's analyses. The quantities of phosphoric acid, chlorine, lime, and magnesia, and ferric oxide, differ but little.*

The following are the mean percentages of the various constituents calculated from Jarisch's four analyses:—

* In a note to Jarisch's paper, Liebig remarks: "The differences in the determinations of potash and soda are doubtless due to the varying amounts of the two alkalis in the blood. Blood of oxen slaughtered here (at Munich) gave by dialysis sodium chloride and an abundance of potassium salts; the concentrated liquid effluoresced with acids and contained a small quantity of phosphate of alkali-metal."

	In 100 parts of Ash	In 100 parts of fresh Blood
Phosphoric anhydride	12.32	0.1103
Sulphuric anhydride	4.01	0.0358
Chlorine	31.43	0.2805
Potash	3.83	0.0342
Soda	42.01	0.3748
Lime	1.25	0.0112
Magnesia	0.65	0.0058
Ferric oxide	8.34	0.0948

Total amount of Ash in fresh Blood.

Calculated	Found
0.8640	0.8922

Dissolved Earths and Phosphoric Acid in Alkaline Blood.—The existence in the blood of earthy phosphates combined with albumin, and thereby kept in solution, has often been assumed, but the earthy albuminates have not hitherto been actually prepared. Fokker, however (*Pflüger's Archiv*, vii. 274), has obtained the albuminates of lime and magnesia by leaving a mixture of albumin with the earth to stand for several hours. Lime-albuminate is most easily prepared by placing filtered white-of-egg in a shallow basin, placing a piece of filter paper on the surface, and strewing pounded lime on it. In a few days a translucent gelatinous layer of lime-albuminate forms on the under side of the paper. Lime albuminate is soluble in water, in solution of sodium chloride, and in phosphoric acid. Its aqueous solutions are not coagulated by boiling, except after the addition of neutral salts. They are precipitated by acids, the precipitate being soluble in excess. Magnesia albuminate is soft, slimy, and much more soluble in water than the lime-compound.

When an aqueous solution of lime-albuminate is precipitated by carbonic acid, the precipitate dissolved by sodium carbonate, and sodium phosphate added to it, a clear sometimes opalescent fluid is obtained, which will remain for many days unchanged, and has a strongly alkaline reaction. It contains lime, which can be precipitated by ammonium oxalate. The alkaline reaction of the liquid shows that the lime is not present as phosphate, and the fact that the solution may be boiled or kept several days *in vacuo* without becoming turbid shows that the lime is not present as carbonate dissolved in excess of carbonic acid. It is present as *lime-phosphate-albuminate*. The alkaline reaction can be due only to alkaline carbonates (or phosphates). The addition of free alkali causes a precipitate of calcium phosphate. If a solution of lime-albuminate is mixed with sodium phosphate, the phosphoric acid combines with the lime, and soda, which again destroys the newly-formed compound, is set free; but if the lime-albuminate is first precipitated by an acid and sodium phosphate then added, the acid used in the precipitation neutralises the soda, which is set free, and the lime-phosphate-albuminate remains in solution.

That lime-albuminate is present in blood is shown by the fact that serum behaves exactly like solutions of lime-albuminate, *i.e.* it can be preserved for some time *in vacuo* without depositing calcium phosphate; but this is gradually thrown down by caustic alkalis and precipitated by ammonium oxalate. The serum must be much diluted before the caustic alkali is added, as an albuminate is otherwise apt to form which interferes with the deposition of the precipitate.

It is probable that all the lime in the serum is present as lime-albuminate, and that no other lime-compounds exist in the blood.

Iron in the Blood of an Invertebrate Animal.—The blood of the *Limax flava* is almost colourless, and contains numerous elliptical corpuscles, about the size of the blood-corpuscles in the cow. It has an alkaline reaction, and consists of water 96.095 p. c., dry residue 3.905, ash 0.767, and iron, reckoned in the metallic state, 0.00069 p. c. Now if iron really forms a constituent of the blood of the snail, it may be expected that, as in the higher animals, it will be present in the blood in larger proportion than in the muscles. At first sight it would appear not to be so, for the snail, freed from its intestines, contains water 84.88, dry residue 15.12, ash 3, and iron 0.001176 p. c., a quantity of iron larger than that in the blood. This is due to the greater proportion of solid residue in the muscles; and when equal quantities of the dry residue of muscle and of blood are compared, the latter is found to contain more than twice as much iron as the former, the numbers being 0.0177 p. c. of iron in dried blood, and 0.0078 in dried muscle. This proportion is very much smaller than in animals with red blood, the dried blood of the ox containing ten times as much iron as the dried muscle. The actual amount of iron in the blood of the limax is only 1/100th of that in red blood. The colourless character of the blood is due to the absence of

hæmoglobin, or to the presence of an analogous substance in small quantity only, since the blood remains yellowish, and does not acquire a red tint even when concentrated by evaporation (Boussingault, *Compt. rend.* lxxv. 173).

Action of Carbon monoxide on the Blood-globules.—Cl. Bernard (*J. Pharm.* [4] xiii. 255) recommends the displacement of oxygen from blood by carbon monoxide (1st *Suppl.* 354), as a method of collecting the gases of blood for analysis. The blood is drawn from a vein or artery, as the case may be, by means of a graduated syringe, into which a volume of carbon monoxide equal to that of the blood to be analysed has been previously introduced; this prevents access of air, and formation of carbon dioxide. The blood is agitated to facilitate the combination of the carbon monoxide and hæmoglobin, and then introduced into a glass globe in which a vacuum has been previously made by means of a mercurial pump.

The gases of the blood are then evolved, and may be submitted to analysis in the ordinary way. In an experiment thus conducted it was found that arterial blood, on its entrance into the muscle of a dog's thigh, contained 7.31 p. c. by volume of oxygen, whilst the venous blood of the same muscle contained only 5 volumes, 2.31 vols. having therefore disappeared in the muscle.

To detect the presence of carbon monoxide in an apartment, Bernard recommends the spectroscopic examination of the blood of an animal which has been kept in it (See further, *Chem. Soc. J.* [2] ix. 839).

Quantity of Ammonia evolved from Blood by Potash and by Permanganates.—Blood yields about one-fifth as much ammonia to potash as to potassium permanganate. 100 c.c. of sheep's blood heated to 150° with potash give off 0.46 gram of ammonia, and the residue heated with permanganate yields 2.20 grams of ammonia (Wanklyn, *Chem. Soc. J.* [2] x. 646).

Separation of the Colouring Matter of Blood by Solution of Tannin.—Traces of blood in urine and other liquids may be detected by adding ammonia or potash, then a solution of tannin, and lastly acetic acid to slight acidulation. If blood is present, a dark coloured precipitate immediately forms, which after treatment with sal-ammoniac and glacial acetic acid, yields splendid crystals of hæmatin (H. Struve, *Zeitschr. anal. Chem.* xi. 29).

Influence of Quinine on the process of Oxidation in the Blood. (A. Schulte, *N. Rep. Pharm.* xx. 539).—Quinine is known to exert great power in arresting the processes of fermentation and putrefaction, and to act as a powerful poison on the lower organisms, or to speak more generally, on all moving bodies consisting of protoplasm. It kills the fungi, bacteria, &c. which accompany fermentation and putrefaction, and puts a stop to those processes themselves. It arrests the motion of the white blood-corpuscles, and thus prevents them from making their exit from the blood-vessels. It therefore diminishes or arrests the formation of pus in inflammation, pus consisting in great measure of an accumulation of white corpuscles which have issued from the vessels. It destroys the power of certain substances to produce ozone, and amongst others, of the red blood-corpuscles: hence when present in the blood, it retards the change of tissue, and thereby lessens the production of heat. It has indeed been shown by Ranke and Kerner that the amount of uric acid and urea excreted in the urine is greatly diminished by large doses of quinine. It remains a question, however, how much of this effect is due to the direct action of quinine on oxidation, and how much to its indirect influence through the nervous system. The former view is supported by an observation of Harley, who found that blood to which quinine had been added, in the proportion of 1 part to 12,000, took up less oxygen and gave off less carbonic acid than normal blood.

The most convenient method of investigating this question of oxidation, is to observe the changes in the alkalinity of the blood. Zuntz noticed that a considerable formation of acid begins to take place in blood immediately after it is drawn, and continues in a lesser degree till putrefaction begins. The amount of acid formed was estimated by the diminution it produced in the alkalinity. The process employed for this purpose depends upon the fact that the colouring matter of blood-corpuscles does not diffuse out of them into sufficiently concentrated solutions of sodium chloride, while the alkalis or salts contained in the corpuscles diffuse readily.

The alkalinity was determined by means of dilute phosphoric acid to which a quantity of sodium chloride had been added, sufficient to prevent the solution of the blood-corpuscles and the consequent interference of their colouring matter with the reaction. The point of saturation was considered to be reached when a distinct reddening of blue litmus-paper was produced, even though the red disappeared immediately. This transient reddening by carbonic acid was chosen rather than the first permanent reddening, because it could be more easily observed. This mode of observation does not give the

absolute amount of alkalinity, but the comparative amount in different samples of blood is all that is wanted; and if they be treated alike as regards temperature, and agitation, &c., the error caused by the carbonic acid is the same in all. The amount of error may be approximately estimated by noting the point at which a transient reddening occurs in the cold solution of sodium carbonate of nearly the same alkalinity as the blood, and then determining the real alkalinity of the boiling solution.

By this mode of observation, Zuntz and Scharrenbroich found that quinine and berberine lessen the production of acid; and this result is confirmed by A. Schulte (*N. Rep. Pharm.* xx. 639), whose experiments show that quinine can stop the formation of acid, both before and after the conglutination of the blood; also that sodium picrate has a similar action to that of quinine, and is nearly as powerful, while cinchonine has a very much smaller effect. Harley found that while quinine lessened oxidation in the blood, other substances, such as snake-poison, increased it. It would seem also, from the experiment of Binz, that similar processes occur in the living body; for when putrid fluids were injected into the circulation of an animal, its temperature rose, but if these fluids were previously mixed with quinine, or if a dose of quinine was injected simultaneously with them, the rise of temperature was arrested or much diminished. Zuntz, to determine the influence of quinine on tissue-change, and the excretion of urea, put himself on a constant diet, and after the daily amount of urea excreted had become constant, took three doses of 0.6 gram of quinine hydrochloride, for two days. The amount of urine at first increased by a third, and then diminished by a corresponding amount. The specific gravity sank from 1.018 to 1.012, the urea sank one-third on the first day on which quinine was taken, and was still further diminished on the second. As soon as the quinine was stopped, the urea increased, and reached its normal amount on the fifth day.

According to Kerner, (*Pflüger's Archiv.* iv. 27) quinine puts a stop to the motions of the white blood-corpuscles, and renders them round and darkly granulated. This action is not due, as Stricker and others have supposed, to the presence of free acid, inasmuch as perfectly neutral hydrochloride or carbonate of quinine in the proportion of 1 part to 400 of fluid, produces this effect, either in aqueous or in alcoholic solution. Solutions of salicin, caffeine, atropine, and sodium arsenite in a similar state of concentration have little or no effect.

On the Composition of the Blood in Chyluria, see Hoppe-Seyler (*Med.-Chem. Untersuchungen*, 1872, 551; *Chem. Soc. J.* [2] ix. 740).—On the Blood and Urine in Leukæmia, see Reichardt, *Arch. Pharm.* [2] cxlv. 142; *Chem. Soc. J.* [2] ix. 421.

Hæmoglobin.—Important observations on the presence of this substance in the muscles of Mollusca, and on its distribution in the living organism, have been made by E. Ray Lankester (*Pflüger's Archiv. f. Physiologie*, iv. 315).

The pharynx of the gasteropods is red, and in *Limæus* and *Paludina* the colour is due to hæmoglobin; this is proved by the spectroscopic appearances and changes. Perhaps as other gasteropods have their pharynges of a red colour, this is in all cases produced by hæmoglobin. The blood of the above and other gasteropods contains, however, no hæmoglobin, and is, in fact, colourless. The only mollusc in which hæmoglobin has been found is *Planorbis* and the allied species, in which the blood is of a brilliant red colour.

The hæmoglobin is distributed through the pale yellow muscular tissue of the pharynx of *Limæus*, and highly refractile granules are also seen. These are apparently identical with the pigment-granules surrounding the ganglion-cells which encompass the nerve-centres, and are of a brilliant yellow or orange colour. The same granular masses are met with in the salivary glands. This yellow pigment gave no distinct absorption-bands, yet the œsophageal ganglia appeared to contain hæmoglobin. It is possible that the yellow granules stand in relation to the development of the hæmoglobin in the muscular tissue, or that occasionally they may become impregnated with hæmoglobin. It is to be expected that the manner in which hæmoglobin is formed in these animals, and the form in which it exists in their muscles, will throw light upon the formation of hæmoglobin in the blood-globules of the Vertebrata.

These observations indicate that the province of hæmoglobin in the animal kingdom is a wide one, and is closely related to the activity of the muscular tissue. It cannot be supposed that the presence of hæmoglobin in the muscles in the above cases is casual. The presence of hæmoglobin in the pharynx muscles of the gasteropods is in accordance with the observation previously made by Lankester, that in all cases the most active and powerful muscles are furnished with hæmoglobin. In keeping with these facts also is the observation, that whilst in man the unstriped muscular fibres of the alimentary canal is free from hæmoglobin, the smooth fibres in the rectum are provided with that substance.

Distribution of Hæmoglobin in various Organisms.—Hæmoglobin has been detected

in the following cases by means of the spectroscope:—1. In the blood of the vertebrata the hæmoglobin is located in the red corpuscles. In *Amphioxus* it is found in the plasma, and not in the corpuscles. 2. In most of the striped muscles of mammalia and birds; but only in the cardiac muscles, and in certain very active muscles of other vertebrata. 3. In the unstriped muscle in the human rectum; in other unstriped muscles it is mostly absent. 4. Its presence in the *Annelida* is variable; in some of these it is accompanied by a second dichroic substance very like hæmoglobin in its spectroscopic relations. 5. It is present in the fluid from the perivisceral cavity of the leech. 6. Hæmoglobin is distributed through the plasma of the so-called blood of the larva of *Chironomus*; but it has been sought in vain in other insects, myriapods, and arachnida. 7. It is also present in the blood-plasma of certain crustaceans, whilst in others it is absent. 8. It is, for the most part, absent from the blood of the molluscs, though it is present in the blood of a gastropod—viz. *Planorbis*. 9. Hæmoglobin is met with in the muscular fibres from the pharynx of gastropod molluscs, as *Limnaeus* and *Paludina*, whilst it is wanting in their blood. 10. There is perhaps some connection between hæmoglobin (which is not met with in plants) and chlorophylloid bodies.

Compound of Hæmoglobin with Carbon monoxide. Carboxy-hæmoglobin (1st Suppl. 354).—Some discussion has arisen as to the manner in which carbon monoxide is united to hæmoglobin, and as to whether the resulting compound is a fixed compound or not. Donders (*Pflüger's Archiv*. iv. 28) states that carbon-monoxide may be expelled from blood saturated with it, by oxygen, carbon dioxide, and hydrogen, even at 0°; oxygen does not convert the monoxide into dioxide, but simply drives it out. If this be the case, it should be possible to pump the carbon monoxide out of blood saturated with it, although it may not be removed quite so easily as oxygen.

The possibility of this, though denied by Rawrocki and Pokrowsky, appears to be established by the experiments of Zuntz (*ibid.* v. 584). When blood saturated with carbon monoxide was placed in a receiver connected with an exhausting pump, and warmed to 37°–42°, an active escape of gas took place, ceasing apparently at the end of half an hour. When, however, the pumping was continued at various intervals, fresh quantities of gas were given off, and a further quantity was obtained by heating the receiver to 60°. The blood so exhausted was found to give the spectrum of reduced hæmoglobin, which was replaced by the spectrum of oxy-hæmoglobin after standing in the air. The hæmoglobin had not undergone decomposition, two analyses giving exactly the same results. The gas obtained was freed from carbon dioxide by caustic potash and from oxygen by potassium pyrogallate. The oxygen obtained, derived in all probability from the air, does not give rise to formation of carbon monoxide.

The gas obtained at 60° was analysed separately from that at 40°. From 31·65 c. c. of dogs' blood, sp. gr. 1071, the quantities were—

at 40° C. — 4·607 c. c. CO (0° and 1 m.)

at 60° C. — 0·998 c. c. CO

Total = 5·605 c. c. CO

i.e., = 17·7 p. c. of the blood-volume.

These experiments demonstrate the important fact that the gas cannot be pumped out all at once, but only at intervals. Schöffner (*Centralbl. f. d. medicin. Wissenschaft*, 1866, No. 42) found that this was also true of carbon dioxide, and he attributed the result to the progressive development of an acid in the blood, by which the gas was set free. Zuntz, however, shows that this supposition is untenable, because he finds that a solution of sodium bicarbonate similarly treated gives off carbon dioxide in the same fitful manner, though the effect cannot in this case be attributed to the gradual development of an acid. Moreover, the total quantity of carbon monoxide obtained agrees with that which was previously dissolved in the blood, whereas if its evolution were due to progressive decomposition, the quantity evolved should be greater.

The preceding results sufficiently account for the fact that other investigators were unable to extract carbon monoxide from the blood by exhaustion, inasmuch as the process was supposed to be complete when no more gas was evolved after the first pumping. They must also modify received ideas regarding poisoning by charcoal fumes. It need no longer be supposed that carbon monoxide cannot be removed from the blood, except by oxidation to dioxide. So long as the heart still beats, there is hope of restoring the blood to its normal condition by energetic artificial respiration.

According to Podolinski (*Pflüger's Archiv*. vi. 568) blood saturated with carbon monoxide is completely deprived of that gas by agitation for half an hour with hydrogen, and more rapidly by oxygen. Nitrogen dioxide absorbed by blood, is

likewise expelled by hydrogen, but less rapidly than carbon monoxide. Hence it appears that the compounds of hæmoglobin with carbon monoxide and nitrogen dioxide are similar in character to oxy-hæmoglobin: the order of stability being, oxy-hæmoglobin, carboxy-hæmoglobin, nitroso-hæmoglobin. Each of the three gases, O, CO, NO, can be expelled by the one immediately following, and each also more easily by the one immediately preceding, than by any other indifferent gas.

According to Keschlakoff and Bogomoloff (*Zeitschr. anal. Chem.* viii. 228) solutions of oxy-hæmoglobin and carboxy-hæmoglobin, through which ammonia is passed gradually, turn brownish-green and no longer exhibit any absorption-bands. Arsine colours solutions of oxy-hæmoglobin, first yellow-brown, then green-brown, the absorption-bands gradually disappearing and being replaced by the band of reduced hæmoglobin, whereupon the solution becomes somewhat red; on the next day, however, the last-mentioned band disappears. Carboxy-hæmoglobin is coloured dingy green by arsine, and its absorption-bands are destroyed.

Absorption of Oxygen by the Blood.—*Estimation of Hæmoglobin.* From experiments made by N. Gréhant (*Compt. rend.* lxxv. 495) it appears that normal arterial blood does not contain as much oxygen as it can take up. The amount obtained from blood from the carotid of a dog under ordinary circumstances was 16.3 volumes p. c.; after the inhalation of oxygen this rose to 23.3 p. c., but blood from the same animal saturated with oxygen by agitation contained 26.8 p. c. The quotient $\frac{26.8}{16.3}$ evidently depends on the rapidity of the circulation through the lungs, the healthy condition of these organs, the activity of the respiratory movements, &c. Thus the relation of the volume of oxygen actually contained in arterial blood to the maximum quantity which it can absorb represents with tolerable exactness the effect produced by the respiratory efforts.

The amount of oxygen absorbed by specimens of blood from different animals of the same species varies with the amount of hæmoglobin they contain, and the quantity of oxygen absorbed affords a ready method of estimating the hæmoglobin. As part of the oxygen, however, is taken up by the salts of the blood and dissolved in the serum, it is better to use carbon monoxide, which is absorbed to a somewhat smaller extent than oxygen, and indicates the amount of hæmoglobin more exactly. Some experiments made by this method seem to show that hæmoglobin is destroyed in the liver.

Influence of Acids upon the Oxygen of Hæmoglobin.—Lothar Meyer observed that the addition of tartaric acid to the blood caused a large proportion of the oxygen contained in it to disappear. This observation has been confirmed by Pflüger and Zuntz, who find that phosphoric acid exerts a similar action, which they attribute to the splitting up of the hæmoglobin by the acid, and the subsequent oxidation of one of the products of its decomposition at the expense of the oxygen in the blood. These experiments have been continued, under Pflüger's directions, by G. Strassburg, who finds that the addition of phosphoric acid to chemically pure hæmoglobin suspended in water, or dissolved in sodium carbonate, causes oxygen to disappear from it in the same manner as from blood. The amount of oxygen loosely combined with dry hæmoglobin at 0° and 1 meter pressure appears from these experiments to be from 0.4483 to 0.8852 c.c. to 1 gram of hæmoglobin, instead of 1.277 c.c. as found by Preyer. The variation in the amount seems to show that oxidation takes place in solutions of hæmoglobin saturated with oxygen, and that part of the oxygen consequently disappears during the process of pumping out the gases of the blood (*Pflüger's Archiv*, iv. 454).

Oxidising Power of the Blood. Schützenberger a. Risler (*Compt. rend.* lxxvi. 440) determine the quantity of oxygen contained in blood by means of a standard solution of sodium hyposulphite $\text{Na}_2\text{S}_2\text{O}_3$ (1st Suppl. 1063) added in sufficient quantity to absorb immediately all the available oxygen; the excess of hyposulphite added is afterwards determined by its power of decolorising a solution of indigo-carmine.

The strength of the hyposulphite solution is previously determined with reference to an ammoniacal solution of copper containing 4.46 grams of cupric sulphate per litre, 10 c. c. of which, when decolorised by the hyposulphite, yield 1 c. c. of oxygen. The hyposulphite solution should be equivalent to about an equal volume of the cupric solution, and to three times its volume of the indigo solution. When the hyposulphite is oxidised by free oxygen, it is converted into sulphate, $\text{Na}_2\text{S}_2\text{O}_4$, each atom of oxygen oxidising 1 mol. of the hyposulphite; but when it is oxidised by the ammoniacal cupric solution, 1 atom of oxygen oxidises 2 mol. of the hyposulphite, probably converting it into an acid of the polythionic series.

The estimation of the oxygen in blood is made by means of a three-necked bottle having the capacity of a litre. Into the middle aperture are fitted, by means of a

caoutchouc stopper, two Mohr's burettes, one containing the hyposulphite solution and the other the indigo. The two other apertures serve for the entrance and exit of a current of hydrogen gas, and for introducing the other liquids by means of a tap-funnel.

Into this vessel are introduced, a half litre of spring water (containing free oxygen); 50 c.c. of water holding in suspension 5 grams of kaolin (which renders the water opaque and makes the changes of tint visible, in spite of the colour of the blood); a small quantity of indigo-carmin; and, lastly, by means of another burette, a quantity of the hyposulphite solution sufficient to absorb the oxygen and decolorise the indigo. The bottle being then closed, the air is expelled by a stream of hydrogen; and by introducing, first, a small quantity of the hyposulphite, then of indigo-carmin, a point is easily found at which the liquid contains neither oxygen nor hyposulphite in excess. 50 c.c. of hyposulphite are now introduced; then by means of the funnel, 5 c.c. of blood; the liquid is shaken, and the indigo-solution allowed to run in drop by drop, till the liquid just acquires a permanent violet tint. Lastly, the volume of hyposulphite equivalent to that of the indigo employed is deducted from the 50 c.c. of hyposulphite, and the quantity of oxygen corresponding with this difference is determined by calculation.

Schützenberger and Risler have hitherto experimented only on ox-blood or dog-blood saturated with oxygen, and with the same blood deoxidised with the air-pump or by carbon monoxide. The general results of their observations are as follow:—

If the oxyhemoglobin of the blood acted on the hyposulphite in the same manner as free oxygen, a minimum of 88 to 90 c.c. of oxygen should be found for 100 c.c. of ox-blood agitated in contact with the air, and a minimum of 50 to 52 c.c. of oxygen for 100 c.c. of blood deoxidised by the air-pump or by carbon monoxide. The difference is 38 to 40 c.c. Now the blood saturated with oxygen which was experimented on, yields to the pump only 19 c.c. for 100. It follows, therefore, that the oxygen of the blood acts on the hyposulphite, not like free oxygen, but like the combined oxygen of an ammoniacal cupric solution. The preceding numbers must therefore be divided by 2.

It appears then that blood saturated with oxygen possesses, with respect to the hyposulphite, an oxidising power equivalent to 45 c.c. of oxygen per cent.; and that blood deoxygenated by the pump or by carbon monoxide has an oxidising power equivalent to 25 or 26 c.c. of oxygen per cent. Blood saturated with oxygen by exposure to the air, or rather oxidised hæmoglobin, possesses therefore an oxidising power $1\frac{1}{2}$ times as great as that which has hitherto been attributed to it according to the volume of oxygen separated by the pump or by carbon monoxide. This additional quantity of oxygen exists in a state of more intimate combination with the colouring matter, and cannot be removed except by chemical reducing agents.

A 10 per cent. solution of blood saturated with oxygen, and then mixed with excess of hyposulphite, exhibits the spectral line of reduced hæmoglobin, and becomes darker, its colour changing to red-violet. This reduced solution, after agitation with air, again yields by titration the same quantity of oxygen as before the reduction.

Hæmatin and its derivatives. (Hoppe-Seyler, *Medicinisch-chemische Untersuchungen*, 1871, 523).—Hæmatin contains, according to Hoppe's analysis, 60.91 to 61.18 p. c. carbon, 5.20 to 5.41 hydrogen, 8.63 nitrogen, and 8.68 to 8.83 iron. From these numbers he formerly deduced the formula $C^{60}H^{5.2}N^{8.6}Fe^{8.7}O^{18}$ (1st Suppl. 355); but he has since proposed the formula $C^{60}H^{5.2}N^{8.6}Fe^{8.7}O^{18}$, which requires 64.35 C., 5.36 H., 8.83 N., and 8.83 Fe. This agrees nearly with the analytical results, so far as regards the hydrogen, nitrogen and iron, but differs greatly in the proportion of carbon it requires; which is more nearly that found by Mulder, viz. 64.63 to 65.01 p. c.

Hæmatoporphyrin and Hæmatolin.—When a solution of hæmatin in oil of vitriol is filtered through asbestos, a beautiful purple-red solution is obtained, which gives a small dark absorption-band just before the line D, and another very sharply defined band between D and E. When this solution is mixed with water, the greater part is precipitated, the precipitate being increased by addition of alkalis to neutralisation. The alkaline aqueous solutions of the precipitate are characterised by a faint band between C and D, a similar faint band between D and E, nearer D, a dark band in the same interval but nearer E, and lastly, a very dark band between E and F. This substance, *hæmatoporphyrin*, is free from iron, and gives by analysis 68.42 p. c. C., 9.58 N., 6.07 H., and 15.93 O., agreeing nearly with the formula $C^{68}H^{6.1}N^{6.1}O^{15.9}$, or $C^{68}H^{6.1}N^{6.1}O^{15.9} \cdot 2H_2O$, which requires 68.34 p. c. C., 9.38 N., 6.20 H., and 16.08 O. Its formation requires the presence of oxygen, and is represented by the equation:

When, on the other hand, hæmatin is acted upon by sulphuric acid in closed vessels,

hæmatolin $C^{56}H^{70}N^{10}O^7$ is formed, which is but very slightly soluble in sulphuric acid, and very slightly soluble in caustic potash. Composition by analysis, 72.94 p. c. C., 10.02 N., 6.95 H., 10.09 O.; by calculation, 72.98 C., 10.02 N., 6.98 H., 10.02 O.

Action of Reducing Agents on Hæmatin.—Hæmatin offers considerable resistance to oxidising agents. It is, however, very sensitive to reducing agents, both in acid and alkaline solutions. By boiling a solution of hæmatin with caustic soda and pulverised zinc, as also by the action of sodium-amalgam on hæmatin in presence of water, reduction-products in great quantity are formed. They are all free from iron, but their separation is a matter of great difficulty. Their solution gives a complicated spectrum, with five absorption-bands. No exact analysis can be given.

Tin and Hydrochloric Acid act on hæmatin, in presence of alcohol, differently, according as the hæmatin is fully dissolved or not. When a concentrated solution, or one containing excess of hæmatin, is heated with tin or copper or zinc on the water-bath, a purple-red solution is formed, with, after a time, a resinous dark violet precipitate. The solution is characterised by two dark absorption-bands between D and E. When hæmatin, or hæmin crystals dissolved in alcohol containing sulphuric acid, are decomposed by hydrochloric acid and tin, and heated, a purple solution is formed, which also has a characteristic spectrum, viz., one band between D and E, another just before D, and another broad band between δ and F, covering the latter line. When the evaporated solution is poured into boiling water, a brownish precipitate is formed, soluble in alcohol. This on evaporation yields a colouring matter, which in properties resembles the oxidised product obtained by distillation from the hæmatin reduced by zinc powder, and appears to consist of $C^{54}H^{70}N^{10}ClO^7$.

Behaviour of Hæmatin when treated with Phosphorous Chloride containing free Phosphorus.—When hæmin crystals are heated with this substance to a temperature of 140° , in closed tubes for 6-8 hours, a purple-brown fluid is formed, which gives a spectrum with three absorption-bands, one between C and D, close to C, a second between D and E—nearer E, and a third between δ and F, beginning from δ , and extending to the middle between δ and F. No evolution of gas follows the opening of the tube. A crust forms on the sides, which, however, is easily separated. This substance is to a certain extent soluble in water, giving the same spectrum as hæmatoporphyrin. From the part insoluble in water a substance is obtained resembling hæmatin: it contains phosphorus, and gives by analysis, 52.67 p. c. C., 7.48 N., 5.11 H., 8.02 P., and 26.72 O.; hence its formula appears to be $C^{56}H^{70}N^{10}P^2O^{12}$ or $C^{56}H^{70}N^{10}O^{10}.4H^2PO^4$ (calc. 52.78 C., 7.24 N., 5.05 H., 8.02 P., and 26.91 O.). The agreement of the spectrum of this substance with that of hæmatoporphyrin seems to show that the latter consists of $C^{56}H^{70}N^{10}O^{10}.2H^2O$, or that it is a hydrate of the same molecule as that contained in the phosphorus-compound (Hoppe-Seyler, *Med.-chem. Unters.* 1871, 643).

Action of Ammonia, Arsine, and Stibine.—Alkaline solutions of hæmatin are coloured orange by ammonia, the absorption-bands become paler; a broad but diffuse shadow appears in the green part of the spectrum, and after some time, an amorphous precipitate falls to the bottom. This precipitate dissolves in acetic acid, and the solution exhibits the bands of acid hæmatin. When arsine is passed into an alkaline solution of hæmatin, the colour of the liquid gradually becomes red, and two of the absorption-bands of reduced hæmatin appear. Agitation with air restores the colour of the alkaline hæmatin, but after a few seconds, the solution begins quickly to redden, and this alternation may be repeated about ten times. If the passage of the arsine be longer continued, the alkaline solution turns brown, and sometimes deposits steel-grey crystals of arsenic on the following day. After this time, no more bands can be seen; nevertheless, the presence of hæmatin may be demonstrated by means of an ammoniacal solution of ferrous tartrate. The bands of reduced hæmatin may be recognised at a much greater degree of dilution than those of the alkaline or of the acid solution, a fact which seems to show that, in spite of the action of the arsine, part of the hæmatin has remained undecomposed. The action of stibine is the same as that of arsine (Koschlakoff a. Bogomoloff, *Zeitschr. anal. Chemie*, viii. 228).

Hæmochromogen.—From the most recent experiments of Hoppe-Seyler (*Med.-chem. Unters.* 1871, 523), it appears that hæmatin is not a direct product of the splitting up of hæmoglobin, but results from such a decomposition accompanied by oxidation. This oxidation takes place, however, so rapidly, that it is only by special precautions that the non-oxidised products can be obtained. When, however, a solution of hæmoglobin is reduced by hydrogen and decomposed by alcohol containing sulphuric acid or caustic potash, in an apparatus from which oxygen is completely excluded, a colouring matter is produced, which is acid, has a purple-red colour in alkaline solutions, and is characterised by certain definite absorption-bands. It is this substance, hæmochromogen, which yields hæmatin by oxidation. It has not yet been isolated or regenerated.

BOILING POINTS OF HOMOLOGOUS COMPOUNDS. 203

by reduction of hæmatin, but its spectrum agrees generally with that of reduced hæmatin (p. 202). Hoppe-Seyler supposes it to have the composition $C^{14}H^{16}N^4FeO^3$, and represents the formation of hæmatin from it by the equation:

BOILING POINTS OF HOMOLOGOUS ORGANIC COMPOUNDS.—

Kopp's well-known law, that the differences in boiling point between consecutive members of the same homologous series are equal, has been called in question by Linnemann (*Ann. Ch. Pharm.* clxii. 39), from whose experiments it appears that these consecutive differences are by no means equal, but exhibit considerable variation. The apparatus used by Linnemann for the fractional distillation of the several compounds and the determination of their boiling points is so contrived as to reduce to a minimum the errors arising from irregular boiling and from overheating (see DISTILLATION, FRACTIONAL). In twenty-five determinations thus made upon eleven different bodies (acids and ethers of the ethyl, propyl, and butyl series), the boiling points of different specimens of the same compound rarely differed from one another by so much as a tenth of a degree, the greatest and least differences observed (both in the case of normal butyl iodide) being 0.3° and 0.02° . This is sufficient to show that the method is susceptible of great accuracy.

The following Table exhibits Linnemann's determinations of the boiling points of a considerable number of compound ethers, &c., of the three groups above mentioned: the second columns giving the observed boiling points; the third the differences between them; and the fourth the differences of those differences, or differences of the second order:—

Chlorides				Bromides			Iodides		
	Boiling point	Difference	Decrease	Boiling point	Difference	Decrease	Boiling point	Difference	Decrease
Butyl . . .	77.96	31.41		99.88	29.06		129.81	27.68	
Propyl . . .	46.48	34.30	2.80	70.82	32.04	2.98	102.18	29.84	2.21
Ethyl . . .	12.18			38.78			72.34		
Fatty alcohols				Fatty acids			Benzole ethers		
	Boiling point	Difference	Increase	Boiling point	Difference	Decrease	Boiling point	Difference	Decrease
Butyl . . .	116.88	19.47		162.32	21.66		247.32	17.85	
Propyl . . .	97.41	18.88	0.59	140.66	22.66	0.90	229.47	18.31	0.46
Ethyl . . .	78.53			118.10			211.16		
Acetic ethers				Propionic ethers			Butyric ethers		
	Boiling point	Difference	Decrease	Boiling point	Difference	Decrease	Boiling point	Difference	Decrease
Butyl . . .	124.30	22.32		145.99	23.65		164.77	21.35	
Propyl . . .	101.98	24.98	2.66	122.44	28.64	0.09	148.42	22.35	1.00
Ethyl . . .	77.00			98.82			121.07		
Ethyl ethers				Propyl ethers			Butyl ethers		
	Boiling point	Difference	Increase	Boiling point	Difference	Increase	Boiling point	Difference	Decrease
Butyrate . .	121.06	22.26		143.42	20.98		164.77	18.78	
Propionate .	98.80	21.80	0.46	122.44	20.46	0.52	145.99	21.69	2.91
Acetate . .	77.00			101.98			124.30		

Boiling Points of Homologous Ethers.

Isomeric ethers, $C^mH^{2m}O^2$			Isomeric ethers, $C^nH^{2n}O^2$		
	Boiling point	Difference		Boiling point	Difference
Propyl acetate .	101.98	3.18	Butyl acetate .	124.30	1.86
Ethyl propionate .	98.80		Propyl propionate .	122.44	1.43
			Ethyl butyrate .	121.01	
Isomeric ethers, $C^nH^{2n}O^2$					
				Boiling point	Difference
Butyl propionate				145.99	2.57
Propyl butyrate				143.42	

From these numbers Linnemann draws the following conclusions:—

1. Equal differences of boiling point in homologous series do *not* correspond with equal differences of composition.
2. In most of the series hitherto studied, the difference of boiling point increases as the amount of carbon becomes greater, at least in the lower terms of the series.
3. In many series, the differences of boiling point are nearly equal, in others they increase with increasing amount of carbon.
4. The isomeric ethers of the fatty alcohols and acids do *not* exhibit equal boiling points.

From these results, and from the close agreement already noticed between the observed boiling points of different samples of the same compound prepared by the preceding method, Linnemann infers that the *observed* boiling points coincide very nearly with the true boiling points, and consequently that the so-called 'calculated' boiling points can no longer be regarded as the true boiling points.

Pierre a. Puchot (*Compt. rend.* lxxv. 1440) have likewise compared the boiling points of a considerable number of compounds belonging to several homologous series, viz., alcohols, ethers and acids of the fatty group, and have come to the conclusion, that the difference between the boiling point of two consecutive terms of the same series is not constant, but subject to very considerable variation. As, however, those chemists take no account of the difference between normal and iso-compounds, it is impossible to know whether the compounds which they compared were really homologous. One point which they particularly notice is, that the boiling temperature of the propylic and butylic terms in each series of acids, ethers, &c., derived from the fermentation alcohols, is less than the difference between any two succeeding terms in the same series. Now, this is just what may be expected to follow from the fact that the propyl alcohol of fermentation is a normal alcohol, whereas all the higher fermentation alcohols that have been examined are iso-alcohols (see *Chem. Soc. J.* [2] xi. 268, 269).

BOLETUS. Many species of boletus become blue on exposure to the air after fresh fracture. By digesting *B. cyanescens* cut up into shreds with alcohol of 92 p. c. an extract is obtained which, after filtration, is brownish-yellow, then becomes green, and gives an intense indigo-blue colour with sodium hypochlorite; after concentration, it yields crystals of mannite, and the mother-liquor, treated with alcohol and ether, yields a golden-yellow solution, which leaves on evaporation a residue becoming deep green-brown with sodium hypochlorite.

The aqueous solution of the colouring matter has a strong acid reaction; hydrochloric acid does not change its brownish-yellow tint; neither does soda-ley, added to alkaline reaction; this, however, prevents the blue coloration with sodium hypochlorite from appearing. The colouring matter contains nitrogen, as, on heating it with caustic potash, ammoniacal vapours are given off; but it does not exhibit any reaction indicative of cyanides, or of aniline (as asserted by Phipson, *Chem. News*, xiv. 301), not giving the characteristic aniline reaction with hypochlorites.

The above-mentioned reactions with sodium hypochlorite have also been obtained, with the colouring matters similarly extracted, from *B. luridus*, *B. Satanas*, *B. Calopus*, and the brown-tubed variety of *B. variegatus* (H. Ludwig. *Arch. Pharm.* [3] calix. 107).

BONE. *Influence of Earthy Phosphates mixed with the Food on the Composition of the Bones.*—The experiments of J. Lehmann (*Ann. Ch. Pharm.* cviii. 357), v. Gohren (*Landwirth. Versuchs-Stationen*, iii. 181), and others have shown that calcium phosphate precipitated by ammonia from an acid solution, can be digested and assimilated by calves, sheep and other animals; and according to Hoppe-Seyler (*Med.-chem. Untersuchungen*, Heft II.), earthy phosphates added to human food are likewise absorbed, and increase the amount of earthy phosphates in the urine. These and other results have led to the idea that the ingestion of earthy phosphates may have some influence on the composition of the bones, and in fact the addition of earthy phosphates to fodder has been somewhat extensively practised.

Papillon (*Compt. rend.* lxxi. 372) fed a pigeon and two white rats for two months on food containing phosphates of strontium, aluminium and magnesium. The bone-ash of the pigeon was then found to contain 8.45 p. c. strontia and 0.66 magnesia, that of one of the rats, 6.95 alumina, and that of the other, 3.56 p. c. magnesia; the general conclusion from these experiments being that considerable quantities of the ingested earthy phosphates were deposited in the bones.

A contrary conclusion has, however, been arrived at by H. Weiske-Proskau (*Zeitschr. f. Biologie*, viii. 239), who made an extensive series of experiments of the same kind on young and old rabbits, but could not find the slightest trace of strontia, or any noteworthy increase of the magnesia, lime, or phosphoric acid in the bones when earthy phosphates were mixed with the food. The age of the animal has an influence on the composition of the bones, those of old rabbits containing more salts than those of young ones. The percentage composition of the bone-ash is much alike in both, but the proportion of magnesia seems to be somewhat higher, and of lime somewhat lower, in young animals. The percentage amount of phosphoric acid is almost the same in all bones, and is on an average 42.17 p. c.

The following Table exhibits the amount and composition of the ash of the bones, free from water and fat, of the animals subjected to the experiment. In the rabbits I—IX, the bones of all the four legs; in X and XI, the whole of the bones were taken for analysis:—

No.	Age	Kind of Salt added to the food	Ash p. c.	Lime p. c.	Magnesia p. c.	Phosphoric acid p. c.
I.	adult	Calcium phosphato	65.60	53.94	1.06	40.03
II.	6 months	" "	62.02	53.77	1.23	42.73
III.	adult	Magnesium phosphate	68.41	54.21	1.09	42.08
IV.	5 months	" "	61.99	53.68	1.24	42.01
V.	adult	Strontium phosphate	68.00	53.93	1.06	42.00

Iron in Bones? According to some authorities, iron is a normal constituent of bone, whilst by others its occurrence in bone is attributed to the retention of colouring matter of the blood. The question has been further examined by Plugge (*Archiv. f. Physiologie*, iv. 101), who, to avoid the source of error just mentioned, macerated the bones in water till no residue was obtained on evaporation. Bones of various animals thus treated yielded not a trace of iron, whence it may be inferred that iron is not a constituent of bone, and that when it is found therein, its occurrence must be attributed either to retained blood, or to impurity in the reagents and vessels employed.

On the Solubility of the Phosphates of Bone-ash in Carbonic acid water, see PHOSPHATES.

On the determination of the relative age of fossil bones from the proportion of soluble and insoluble ossein contained in them, see A. Schenker-Kestner (*Compt. rend.* lxxix. 1207; *Chem. News*, xx. 311; *Jahresb.* 1869, 1249).—Objections against Schenker-Kestner's conclusion have been made by Elie de Beaumont (*Compt. rend.* lxxix. 1211). On the determination of the age of fossil bones from their chemical composition, see also Wibel (*Jahresb.* 1869, 1250).

BORACITE.—This mineral, hitherto found at Stassfurt only in microscopic crystals, has lately been obtained from the residues of the potassium chloride preparation in crystals of three varieties, viz.: 1. Small kidney-shaped druses consisting of an envelope of transparent greenish crystals about 0.5 mm. in shape, enclosing a bluish or greenish grey microcrystalline nucleus composed of crystals of the same kind. 2. Small crystalline groups or nodules consisting of light green translucent to transparent crystals about 5 mm. long, enclosing a nucleus of white to greenish colour. 3. Larger druses in which a white, fine-grained nucleus of Stassfurtite gradually passes, towards the surface, into a greenish, fine-grained crystalline mass, surrounded wholly or partially by very small crystalline groups, and a few isolated crystals about 2 mm. in size.

All the crystals are well developed, and show no signs of efflorescence. They exhibit distinctly the combination $\frac{O}{2} \cdot \infty O \infty \cdot \infty O$; in some specimens the face

$-\frac{O}{2}$ may be recognised with a lens; in a few the face $-\frac{2O2}{2}$. The tetrahedron is almost always predominant.

The crystals have a vitreous lustre, no distinct cleavage, a conchoidal fracture; hardness = 7; mean density = 2.91. They contain boric acid and magnesia, with small quantities of ferrous oxide and chlorine, from which, and from their morphological and physical characters, it is inferred that they consist of boracite, $MgCl^{12} \cdot 2(3MgO \cdot 4B^2O^3)$.

Stassfurtite, which has the same composition, and forms the nucleus of some of the boracite druses above mentioned (3), appears to be merely the cryptocrystalline form of boracite (B. Schultze, *Jahrbuch f. Mineralogie*, 1871. 844).

BORNEOL, $C^{10}H^{18}O$.—This compound is formed in small quantity by the action of alcoholic potash on camphor: $C^{10}H^{18}O + H^2O = C^{10}H^{16}O + O$, the nascent oxygen resinising part of the camphor (Bertholot, i. 626).—and in much larger quantity by acting on a solution of camphor in toluene with sodium, and treating the product with carbonic acid (Baubigny, 1st Suppl. 358):

and

If the camphor be dissolved in a petroleum oil of rather high boiling point, and potassium be used instead of sodium, potassium campholate and borneol are formed by the mutual action of the potassium-borneol and potassium-camphor first product; thus—

The natural borneol and that synthesized by the above two sets of reactions, exhibit respectively the rotatory powers, $\alpha = +33.4^\circ$, 44.9° , and 42.4° .

Borneol treated with phosphorus pentachloride or hydrochloric acid yields a chloride $C^{10}H^{17}Cl$, which melts at 132° , and is converted into ordinary camphor by hypochlorous acid—

borneol itself is also converted into ordinary camphor by the same reagent:

Bromine acts on borneol, forming first camphor and hydrobromic acid; and finally a mixture of monobromocamphor and borneol bromide. Phosphoric anhydride acts on borneol, forming a hydrocarbon, $C^{10}H^{16}$ (the *borneene* of Pelouze), boiling at 176° – 180° , and an isomeric condensation-product distilling at 250° – 280° . Borneene smells like turpentine, but does not unite with hydrochloric acid or with hypochlorous acid (Kachler, *Ann. Ch. Pharm.* clxiv. 75).

Respecting the constitutional formula of borneol, see CAMPHOR.

BORNESITE, $C^8H^{14}O^2$.—(A. Girard, *Compt. rend.* lxxiii. 426).—A sweet volatile substance occurring in the caoutchouc of Borneo. It is crystalline, very soluble in water, slightly soluble in alcohol, melts at 175° without alteration, and, like dambonite (1st Suppl. 541), sublimes at 205° with slight decomposition. It does not ferment, neither does it reduce the potassio-tartrate of copper, but acquires the property of reducing this reagent by being boiled for several minutes with water.

slightly acidulated. Treated with a mixture of sulphuric and nitric acids, it forms a nitrated product, insoluble in water, soluble in alcohol, from which it is deposited in the crystallised state, melting at 30°–35°, and detonating loudly when struck.

Bornesite heated to 120° in a closed vessel with fuming hydriodic acid, decomposes, like dambonite, into methyl iodide and dambose:

Dambonite and dambose have no effect upon polarised light, but bornesite possesses a rotatory power of 32° to the right, or nearly half that of pure cane-sugar under similar circumstances. Dambonite and bornesite may be regarded as dambosates of methyl: dambonite = $\text{C}^s\text{H}^n(\text{CH}^m)\text{O}^s$; bornesite = $\text{C}^m\text{H}^n(\text{CH}^s)\text{O}^s$.

BORON. Boric chloride, BCl_3 , is easily prepared by heating finely powdered boric anhydride to 150° for three or four days in sealed tubes, with twice its weight of phosphorus pentachloride. The tubes must be well cooled before they are opened, and then warmed on a water-bath. Boric chloride then distils over, and a further quantity may be obtained by heating the white residue over the open fire. On heating to a higher temperature and finally to redness, there remains a white infusible mass, which is insoluble in water, and is resolved by prolonged boiling with water on alkalis, into boric and phosphoric acids. This body is probably identical with the compound of boric and phosphoric oxides described in the *First Supplement*, p. 360.

These experiments show that in the action of phosphorus pentachloride on boric oxide, there is formed, beside the trichloride, an oxychloride of boron, which does not give off the trichloride till heated above 100°. And, in fact, if the trioxide and trichloride of boron are heated together to 150° in molecular proportions, the contents of the tube are converted into a white gelatinous mass, which, when heated to 100° gives off half the boron chloride employed in the reaction. At a higher temperature, the white solid residue gives off an additional quantity of the chloride and leaves the trioxide. The reaction between phosphorus pentachloride and boric oxide is therefore that which is represented by the equation:

Phosphorus trichloride does not act on boric oxide even when heated with it for a fortnight to 200°. On the other hand, the bromochloride, PCl_2Br , acts readily on boric oxide, with formation of boric chloride and separation of bromine. Bromide of boron is not thereby produced, or at all events only in extremely small quantity. The tribromide, di-iodide and tri-iodide of phosphorus do not act on boric oxide. Boric chloride is not converted into the corresponding cyanide, either by cyanide of potassium, or by cyanide of silver.

Boric chloride may be distilled over sodium without decomposition; at 150° however a small quantity of boron is separated. Zinc-dust does not act upon it even at 200°. The chloride acts readily on bodies containing the radical HO or NH_2 . A mixture of acetic acid and anhydride, treated with boric chloride, yields a crystalline compound, which is resolved by water into boric and acetic acids, hydrogen chloride and acetyl chloride being formed at the same time. By the action of boric chloride on the crude mixture of ethylamines (obtained by heating ethyl iodide with ammonia) a compound is obtained which melts when heated, then sublimes undecomposed, and if heated for a day to 200°, yields products of decomposition, among which are ethyl chloride and boron nitride (Gustavson, *Zeitschr. f. Chem.* [2] vi. 521).

Boric Oxide, Acid, and Salts. *Compound of Boric Oxide and Phosphoric Oxide.* $\text{B}_2\text{O}_3 \cdot \text{P}_2\text{O}_5$.—When crystallised boric acid is heated to boiling in a platinum dish with concentrated aqueous phosphoric acid, the liquid first becomes milky, and then dries up to a white earthy mass, which when heated before the blowpipe, or even in a platinum crucible over a gas-flame fed by a blast of air, does not melt but retains its earthy character, merely becoming covered with an enamel-like crust when the phosphoric acid is in excess. This compound is not decomposed by water even at the boiling heat, and the excess of phosphoric acid may be removed from it by boiling water. It then contains boric and phosphoric oxides in equal number of molecules. Concentrated acids are without action upon it; caustic alkalis at the boiling heat dissolve it to a clear liquid. The pulverised substance heated with sodium yields sodium phosphide, together with a black scoriaceous substance, perhaps consisting of boron phosphide (A. Vogel, *Zeitschr. f. Chem.* vi. 125).

Action of Phosphoric Oxychloride on Boric Oxide.—When boric oxide is heated with phosphoric oxychloride in closed tubes, to 150°–170°, for eight or ten hours, a white

mass, $\text{P}^2\text{O}^5 \cdot \text{B}^2\text{O}^3$, is formed, whilst colourless crystals of a compound, $\text{POCl}^3 \cdot \text{BCl}^3$, sublime in the upper part of the tube. The latter melts in a closed tube at 73° , and when sublimed splits up into boric chloride and phosphoric oxychloride. Crystals of the chlorinated compound are also formed on passing the vapours of boric chloride into phosphoric oxychloride, and by heating boric chloride with phosphoric anhydride to 200° for two or three days, the reaction being:

It is decomposed in contact with water, or by the moisture of the atmosphere, phosphoric acid, boric acid, and hydrochloric acid being formed. The white mass $\text{P}^2\text{O}^5 \cdot \text{B}^2\text{O}^3$ is probably a mixture of phosphoric with boric anhydride, as it is resolved by water into phosphoric acid and boric acid, but if previously heated to redness it forms the insoluble compound $\text{B}^2\text{O}^3 \cdot \text{P}^2\text{O}^5 = \text{PBO}^4$, described by Vogel (Gustavson, *Deut. Chem. Ges. Ber.* iv. 975).

Action of Borates on Ammonia Salts.—This reaction, studied in 1848 by Bolley (*Ann. Ch. Pharm.* lxxviii. 123), has been further examined by R. C. Woodcock (*Chem. Soc. J.* [2] ix. 785). Bolley observed that free ammonia is evolved on mixing solutions of borax and sal-ammoniac containing equal numbers of molecules of the two; and that the solution when slowly evaporated, deposits crystals having the composition of a tetraborate $\text{Na}^2\text{O} \cdot 4\text{B}^2\text{O}^3 + 10\text{H}^2\text{O}$ or $2\text{NaBO}^2 \cdot 3\text{B}^2\text{O}^3 + 10\text{H}^2\text{O}$; also that an excess of sal-ammoniac converts the borax entirely into sodium chloride and boric acid. Woodcock finds that when 4 mol. of sodium metaborate NaBO^2 (i. 645) are mixed with 2 mol. of sal-ammoniac, ammonia is copiously evolved, and the whole decomposes very rapidly and completely, leaving only the diborate (borax) and sodium chloride:

A mixture of commercial borax (3.57 grams) and sal-ammoniac (0.5 gram) dissolved in about 2 ounces of water and distilled, gave off the whole of the ammonia, leaving a residue of sodium chloride and Bolley's tetra-metaborate:

Borates either acid or normal may be advantageously employed for liberating ammonia from its salts, the action taking place neatly and perfectly and without frothing.

Calcium Borate.—This salt is found in the dried-up bed of a river on the Pampa of Tamarugal, near Tarapaca in Peru, and is collected by digging out the sand beneath the surface-crust of salt. It occurs in white nodules, having a shining, pearly, lamellar fracture, associated with yellowish prisms of glauberite, the whole being almost completely soluble in strong acids, but very slightly in water. It originates probably from the action of the acid emanations of the neighbouring volcano of Salgu on the calcium carbonate of the soil. It is a calcium diborate with 8 mol. of water, $\text{CaO} \cdot 2\text{B}^2\text{O}^3 + 8 \text{aq.}$ mixed with varying quantities of glauberite, sodium chloride, silica, alumina, and iron. The boric anhydride averages 17 p.c. (Thiercelin, *Bull. Soc. Chim. de Paris* [2] xvii. 387).

On the heat evolved in the combination of boric acid with ammonia, see **HEAT OF COMBINATION**.

Boric Anhydrosulphate, $\text{B}^2\text{H}^2\text{S}^2\text{O}^{12} = 2\text{H}(\text{BO})^2\text{SO}^4 \cdot \text{SO}^4$, is formed by dissolving boric acid in strong sulphuric acid, and adding sulphuric anhydride, or by dissolving boric acid in fuming sulphuric acid. It separates, after some time, in leaf-like crystals, which melt and give off sulphuric anhydride when heated (Schultz-Sellack, *Deut. Chem. Ges. Ber.* iv. 12).

BRAIN. The composition of the grey and white matter of the brain has been examined by D. Petrovsky (*Pflüger's Archiv. f. Phys.* vii. 367). The grey layer was separated from the white by water, and a portion of the white matter was taken from the interior. Each substance was rubbed up rapidly in a mortar, and three extracts and a residue were obtained by digestion in cold alcohol, ether, and hot alcohol. The cold alcoholic extract contained a substance soluble, and another insoluble in anhydrous ether; the ether extract, lecithine, cholesterin, and fats; the warm alcoholic extract, lecithine and cerebrin; the residue, albuminous substances and salts. The portion of the cold alcoholic extract insoluble in ether does not contain sugar.

The dried grey substance consists about half of albumin and a quarter of cholesterin and fats, with very little cerebrin, its principal constituents therefore being albumin and water. In the white matter, on the contrary, cholesterin and fats form much more than half the dried mass, albumin a quarter of the whole substance, and cerebrin is present in considerable quantity.

BRAZILIN, $\text{C}^{22}\text{H}^{10}\text{O}^7$ (E. Kopp, *Deut. Chem. Ges. Ber.* vi. 446).—This compound

matter may be advantageously prepared from the dark brown-red crusts consisting of brazilin and a lime-brazilin lake, together with mechanical impurities and a resinous substance, which are deposited in considerable quantity during the preparation and storage of commercial extract of Brazil wood.

These crusts are saturated with water containing 5 p. c. of hydrochloric acid, and the washed residue is boiled with water containing 10 to 15 p. c. alcohol. The filtrate on cooling deposits the brazilin in beautiful yellowish crystals, which are easily purified by crystallisation from hot water. The crusts may also be boiled directly with water acidulated with hydrochloric or sulphuric acid, and the brazilin, which separates from the filtrate on cooling, purified by recrystallisation. The wash-waters and mother-liquors evaporated to dryness, with addition of a little chalk, leave a residue which yields resorcin by dry distillation.

Pure brazilin is colourless and gives with de-aerated water, colourless solutions which impart but faint colours to mordanted cotton. By contact with the air these solutions acquire a yellow and afterwards a reddish-yellow colour and an increased tinctorial power; at the same time, however, they become less and less capable of yielding crystallised brazilin.*

Pure brazilin dissolves in dilute soda-ley with splendid carmine colour; and on heating this solution in the water-bath in a well-closed vessel with zinc-dust, reduction takes place, in consequence of which the liquid again becomes colourless. This colourless solution affords one of the most delicate tests for oxygen, the slightest access of air causing it to assume a deep carmine colour.

Brazilin (or the crusts from extract of Brazil wood, subjected to dry distillation in an iron or copper retort, yields, together with a large quantity of tumefied charcoal, a slightly coloured distillate, which, when passed through a wet filter (to separate tarry products), and concentrated on the water-bath, deposits on cooling, well-defined crystals of resorcin; this, indeed, is the simplest and easiest method of obtaining resorcin.

Brazilin is related to hæmatoxylin and resorcin in the manner shown by the following equation:—

BROMACETOPHENONE. See ACETOPHENONE.

BROMAL, $C^2HBr^3O = CBr^3 - CHO$.—This compound, discovered by Löwig (1st Suppl. 666), has been further examined by L. Schäffer (*Deut. Chem. Ges. Ber.* iv. 366). His mode of preparation is the same as that of Löwig, excepting that he uses the bromine in the state of vapour and in relatively smaller quantity. The bromal is found in the portion of the product which passes over on distillation between 165° and 180°, and is separated as a hydrate by mixing this liquid with water and repeatedly crystallising. The hydrate, $C^2HBr^3O.H^2O$, melts at 53.5° and breaks up on distillation into water and anhydrous bromal, which boils at 172°–173°, and remains liquid at –20°. Bromal unites with absolute alcohol, forming the *alcoholate* $C^2HBr^3O.C^2H^2O$, which crystallises in thick needles, melts at 44°, and is decomposed by distillation into alcohol and bromal. Bromal treated with fuming nitric acid yields tribromacetic acid $CBr^3.COOH$.

The other products of the action of bromine on absolute alcohol are bromoform, carbon tetrabromide, dibromacetic acid, ethyl acetate, ethyl bromide and hydrogen bromide.

BROMHYDRINS. (L. Henry, *Ann. Ch. Pharm.* cliv. 363.)

Tribromhydrin C^3HBr^3 .—This compound, obtained from glycerin, does not exhibit the properties hitherto ascribed to it on the authority of Berthelot a. De Luca (1st Suppl. 668), but rather agrees, both chemically and physically, with the tribromide of allyl which Wurtz obtained by the action of bromine on allyl iodide.

To obtain it in the pure state, Henry treated 1,600 grams of glycerin with 1,600 grams of phosphorus tribromide, obtaining thereby 800 grams of crude dibromhydrin, which was purified by systematic fractionation (80 grams of allyl bromide boiling at 70° are obtained as secondary product). The dibromhydrin was converted into tribromhydrin by treatment with phosphorus pentabromide; the phosphorus oxybromide and hydrobromic acid formed in the reaction were removed by successive washing with water and sodium carbonate; and the tribromhydrin which remained in the form of a heavy oil was dried with calcium chloride and then distilled. It passed over, with continuous evolution of hydrobromic acid,† almost wholly between 200° and 221°, the

* These results are quite in accordance with those published some years ago by Preisser (l. 656), which have hitherto been treated as unworthy of credit.

† The hydrobromic acid probably originated, according to Henry, from glyceric bromophosphine formed by the action of the phosphorus oxybromide on the dibromhydrin, at all events not from the

principal portion between 219° and 221° . In a subsequent communication (*Deut. Chem. Ges. Ber.* iii. 601) Henry states that as tribromhydrin is very apt to retain water, and on account of its great density, which exceeds that of calcium chloride, is by no means easy to dry, it is best purified, not by simple rectification, but by crystallising it, removing the still liquid portion, and rectifying the crystals apart.

Pure tribromhydrin is undistinguishable from tribromide of allyl. It forms a colourless faintly ethereal liquid, insoluble in water, having a specific gravity of 2.407 at 10° , and solidifying in the cold to slender prismatic crystals, which melt at 16° to 17° . The solidifying point of the perfectly fused substance is perhaps much lower.

Heated in an oil-bath under ordinary pressure with potassium hydrate (in lumps) it behaves exactly like allyl tribromide, a brisk reaction setting in at 140° – 180° , and a heavy oily liquid distilling over (together with a watery liquid), which in boiling point and amount of bromine, is intermediate between epibromhydrin C^3H^3BrO (b. p. 138° – 140°), and epibromhydrin $C^3H^3Br^2$ (b. p. 150° – 152°). The liquid boiling at 180° described by Berthelot a. De Luca as tribromhydrin is, according to Henry, not properly designated by this name, and the body boiling at 210° , which they obtained as a bye-product in the preparation, and to which they assigned the formula $C^3H^3Br^2 + H^2O$ or $C^3H^3.OH.Br^2 + 2HBr$, was impure tribromhydrin.

Berthelot (*Compt. rend.* lxx. 681) attributes the failure of Henry to obtain the true tribromhydrin (the existence of which as an individual compound distinct from allyl tribromide was demonstrated by himself and De Luca), and likewise the oxygenated addition-product, to the circumstance that Henry's experiments were performed under conditions different from those of Berthelot a. De Luca's. To meet this objection Henry (*Deut. Chem. Ges. Ber.* iii. 601) prepared tribromhydrin precisely according to the method described by Berthelot and De Luca, and obtained a product identical with the former. A similar result was obtained by the action of phosphorus pentabromide on epibromhydrin.

BROMINE. For the recovery of bromine from the residues of chemical operations containing alkaline bromides, Bolas a. Groves recommend distillation with potassium dichromate and dilute sulphuric acid. The solution of the alkaline bromide is introduced into a retort with the requisite quantity of the acid chromate in crystals, and an excess of sulphuric acid, previously diluted with half its weight of water, is gradually added; heat may be applied after the first powerful reaction is over. By this method, nearly the whole of the bromine is easily recovered, and there is no danger of breaking the retort (*Chem. Soc. J.* [2] ix. 784).

To obtain bromine perfectly free from chlorine and iodine, Adrian (*J. Pharm.* [4] xi. 20) washes it with water and small quantities of ether, which dissolves chlorides of bromine, then digests it with a small portion of starch-paste to remove the iodine, and finally distils it.

The solidifying point of bromine has been variously given as -7° , -7.3° , -18° , -22° and -25° . According to H. Baumhauer (*Deut. Chem. Ges. Ber.* iv. 927) it is -24.5° . Solidified bromine is a red-brown crystalline mass. The presence of water raises the solidifying point, owing to the formation of the hydrate.

Action of Heat.—When a narrow tube is half filled with liquid bromine, half with bromine-vapour, and after being sealed, is gradually heated till the temperature is raised above the critical point at which the liquid and gaseous states merge into one another (*1st Suppl.* 402) the whole of the bromine becomes quite opaque, and the tube has the aspect of being filled with a dark red opaque resin. A measure of the change in the power of transmitting light in this case may be obtained by varying the proportion of liquid and vapour in the tube. Even liquid bromine transmits much less light when strongly heated in a sealed tube than in its ordinary state (Andrews, *Chem. News*, iv. 75).

Detection of Bromine.—The following method of detecting bromine, chlorine, and iodine in organic substances, is founded on that of Berzelius for the detection of these elements in minerals, by means of cupric oxide and microcosmic salt. Some pure cupric oxide is placed on a loop of platinum-wire and heated for a short time to cause the oxide to adhere to the wire. If some of the suspected substance be now added and the loop again heated in the lower and inner edge of the flame of a gas-burner, the flame will assume a characteristic green or blue colour if either of the haloids be present. This reaction is applicable to all organic compounds (Beilstein *Deut. Chem. Ges. Ber.* v. 620).

Detection of Bromine in Urine.—The colour imparted by bromine, as well as by iodine, to chloroform or to carbon sulphide, is destroyed by agitation with urine, and tribromhydrin: for when the distillate, after removal of the dissolved hydrobromic acid by sodium carbonate and of the water by calcium chloride, was again rectified, the greater portion passed over at 219° – 221° without decomposition.

this decolorising action has been attributed partly to uric acid and its salts, partly to the colouring matters of the urine, the iodine or bromine being supposed to fix itself on these constituents. There is, however, a difference in the behaviour of the two haloid elements under these circumstances, iodine when thus fixed being liberated with comparative facility by chlorine or by bromine, whereas the liberation of bromine by means of chlorine is more difficult. When equal quantities of potassium bromide are dissolved in equal volumes of distilled water and of urine, and the two solutions, after addition of carbon sulphide, are treated with chlorine-water, the former acquires a splendid red colour on addition of a single drop of the reagent, whereas the latter (the one containing the urine) requires a considerable quantity of chlorine-water before it exhibits any colour at all, and even then the tint is not red but only sulphur-yellow.

This difference appears to be due to the action of urea. This substance does not interfere with the liberation of iodine from its compounds by chlorine-water. Two test-tubes containing equal quantities of potassium iodide dissolved in equal volumes of water, the one pure, the other containing urea, exhibit exactly the same depth of violet colour when chloroform and a few drops of chlorine-water are added to each of them. But when a similar experiment is made with bromide of potassium, the result is very different, the chloroform in the tube containing the pure aqueous solution of the bromide acquiring a splendid orange-red colour on addition of chlorine-water, whereas that in the tube containing the solution to which urea has been added, acquires only a yellow colour. It is probable that urine contains also other substances capable of exerting this peculiar action on bromine, which appears to be different from that which is exerted by uric acid and the urinary pigments (Bizio, *Gazzetta chimica italiana*, ii. 339).

To detect alkaline bromides in urine, Cuigniet (*J. Pharm.* [4] x. 29) evaporates the liquid to dryness over the open fire, and ignites the residue gently for some time till the greater part of the organic matter is destroyed, and an aqueous extract of the residue appears quite colourless. The bromine may then be liberated with chlorine-water and recognised by the colour which it imparts to ether or to carbon sulphide. The quantitative estimation is made with a titrated solution of sodium hypochlorite. The aqueous extract is acidulated with citric acid, which does not act on the alkaline bromides, but liberates chlorine from the hypochlorite, and the bromine set free by this chlorine is taken up by repeated addition of carbon sulphide. As the liquid is thereby kept constantly colourless, it is easy to recognise the moment when an additional drop of the hypochlorite solution no longer imparts a perceptible colour to the carbon sulphide.

On the use of Bromine instead of Chlorine in Chemical Analysis, see ANALYSIS p. 70.

On the Volumetric Estimation of Bromine, see ANALYSIS, VOLUMETRIC, p. 71.

On the Estimation of Bromine in Platinum Compounds, see PLATINUM.

Hydrogen Bromide or Hydrobromic acid. Champion & Pellet (*Compt. rend.* lxx. 620) prepare this acid by the action of bromine on paraffin. The apparatus used consists of two tubulated retorts, one containing bromine, and the other paraffin, (melting at 55°), the first being heated to about 65° , the second to 185° by means of an oil-bath or sand-bath. The retorts are connected by a tube which leads the bromine-vapour below the surface of the paraffin. A U-tube filled with phosphorus and wet fragments of glass serves to free the evolved hydrobromic acid from bromine mechanically carried over. The bromine acts on the paraffin, forming hydrobromic acid and substitution-products. After a certain time the passage of the bromine may be discontinued, because the brominated paraffin thus formed decomposes at about 180° , giving off nearly all the bromine that it has taken up, in the form of hydrobromic acid. Aqueous hydrobromic acid saturated at 0° by this process has a specific gravity of 1.78, and a composition agreeing with the formula $\text{HBr} \cdot \text{H}^2\text{O}$. When heated, it gives off part of its hydrobromic acid, leaving the hydrate $\text{HBr} \cdot 5\text{H}^2\text{O}$, which has a specific gravity of 1.48, and boils at 126° .

The following modification of the ordinary mode of preparation by the action of water on phosphorus bromide is given by Topsøe (*Zeitschr. f. Chem.* vi. 635). The materials used are 1 part of amorphous phosphorus, 10 parts of bromine, and 15 parts of water, a convenient portion of the water being put into the bulb-receiver, and the bromine added by drops. On distilling the product, the aqueous acid is obtained as a colourless liquid, the density and strength of which continually increase till the boiling point rises to 125° – 126° , at which the maximum strength is attained. When the temperature rises still higher towards the end of the distillation, the acid which passes over becomes weaker, an effect which appears to be due to the fact that, at this high temperature, the residual phosphoric acid gradually gives up a portion of its water. The strongest hydrobromic acid obtained in the distillation has a specific gravity of 1.490, contains 48.17 p. c. HBr , and boils at 125° – 126° (under a baro-

metric pressure of 758 mm.; at 124° under 747 mm.) It fumes rather strongly in the air, and may be kept for a long time without decomposition.

The same method may be applied to the preparation of a still stronger acid, if the quantity of water to be acted upon by the bromine and phosphorus in the flask, be reduced to a fifth of the weight of the bromine. The gaseous hydrogen bromide, which after a while is given off with great regularity, is then passed into water, or into an aqueous acid prepared as above.

The following Table exhibits the density of hydrobromic acid of various strengths, as determined by Topsoë (*loc. cit.*):—

Temperature	Specific gravity	Percentage	Equivalent
°			
14	1·490	48·17	168·2
14	1·485	47·87	169·2
13	1·460	46·09	175·7
14	1·451	45·15	178·2
13	1·438	44·62	181·5

14	1·055	7·67	1056·1

All the values given in this table were determined directly, the percentages of acid by titration with soda. The specific gravities are referred to water at the same temperature, as unity.

The last column, headed 'Equivalent,' gives the quantities of the several aqueous acids containing 1 molecule of HBr = 81.

BROMOFORM. The conversion of this compound into carbon tetrabromide (1st *Suppl.* 400) takes place readily when a mixture of bromoform, bromine, and dilute potash is exposed to direct sunshine for five or six days:—

If no potash is present, the reaction goes on much more slowly (Habermann, *Deut. Chem. Ges. Ber.* vi. 174).

BROMOPICRIN, CBr³NO².—(Bolas & Groves, *Chem. Soc. J.* [2] viii. 163, 775). This compound, which Stenhouse obtained by distilling picric acid with solution of calcium hypobromite (i. 923), may be conveniently prepared as follows: 4 parts of lime slaked with 50 parts of water are introduced into a glass flask, and after complete cooling, 6 parts of bromine are gradually added, care being taken to avoid rise of temperature; 1 part of picric acid is then added, and the mixture quickly distilled from a retort. The first fourth of the distillate contains the whole of the bromopicrin, which may be separated by water and dried over calcium chloride. The quantity thus obtained amounts to 46·5–49·5 p.c. of the bromine employed.

Bromopicrin is liquid at ordinary temperatures, but when quite pure, solidifies at low temperatures to a mass of prismatic crystals which melt at 10·25°. If the bromine used in the preparation contained chlorine, the melting point of the bromopicrin is lower. Its sp. gr. is 2·811 at 12·5° and its index of refraction for the line D at 20° is 1·57. It mixes in all proportions with benzene, carbon bisulphide, carbon tetrachloride, chloroform, light petroleum oil, and alcohol: from the alcoholic solution it is precipitated by water. It dissolves iodine, forming a violet liquid, also indigo in small quantity, and naphthalene with great facility. When treated with powerful brominating agents, it is partly converted into carbon tetrabromide (1st *Suppl.* 400).

Bromopierin, as observed by Stanhouse, decomposes rapidly when heated a little above 100° , and with explosive violence when a small quantity is quickly evaporated down, so that the side of the vessel becomes very hot; but when a considerable quantity is slowly heated, it decomposes quietly, yielding carbon tetrabromide (about 30 p.c. of the bromopierin) and a dark brown pungent liquid, which boils at 56.5° and has nearly the composition NOBr^4 (bromine by analysis 92.84 p.c.; by calculation 91.42). Under reduced pressure, bromopierin may be distilled without decomposition. Heated with aqueous potassium cyanide it is entirely decomposed, cyanogen bromide being at first formed, but on further heating this compound is destroyed, and a dark brown compound remains in solution.

BROMOXAFORM. $\text{C}^3\text{HBr}^3\text{O}^2$. *Pentabromomethyl acetate*. (Lagermarch, *Zeitschr. f. Chem.* [2] vi. 299.) This body, which Cahours obtained by the action of bromine on potassium citrate, and on dibromocitraconic acid (1st Suppl. 370), is likewise produced by the action of bromine on pyrotartaric acid:

A mixture of 10 parts pyrotartaric acid (purified by once recrystallising from water and pressing) 24 pts. bromine, and 10 c.c. water is heated to 120° as long as brown fumes continue to escape, but no longer; otherwise further decomposition will take place, attended with separation of carbon. The contents of the tube, after cooling, consist of a pale yellow liquid and usually a white crystalline mass: on opening it, carbon dioxide escapes. The crystals are washed with a little water on a funnel having its neck stopped with fragments of glass, and the filtrate is mixed with 4 or 5 times its volume of water, and left to itself.

Bromoxaform thus purified melts at 74.5° . It is insoluble in water, easily soluble in alcohol and ether, and crystallises from the latter in white, silky needles, from alcohol in long four-sided prisms. The solutions are neutral. The ethereal solution decomposes in direct sunshine, with separation of bromine and a yellow unctuous mass. Bromoxaform dissolves in cold potash-ley, but is decomposed when heated therewith, yielding bromoform and oxalic acid:

BRUCINE. On the decomposition of brucine-salts by the electric current, see ALKALOIDS (p. 42).

Brucine as a Test for Nitric Acid.—It has already been noticed (1st Suppl. 370) that brucine treated with a chlorate or with chlorine tetroxide in presence of strong sulphuric acid, assumes an orange-red colour like that produced with nitric acid, but distinguished from the latter by not turning violet on addition of stannous chloride. According to Schün (Zeitschr. anal. Chem. 1870, 209) a solution of brucine in strong sulphuric acid is coloured rose-red and subsequently yellow by chlorine-water, hydrogen dioxide, potassium chlorate, sodium hypochlorite, chromic acid, potassium chromate, potassium ferricyanide and platonic chloride. Cupric chloride, gold chloride and ferric chloride produce the same effect under certain circumstances. It appears then that the production of a yellow or orange colour with brucine cannot be regarded as a trustworthy indication of the presence of nitric acid unless this colour is changed to violet on addition of stannous chloride.

According to S. Cotton (*J. Pharm.* [4] x. 18), solutions of brucine in nitric acid heated to 40° – 50° and mixed with a strong solution of sodium sulphhydrate, assume first a violet, and then, on addition of an excess of the reagent, a green colour, the colour however disappearing after a day, with formation of a greenish precipitate. Alkalies do not alter the colour; dilute acids eliminate hydrogen sulphide, and change the colour to rose-red; 0.002 gram of brucine suffices to colour distinctly half a litre of water in this manner. As morphine does not exhibit any similar reaction, these two colour-reactions, the first of which is likewise produced by alkaline sulphates and thiosulphates, and by stannous chloride, may serve for the distinction of the two bases.

Periodides of Brucine.—Some of these compounds, prepared by Jørgensen, have already been described (1st Suppl. 371). The same chemist has also obtained the following penta-iodides:

These compounds form crystals having an almost metallic lustre, and behave towards reagents very much like the tri-iodides.

In crystallising the penta-iodide of ethylbrucine from hot alcohol, a small quantity of iodine is lost by each crystallisation. After eight or ten crystallisations, the tri-iodide comes down with the penta-iodide. Crystallisation of the penta-iodide from a strong solution of iodine causes it to take up an excess of iodine. By adding potassium iodide to a solution of brucine in hydrochloric acid, and leaving the mixture to slow oxidation, reddish-yellow needles were obtained, having the composition of a di-iodide of brucine, $C^{23}H^{12}N^2O \cdot HI^2$. This compound is probably a double salt of hydriodide and hydro-triiodide of brucine: for on cooling its alcoholic solution crystals of the tri-iodide were deposited, and the filtrate contained hydriodide of brucine.

A substance having the composition of a hexiiodide of amylbrucine, $C^{23}H^{12}N^2O \cdot C^6H^{11}I^6$, was obtained by adding to an alcoholic solution of the tri-iodide the calculated quantity of iodine. It appears in the form of bluish-green needles. It is difficultly soluble, even in boiling alcohol, and the solution deposits the tri-iodide on cooling (*J. pr. Chem.* [2] iii. 145).

BUCKWHEAT. *Polygonum fagopyrum*.—The composition of buckwheat grain from various localities has been determined by H. Weisk-Proskau (*Wochenblatt der Anzeigen du Landwirthschaft*, Sept. 6, 1871) with the following results:—

	Ordinary	Scotch	Tartarian
Water	9.57	10.57	10.62
Albuminoids	10.75	10.69	11.19
Soluble Carbohydrates } and Fat	61.39	61.10	53.58
Crude fibre	15.55	14.96	20.01
Ash	2.74	2.68	4.60

BUTYL ALCOHOLS and ETHERS.—1. *Normal Butyl Alcohol*, $CH^3CH^2CH^2CH^2OH$. The preparation of this alcohol from butyric acid by converting the acid into a calcium salt, distilling this salt with an equivalent quantity of calcium formate, and reducing the resulting butyric aldehyde with sodium-amalgam (1st Suppl. 372), has been described in detail by Lieben & Rossi (*Ann. Ch. Pharm.* clviii. 137; *Chem. Soc. J.* [2] ix. 516). To obtain pure butyric acid for the purpose, the acid obtained by fermentation was freed as far as possible from acids of higher boiling point by fractional distillation, and the portion boiling between 155° and 165° (or better between 159° and 164°) was dissolved in water, separated from the insoluble oil consisting of the higher acids, and converted into a calcium salt, which separated as a crust on the surface and could be skimmed off. The concentration and removal of the salt may be carried on for a longer or shorter time, according to the purity of the butyric acid used; generally speaking, however, the last mother-liquors do not yield a pure product. Butyric acid thus obtained boils at 163.2 under a pressure of 748.7 mm.

To prepare butyric aldehyde, the purified calcium butyrate, after being well pressed and dried, was intimately mixed with an equal weight of calcium formate, and the mixture was dried at about 100° , and then distilled in portions of about 10 grams from small retorts, the sides and bottoms of which were heated with charcoal. A brownish distillate was thus obtained, generally containing a little water, and on fractionally distilling it, the boiling point rose from 50° to 200° , but by repeated fractionation a portion boiled between 70° and 80° was obtained which was nearly pure butyric aldehyde. It amounted to about half the crude product, the other half consisting partly of aldehydes of lower boiling point, but chiefly of substances boiling above 130° , and not consisting of aldehydes. Alkaline bisulphites are not adapted for the purification of butyric aldehyde; they are of course useless for the separation of the lower aldehydes, and the bodies of higher boiling point can be more easily separated by fractional distillation. Normal butyric aldehyde obtained as above boils at about 75° ; it has the characteristic, pungent, slightly cough-provoking smell of aldehydes in general, dissolves in about 27 parts of warm water, and reduces silver oxide.

To convert the aldehyde into butyl alcohol 10 grams of it were mixed with 800 grams of water, that is, nearly but not quite enough to effect its solution. This mixture was treated successively with seven portions of 100 grams of 1 p.c. sodium-amalgam (theory requires 8.4 grams of sodium), the equivalent quantity of sulphuric acid being added at the same time as the sodium-amalgam, so as to keep the liquid always somewhat acid. When the action was ended, the liquid was distilled and the distillate

again treated with 300–400 grams of sodium-amalgam, together with the same quantity of sulphuric acid as above. The liquid was again distilled, and the products of the several operations purified together.

A small quantity of insoluble oil, which always forms during the operation, may be removed by filtration through wet filter-paper, and the butyl alcohol separated from the filtrate by a series of distillations. The butyl alcohol passes over with the first portions of the water. 100 grams of butyric aldehyde gave in different operations 80–90 grams of crude moist butyl alcohol. This product was dried as perfectly as possible with fused potassium carbonate; by far the largest quantity distilled between 110° and 120°, and it was easy to obtain the pure alcohol from the fraction which boiled between 113° and 117°. It is very difficult to remove the last traces of water from the butyl alcohol.* This may, however, be effected by digestion, first with lime or baryta, and then by repeated distillation from sodium.

Normal butyl alcohol thus prepared gave in three combustions:

Carbon	64.35	64.30	64.70	Calculated
Hydrogen	13.41	13.53	13.33	64.86
				13.51

Its vapour-density was found by experiment to be 2.65, the calculated value being 2.56. Its specific gravity, as compared with that of water at the same temperature, is as follows:—

Temperature	0°	20°	40°	99.1°
Specific gravity	0.8242	0.8108	0.7998	0.7734

Another specimen of the alcohol obtained from the pure iodide by converting first into acetate and then into alcohol, gave

Temperature	0°	20°	40°	98.9°
Specific gravity	0.8230	0.8105	0.7994	0.7735.

This specimen of alcohol gave on combustion, carbon 64.72 p. c. of carbon.

The alcohol is not miscible with water, and like the aldehyde, requires a large excess of water to dissolve it. It dissolves in aqueous hydrochloric and hydrobromic acids. Sodium dissolves in it, forming an alcoholate which crystallises in a glistening mass of needles. This compound dried in the oil-bath yields a body which appears to have the composition NaOC_4H_9 (Lieben and Rossi).

Linnemann (*Ann. Ch. Pharm.* clxi. 178–190) in preparing butyl alcohol from butyric aldehyde (obtained as above from butyric acid free from higher homologues), obtained a mixture of normal primary alcohol, with secondary and tertiary butyl alcohols, and methyl alcohol, as by treatment with gaseous hydriodic acid and fractional distillation of the product, it yielded methyl iodide, secondary and tertiary butyl iodide, and normal butyl iodide, boiling respectively at 41°–46°, 97°–99°, 115°–126°, and 127°–129°. The last-mentioned iodide, after repeated rectification, had the corrected boiling point 129.95° and sp. gr. 1.5909 at 16°. By converting this iodide into benzoate, purifying this ether by fractional distillation, saponifying it with potash, and dehydrating the volatile product with caustic baryta, normal butyl alcohol was obtained, having the corrected boiling point 116.88°. Another specimen obtained in like manner from a mixture of pure acetate, propionate and butyrate of butyl boiled at 116.96 (corr.). The alcohol from the benzoate was optically inactive, did not solidify at –22°, was soluble in 12 volumes of water at 22°, and dissolved 0.15 vol. water at the same temperature.

Linnemann has also prepared normal butyl alcohol by the action of sodium-amalgam on butyric anhydride or on a mixture of the anhydride with butyric acid, or of the acid with butyryl chloride, the last-mentioned method—which was also employed by

* In a note by Lieben, to the paper above quoted, the different methods of drying alcohols are discussed. Melted potassium carbonate and anhydrous copper sulphate were not found capable of drying the alcohol. The sulphate remained unaltered in butyl alcohol containing 2 p.c. of water. Lime and baryta set better; but one treatment, even with a considerable quantity of lime, is seldom sufficient to effect the object. With respect to sodium, it has been frequently pointed out, especially by Chapman, that it does not confine its action to the water in the alcohol, but at the same time acts on the alcohol, and produces an alcoholate, and water will be found in the distillate, even though there be more than sufficient sodium present to combine with all the water. This observation is quite correct; but Chapman's conclusion that, therefore, sodium is not available for drying alcohols is not confirmed, as Lieben finds that the best method of drying alcohols is to distil them repeatedly from small quantities of sodium. He observes that it is necessary to heat the alcohol far above its boiling point in an oil-bath, to separate it from the alcoholate. To this Chapman replies (*Chem. Soc. J.* (2) ix. 518), that in the case of amyl alcohol, at all events, this method of drying is not available, as the hydrate of sodium, when distilled with a large excess of amyl alcohol, is completely decomposed into amylate and water. Common alcohol may be dried as above, but propyl and butyl alcohols from fermentation, not without great difficulty. On the other hand, caustic baryta dries these compounds perfectly.

Saytsoff (*J. pr. Chem.* iii, 76)—yielding the largest product. The distillate consists wholly or partly of butyl butyrate, which is decomposed by distillation with potash, and the butyl alcohol which then passes over is dehydrated with baryta. Linnemann purifies the butyl alcohol obtained by either of these methods, by converting it into iodide, submitting the latter to fractional distillation, converting the portion which boils at 127° – 130° into benzoate, and decomposing the latter with potash as above.

Normal Butylic Ethers. The haloid ethers are prepared by the action of the corresponding haloid acids on the alcohol—e.g. the *chloride* by saturating the alcohol with hydrochloric acid gas; heating the resulting liquid with a small quantity of fuming hydrochloric acid to 70° , and finally to 100° in a sealed tube, till it separates into two layers which remain of constant volume, and purifying the upper layer, which consists of butyl chloride, by washing with strong hydrochloric acid, then with an alkali, and finally with water; then drying with calcium chloride, and rectifying. The *bromide* and *iodide* may also be prepared by treating the alcohol with bromine or iodine and amorphous phosphorus; the bromide also from the iodide, by decomposition with cupric bromide; and the chloride from the iodide by the action of mercuric chloride. The *acetate*, *propionate*, *butyrate*, and *benzoate* are obtained by decomposing the iodide with the corresponding silver salts. The following Table exhibits the boiling points and specific gravities of these ethers, as determined by Linnemann and by Lieben and Rossi:—

Normal Butyl Ethers.

	Boiling point	Specific gravity	Authority
Chloride	77.6° (bar. at 741.3 mm.)	0.9074 at 0° 0.8874 „ 20° 0.8972 „ 14°	Lieben a. Rossi — Linnemann
Bromide	100.4° (bar. at 744 mm.)	1.305 „ 0° 1.2702 „ 20° 1.2571 „ 40° 1.2990 „ 20°	Lieben a. Rossi — — Linnemann
Iodide	129.6° (bar. at 738.2 mm.)	1.643 „ 0° 1.6136 „ 20° 1.5894 „ 40°	Lieben a. Rossi — —
Cyanide	129.65°	1.5804 „ 18°	Linnemann
Acetate	140.4° (bar. at 739.3 mm.) 125.1° („ „ 740)	0.8164 „ 0° 0.900 „ 0° 0.8817 „ 20° 0.8659 „ 40°	Lieben a. Rossi — — —
Propionate	124.30°	0.8768 „ 23°	Linnemann
Butyrate	146° 165.5° (bar. at 735.7 mm.)	0.8828 „ 15° 0.8885 „ 0° 0.8717 „ 20° 0.8570 „ 40° 0.8760 „ 12°	— Lieben a. Rossi — — Linnemann
Benzoate	164.8° 247.32°	1.000 „ 20°	—

The chloride, butyrate and benzoate are insoluble in water; the acetate dissolves in 90 parts of water at 20° (Linnemann).

Brominated Butyl Bromide $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Br}$. Br obtained by heating 8 parts of the normal bromide with 9 of bromine to 150° for five hours boils at 166° – 167° : hence it appears to be identical with Wurtz's dibromide of ethyl-vinyl, boiling at 166° (*1st Suppl.* 377) and isomeric with the dibromide of methyl-allyl, boiling at 156° – 159° , (*ibid.* 376) from both of which again, the dibromide of isobutylene differs, its boiling point being 149° (Linnemann).

Normal Butyl Iodide is not much acted upon by sodium butylate in the cold, but on heating the materials in a flask, with inverted condenser, a small quantity of butylene is evolved, and butyl oxide $(\text{C}_4\text{H}_9)_2\text{O}$ is formed:

also

The normal butyl oxide thus obtained boiled, after repeated distillation over

sodium, at 140.5° (bar. at 741.5 mm. corrected and reduced to 0°). Sp. gr. = 0.784 at 0°, 0.7685 at 20°, 0.7556 at 40° (Lieben a. Rossi, *Ann. Ch. Pharm.* clxv. 109).

Butyl iodide heated in like manner with silver carbonate yields a product separable by fractional distillation into normal butyl carbonate, butyl alcohol, and butyl ether:

Normal butyl carbonate has a sp. gr. of 0.9407 at 0°, 0.924 at 20°, 0.911 at 40°, and boils at 207° (bar. 740 mm.); fermentation butyl carbonate, according to Wurtz, at 190° (Lieben a. Rossi).

The difference of boiling point between the oxide and carbonate of normal butyl, (which contain 2 atoms of butyl), and the corresponding isobutyl ethers, is about twice as great as that which exists between normal and isobutyl ethers, which contain only 1 atom of butyl, such as the chloride, acetate, cyanide, &c.

Normal Butylsulphuric acid is formed by gradually adding sulphuric acid to cooled butyl alcohol. On diluting with water, neutralising with baryta-water, crystallising, and drying over sulphuric acid, the *barium salt*, $\text{Ba}(\text{C}^4\text{H}^9\text{SO}^4)^2 + \text{H}^2\text{O}$, is obtained: it is stable at 60°, but decomposes at 100° (Lieben a. Rossi).

Butyl-ethyl oxide or Butyl-ethyl ether, $\text{C}^4\text{H}^9\text{O} = \begin{smallmatrix} \text{C}^4\text{H}^9 \\ \text{C}^2\text{H}_5 \end{smallmatrix} \text{O}$, is obtained, together with a small quantity of butylene, by heating butyl bromide or iodide with sodium ethylate or alcoholic potash, the quantity of butylene being larger with the latter reagent than with the former. When 10 grams of normal butyl iodide were warmed with a solution of 5 grams of potash in 15 grams of 90 p.c. alcohol, and 5 grams of solid potash, in a flask provided with a reversed condenser, only one-third of the butyl iodide was converted into butylene, the chief product, even with this large excess of potash, being butyl-ethyl ether. This ether boils at 91.7° under a pressure of 742.7 mm. Its specific gravity is 0.7694 at 0°, 0.7522 at 20°, and 0.7367 at 40° (Lieben a. Rossi).

Isobutyl Alcohol.— $\text{CH}(\text{CH}^3)_2.\text{CH}^2\text{OH}$. This alcohol, separated by Linnemann's method of fractional distillation (see DISTILLATION) from the products of the alcoholic fermentation of corn or molasses, is optically inactive, boils at 108.39°, has a sp. gr. of 0.8003 at 18°, and dissolves in 15 parts of water at 15° (Linnemann, *Ann. Ch. Pharm.* cxl. 195).

It may be formed systematically from normal butyl alcohol by the following series of processes: 1. The normal alcohol is converted into normal butyric acid by oxidation with chromic acid. 2. The ammonium salt of this acid distilled with dry zinc chloride yields butyronitril, $\text{C}^4\text{H}^7\text{N}$. 3. The nitril treated with hydrochloric or sulphuric acid and zinc takes up 4 atoms of hydrogen, and is converted into normal butylamine $\text{C}^4\text{H}^{11}\text{N}$. 4. This base heated with silver nitrite and water (1st *Suppl.* 63) yields a butyl alcohol which boils between 105° and 110°, dissolves in 8 to 9 parts of water at 22°, is converted by oxidation into an acid having the composition $\text{C}^4\text{H}^8\text{O}_2$, and yields an iodide boiling between 119° and 121°: it is therefore identical with the butylic alcohol of fermentation (1st *Suppl.* 373) (Linnemann a. von Zotta, *Ann. Ch. Pharm.* clxii. 3).

2. From isobutyric acid, by distilling the calcium salt of that acid with calcium formate, and treating the isobutyric aldehyde $\text{CH}(\text{CH}^3)_2.\text{CHO}$, thereby obtained, with sodium-amalgam (Linnemann a. von Zotta, *ibid.* 7).

3. From tertiary butyl alcohol, or trimethyl carbinol, by converting

this alcohol into the corresponding butylene or dimethyl-ethylene $\text{H}^3\text{C}-\overset{\text{CH}^3}{\underset{\text{C}}{\text{C}}}-\text{CH}^3$, combining this hydrocarbon with hypochlorous acid, and treating the resulting isobutylic chlorhydrin,

changed for hydrogen, and isobutyl alcohol $\text{C} \begin{cases} \text{CH}(\text{CH}^3)^2 \\ \text{H}^2 \\ \text{OH} \end{cases}$ is produced (1st *Suppl.* 376).

The same result is attained by heating the dibromide of dimethyl-ethylene CH^3Br
 $\text{H}^3\text{C}-\text{C}-\text{CH}^3$ (which is identical with monobrominated trimethyl-carbinyl bromide,
 Br

and with the dibromide of isobutylene, and may also be produced by acting on isobutyl-iodide with bromine not in excess) with 20 volumes of water to 150°–160° for 24 hours, whereby isobutyric aldehyde is formed:

which may be converted into the alcohol by sodium-amalgam (Linnemann a. von Zotta, *Ann. Ch. Pharm.* cxlii. 33).

Isobutyl Bromide, $\text{CH}(\text{CH}^3)^2\text{CH}^2\text{Br}$, prepared by treating the alcohol with phosphorus and bromine, and purified in the usual way by washing, drying and fractional distillation, is a colourless mobile liquid having a pleasant but slightly alliaceous odour, boiling at 90.5°, and having a specific gravity of 1.249 at 0°, 1.191 at 40.2° and 1.1408 at 73.5° (Pierre a. Puchot, *J. Pharm.* [4] xiii. 9).

Isobutyl Chloride, $\text{CH}(\text{CH}^3)^2\text{CH}^2\text{Cl}$ prepared by saturating the alcohol with hydrogen chloride, or treating it with phosphorus pentachloride, is a limpid liquid, having a pleasant, ethereal, but slightly alliaceous odour, and boiling at 60° under ordinary pressure. Sp. gr. = 0.8953 at 0°, 0.8651 at 27.8°, 0.8281 at 59°. Its specific volume at different temperatures is given in the following table, the volume at the boiling point being taken as unity:—

Distance in degrees Centigrade from the boiling point	Specific Volume
0	1.0000
10	0.9848
20	0.9705
30	0.9570
40	0.9443
50	0.9322
60	0.9208
70	0.9101

(Pierre a. Puchot, *Compt. rend.* lxxii. 832).

Isobutyl Iodide, $\text{CH}(\text{CH}^3)^2\text{CH}^2\text{I}$, boils at 120.63° (Linnemann), at 122.5° (Pierre a. Puchot). On heating it with water in a retort, the two liquids distil over together at a constant temperature of 95° or 96°, the distillate containing 70 parts butyl iodide to 21 parts water, whatever be the proportion of the two in the retort. During the distillation bubbles of vapour are seen to rise from the junction of the two layers of liquid, each bubble carrying with it a drop of iodide (Pierre a. Puchot, *Compt. rend.* lxxiv. 224).

Secondary Butyl Alcohol, or Ethyl-methyl Carbinol,

originally obtained by the action of hydriodic acid on erythrite, and afterwards by the successive action of zinc-ethyl and hydriodic acid on chlorinated ethyl oxide (*1st Suppl.* 373), may likewise be formed from normal butyl alcohol, by first converting that alcohol into the corresponding iodide $\text{CH}^3\text{CH}^2\text{CH}^2\text{CH}^2\text{I}$, heating this iodide with an alcoholic solution of potash, whereby butylene is produced, and combining this butylene with hydriodic acid, whereby secondary butyl iodide is obtained:

The iodide thus obtained, which distils almost wholly between 116° and 120° , is converted in the ordinary way into the corresponding acetate $(\text{CH}^{\text{a}})(\text{C}^{\text{a}}\text{H}^{\text{a}}).\text{CH}(\text{OC}^{\text{a}}\text{H}^{\text{a}}\text{O})$, (b.p. 110° – 113°), and this, by saponification, into secondary butyl alcohol, boiling between 97° and 100° . This alcohol yields by oxidation methyl-ethyl ketone and acetic acid (Saytzeff, *Zeitschr. f. Chem.* vi. 327).

When normal brominated butyl bromide, $\text{CH}^{\text{a}}-\text{CH}^{\text{a}}-\text{CHBr}-\text{CH}^{\text{a}}\text{Br}$ (identical with the dibromide of normal butylene) is heated with 20 times its volume of water to 150° for 24 hours, a ketone boiling between 75° and 80° is formed, which is doubtless ethyl-methyl ketone, produced by the reaction:

and this ketone by hydrogenation would doubtless yield ethyl-methyl carbinol (Linne-mann, *Ann. Ch. Pharm.* cxlii. 1).

Tertiary Butyl Alcohol, or Trimethyl Carbinol, $\text{C}(\text{CH}^{\text{a}})^3.\text{OH}$.

—This alcohol, originally formed by the action of water on the product obtained by treating acetyl chloride with zinc-methyl (Butlerow), was afterwards obtained by combining isobutylene (from isobutyl iodide) with hydriodic acid, whereby tertiary butyl iodide or trimethyl-carbinyl iodide $(\text{CH}^{\text{a}})^3.\text{CI}$ is produced, and decomposing this iodide with moist silver oxide (Markownikoff, see 1st Suppl. 374). Butlerow (*Zeitschr. f. Chem.* [2] vi. 237) modifies the process by passing the gaseous isobutylene into sulphuric acid, whereby trimethyl-carbinyl-sulphuric acid is formed:

and converting this acid into trimethyl carbinol by distillation with water. The details of the process are as follows:—

1. Isobutyl iodide is prepared by passing hydrogen iodide into boiling isobutyl alcohol in an apparatus provided with a condensing tube; at ordinary temperatures very little iodide is formed, but the alcohol saturated with hydrogen iodide at ordinary temperatures takes up a larger quantity when heated, and is then completely converted into isobutyl iodide. Butlerow recommends this process for preparing the iodides of the rarer alcohols.

2. To prepare isobutylene, 4 parts of alcoholic potash (1 part KHO to 3 parts alcohol of 90 p.c.) and $\frac{1}{2}$ part pulverised potassium hydrate are introduced into a flask provided with a funnel and condensing tube, and 2 parts of isobutyl iodide are gradually poured in through the funnel. The mixture is gently heated to start the reaction, which then goes on of itself, but towards the end heat must be again applied, only, however, to the sides of the flask, to prevent fracture. If less than the preceding quantity of potash be used, the quantity of isobutylene obtained is small, probably in consequence of the formation of ethyl-isobutyl ether. The isobutylene gas, after washing with alcohol and then with water, is collected in a gas-holder. 100 grams of isobutyl iodide thus treated yielded 10 to 11 litres of isobutylene.

3. The absorption of the isobutylene by sulphuric acid is effected as follows:—Within an upright Liebig's condenser 0.5 to 0.6 met. long is fixed a tube 1 centimeter in diameter, filled with coarsely pounded glass, and closed at top and bottom with caoutchouc stoppers. Through the lower of these stoppers are inserted two delivery tubes, one, intended for the butylene, passing upwards to the height of a decimeter into the pounded glass, while the other, which serves as exit-tube for the sulphuric acid, reaches only to the upper surface of the stopper. This last tube is bent upwards

outside the condenser, to the length of 8 centimeters, and then backwards like a fork. This tube consequently always remains full of acid, and thus stops the passage of the gas. Into the upper stopper are fitted a gas-delivery tube and a funnel-tube, provided with a stop-cock, through which the sulphuric acid drops slowly on to the glass. The dried isobutylene is now slowly admitted from below, care being taken to provide good refrigeration during the whole of the experiment, since in the absorption of the gas by the acid (3 parts H_2SO_4 to 1 part water) much heat is evolved which gives rise to the formation of an oily by-product. For the same reason the acid saturated with the isobutylene must be slowly dropped into cold water, and only a very dilute solution subjected to distillation. The watery distillate which contains the trimethyl carbinol is filtered to separate a trace of oil, then saturated with dry potassium carbonate to separate the alcohol. 85 litres of butylene yielded by this process 20 grams of dry trimethyl carbinol: consequently the 10 litres of isobutylene obtained as above from 100 grams of isobutyl iodide would yield 23.5 grams of trimethyl carbinol. Pure fermentation butyl alcohol should accordingly yield about half its weight of the tertiary alcohol.

Hydrochloric acid heated with isobutylene acts upon it in the same way as hydriodic acid, converting it into tertiary butyl chloride:

The action does not take place at ordinary temperatures; but when isobutylene is condensed by strong cooling in tubes containing very concentrated hydrochloric acid, and the tubes, after being sealed, are heated for several hours in a water-bath, the whole of the isobutylene is converted into the tertiary chloride, which floats as a layer on the top, no gas being evolved on opening the tube. The tertiary chloride, heated with water in a retort with reversed condenser, is converted into trimethyl carbinol (Salessky, *Ann. Ch. Pharm.* clxvi. 92).

Other methods of passing from isobutyl alcohol to the tertiary alcohol have been devised by Linnemann (*Ann. Ch. Pharm.* clxii. 12). α . A mixture of freshly precipitated silver oxide or mercuric oxide and glacial acetic acid acts on isobutyl iodide at ordinary temperatures, producing trimethyl-carbinyl acetate and trimethyl carbinol, together with isobutylene and a small quantity of a gas not absorbed by bromine. From the isobutylene thus formed, a further quantity of trimethyl carbinol may be obtained by Butlerow's process above described. This method of preparing trimethyl carbinol and its derivatives appears indeed to be the most productive known, inasmuch as 100 parts of isobutyl iodide thus treated yield directly 27.5 parts of trimethyl carbinol and 11 parts of isobutylene, which when treated by Butlerow's method yield an additional 11 parts of trimethyl carbinol, in all therefore 38 parts of the tertiary alcohol, the theoretical yield being 40, whereas Butlerow's process directly applied to 100 grams of isobutyl iodide yielded, as above stated, only 23.5 grams of trimethyl carbinol.

The formation of trimethyl carbinol from isobutyl iodide by means of silver oxide and glacial acetic acid may be explained by supposing that the elements of hydriodic acid are first removed, forming isobutylene, which, in the nascent state, combines with the elements of the acetic acid forming trimethyl-carbinyl acetate. The simultaneous formation of this acid, trimethyl carbinol, and isobutylene is in favour of this view.

According to Butlerow (*Ann. Ch. Pharm.* clxviii. 143), the butyl alcohol obtained by this process is a mixture of about equal parts of trimethyl carbinol and isobutyl carbinol, so that the advantage obtained by it is not so great as stated by Linnemann. Butlerow also finds that the quantity of silver oxide used by Linnemann, viz., that obtained from 50 parts of silver nitrate to 30 grams of the isobutyl iodide, which is about twice the calculated quantity, affords no advantage, the oxide from 30 grams of silver nitrate being quite sufficient for the same quantity of iodide.

β . Isobutyl bromide treated with mercuric oxide and glacial acetic acid likewise yields trimethyl carbinol; but silver oxide does not act upon it. Isobutyl chloride is scarcely acted upon by either of these oxides mixed with glacial acetic acid.

γ . Iodine monochloride converts isobutyl iodide into trimethyl-carbinyl chloride thus:

and this chloride (b.p. 46° – 52°) heated to 100° with water for several hours is almost wholly converted into trimethyl carbinol.

8. Isobutyl iodide heated with dry silver cyanate yields isobutyl cyanate; and this ether mixed with finely powdered potassium hydrate and heated in small quantities at a time, gives off vapours, not of isobutylamine, but of trimethyl-carbinylamine or tertiary butylamine, $C(CH^3)_3.NH^2$; and the hydrochloride of this amine heated with silver nitrate and water yields trimethyl carbinol (Linnemann).

For the dehydration of trimethyl carbinol, Butlerow combines it with calcium chloride and decomposes the resulting compound by distillation. Linnemann prefers the use of caustic baryta, as he finds that the alcohol, in distillation from its compound with anhydrous calcium chloride, which requires a temperature of 150° – 200° , is partly etherified; if the calcium chloride used contains so much water that the alcohol can be distilled off in the water-bath, the distillate contains as much water as the original alcohol before treatment with calcium chloride. By repeated treatment with caustic baryta in sealed tubes and subsequent fractional distillation, Linnemann obtained from the crude product, 74 p.c. of pure anhydrous trimethyl carbinol.

Trimethyl carbinol crystallises at temperatures below $+20^{\circ}$ in large rhombic, doubly refracting prisms, which melt at 25° – 25.5° and readily attract water, whereby they are liquefied (Butlerow, *Zeitschr. f. Chem.* [2] vii. 273). According to Linnemann, it melts at 23° – 24° and often remains liquid at temperatures below the melting point, solidifying suddenly on agitation or on throwing into it a piece of thin platinum wire. It boils at 82.94° (Linnemann); at 82.5° under a pressure of 750 mm. (Butlerow). Sp. gr. = 0.7792 at 37° (Linnemann); 0.7788 at 30° ; its coefficient of expansion between 30° and 50° is 0.0136 for 1° (Butlerow). On adding water to anhydrous trimethyl carbinol, considerable contraction takes place. The hydrate $2C(CH^3)_3.OH + 11H^2O$ is liquid at 0° , boils constantly at 80° and crystallises at the temperature of a mixture of snow and salt, in fine, silky needles (Butlerow).

Tertiary Butyl Chloride, $C(CH^3)_3Cl$, is obtained by passing isobutylene into very strong hydrochloric acid in tubes cooled by a freezing mixture, then sealing the tubes, and heating them to 100° for several hours:

An oily liquid is thereby formed which is converted into trimethyl carbinol by boiling with water (Salessky, *Ann. Ch. Pharm.* clxv. 92).

Tertiary Butyl Iodide, $C(CH^3)_3I$, heated with dry mercuric cyanide is converted into the corresponding cyanide, according to the equation:

The reaction is very violent, and must be moderated by cooling, but even then, a certain quantity of gaseous isobutylene is given off. The product distilled with water yields an oil containing the nitril, C^3H^7CN , together with a small quantity of isocyanide, which may be decomposed by hydrochloric acid. The portion of the oil boiling at 90° – 120° consists chiefly of the nitril; the higher portions up to 200° which constitute the larger portion, consist mainly of polymeric isobutylenes. The nitril boils at about 103° . On decomposing it in a digester with alcoholic potash, extracting the potassium salt with alcohol, distilling it with sulphuric acid, and dehydrating the distillate with phosphoric anhydride, trimethyl-acetic acid, $C(CH^3)_3.CO^2H$, is obtained, which solidifies immediately to a vitreous mass interspersed with crystals, melts at 31° – 36° and boils at 181° (Butlerow, *Deut. Chem. Ges. Ber.* v. 478).

BUTYLAMINES. (Lieben a. Rossi, *Ann. Ch. Pharm.* clviii. 172; Linnemann, *ibid.* clxii. 3). *Normal butylamine*, $C^4H^9N = N \begin{Bmatrix} CH^3CH^2CH^2(CH^3) \\ H^2 \end{Bmatrix}$, is prepared by heating butyl chloride to 100° – 110° in sealed tubes for two days with solid potassium cyanate and alcohol, and digesting the resulting alcoholic liquid, which contains butyl cyanate, with caustic potash. On distilling the liquid to dryness, adding water and again distilling, acidulating the mixture of the two distillates with hydrochloric acid, again evaporating to dryness, and exhausting the residue with alcohol, a solution is obtained, containing the hydrochlorides of butylamine, dibutylamine and tributylamine, while sal-ammoniac remains undissolved. The alcoholic extract evaporated to dryness and distilled with lime from a combustion-tube, the front part of which contains anhydrous baryta, yields a mixture of the three normal butylamines, from which the monobutylamine is easily separated by fractional distillation; the di- and tri-butylamine are less easy to separate. The three butylamines are likewise obtained as by-products in the preparation of normal valeric acid from butyl cyanide (Lieben a. Rossi.)

Normal butylamine may also be prepared by hydrogenising butyronitril C^4H^7N , (boiling at 115° – 117°) which is obtained by distilling with zinc chloride the ammonium salt of normal butyric acid. By mixing this butyronitril with hydrochloric or sulphuric acid, and allowing the mixture to flow on to zinc, a small quantity of butylamine is formed, and an additional quantity may be obtained by distilling off the unaltered nitril and repeating the process from twenty to twenty-five times (Linnemann).

Normal butylamine is a colourless, hygroscopic, ammoniacal-smelling, fuming liquid, which boils at 75.5° under a pressure of 740 mm. and has a sp. gr. of 0.7553 at 0° , 0.7333 at 20° (Lieben a. Rossi); boils at 76° – 77° and has a sp. gr. of 0.740 at 20° (Linnemann). Its vapour produces a feeling of heat on the skin, and strongly attacks cork and caoutchouc. It mixes in all proportions with water, and the solution precipitates the salts of lead, aluminium, magnesium, copper and silver. The copper and silver precipitates, and apparently also the aluminium precipitate, are soluble in excess of butylamine.

Hydrochloride of Butylamine is very soluble in alcohol, melts at 195° , decomposes to a great extent when distilled (Linnemann).

The platino-chloride, $2(C^4H^9N.HCl).PtCl_4$, crystallises in golden-yellow plates slightly soluble in cold, moderately soluble in hot water; soluble also in alcohol.

Normal butylamine is converted by nitrous acid, not into normal butyl alcohol, but into isobutyl alcohol (Linnemann); see p. 217.

Dibutylamine $NH(C^4H^9)^2$, boils at 160° and forms a platino-chloride, crystallising in long needles which melt and dissolve easily in hot water, very sparingly in cold water.

Tributylamine $N(C^4H^9)^3$, is prepared by heating with butyl iodide and alcohol, the mixture of primary, secondary, and tertiary amines obtained as a by-product in the synthesis of normal valeric acid from butyl cyanide. By boiling the product with caustic potash, tetrabutylammonium iodide and tributylamine are formed. The former is not attacked by boiling caustic potash, but is quickly decomposed by moist silver oxide. The latter boils between 211° and 215° (corr.) under a pressure of 740 mm. (tributylamine from fermentation butyl alcohol boils at about 30° lower); it forms a crystalline hydrochloride, from which caustic potash or ammonia precipitates the base as an oily liquid (Lieben a. Rossi, *Ann. Ch. Pharm.* clxv. 109). The platino-chloride $2(C^4H^9N.HCl).PtCl_4$ crystallises in groups of small needles, which melt and are slightly soluble in warm water, very slightly soluble in cold water, more freely in alcohol (Linnemann).

Isobutylamine, $N\begin{smallmatrix} CH^2CH(CH^3) \\ H^2 \end{smallmatrix}$, discovered by Wurtz, and already described under the name of tetrylamine (v. 737) is obtained by distilling a mixture of the potassium salt of isobutylsulphuric acid and potassium cyanate, and treating the product with caustic potash. It boils at 69° – 70° (Wurtz), at 65.8° – 68.3° under a pressure of 743 mm. (Linnemann); has a sp. gr. of 0.7357 at 15° ; dissolves in all proportions of water, and solidifies on exposure to the air, forming a carbonate. Its hydrochloride dissolves in 0.73 pt. water at 15° , and melts at 160° (below 100° according to Wurtz). The platino-chloride is slightly soluble in water (Linnemann).

Hydrochloride of isobutylamine distilled with silver nitrite and water yields, not isobutyl alcohol, but tertiary butyl alcohol or trimethyl carbinol $C(CH^3)_3.OH$, boiling at 81° – 85° ; and it has been already stated that normal butylamine similarly treated yields isobutyl alcohol; it is found also that normal propylamine gives isopropyl alcohol. The action of nitrous acid on monamines, may therefore be described as always producing the alcohol of a radicle containing one more methyl group than the original amine (provided of course that the amino is capable of forming an isomeride containing one more methyl group) (Linnemann).

Isobutylamines prepared by K. Reimer from isobutyl alcohol obtained by Krämer a. Pinner's process from the 'first runnings' of fused oil, are described by A. W. Hofmann (*Deut. Chem. Ges. Ber.* iii. 756). The alcohol boiled at 108° ; treated with bromine and phosphorus it yielded (besides butylene hydrobromide) isobutyl bromide boiling at 87° – 88° . This bromide heated to 150° with alcoholic ammonia yielded a mixture of three isobutylamines, which were but imperfectly separable by fractional distillation, but were easily separated by the application of Hofmann's oxalic ether method to the suitable fractions, into mono-isobutylamine boiling at 62° – 65° and di-isobutylamine boiling at 120° – 122° . The highest boiling portion of the crude mixture of bases, when further treated with the isobutyl bromide, yielded the hydrobromide of a nearly pure tri-isobutylamine $N(C^4H^9)^3$ boiling at 177° – 180° . This base digested with the bromide yielded, not the tetrabutylammonium compound

The *sulpho-carbimide*, or *isoculpho-cyanate*, $N\{C\{CS\}_2\}_{C^*H^*}$, derived from mono-isobutylamine, boils at 161° – 168° , and forms with ammonia a well-crystallised urea $CS\{NH^*\}_2[NH\{C^*H^*\}]$ melting at 90° – 91° . The isomeric *isobutyl sulpho-cyanate* $S\{C\{CN\}_2\}_{C^*H^*}$ produced by the action of potassium sulphocyanate on isobutyl sulphate boils at 174° – 176° .

Tertiary Butylamine or *Trimethyl-carbinylamine*, $N\{C(CH^*)_3\}_H$, is prepared by heating isobutyl iodide with dry silver cyanate, mixing the resulting solid compound of silver iodide and isobutyl cyanate with finely pulverised potassium hydrate, and heating the mixture by small quantities at a time. Vapours of trimethyl-carbinylamine (not of isobutylamine) are then given off; these may be absorbed by hydrochloric acid, and the resulting hydrochloride of tri-carbinylamine separated from sal-ammoniac by digestion with alcohol after evaporation to dryness.

Pure trimethyl-carbinylamine separated from the hydrochloride by distillation with an alkali, is a liquid boiling at 45° – 46° and having a sp. gr. of 0.6987 at 16° . Its hydrochloride melts above 250° and is distillable; it dissolves in 1.7 parts of water at 15° . The *platinochloride* is somewhat soluble in alcohol. The hydrochloride boiled with silver nitrite and water yields trimethyl carbinol.

The boiling points of the iodides and amines of the alcohol-radicles exhibit a constant difference of about 53° *c. g.*

		Iodide	Amine	Difference
Ethyl	CH^*CH^*	72	18.7	53.3
Propyl	$CH^*CH^*CH^*$	102.2	49	53.2
Butyl	$CH^*CH^*CH^*CH^*$	120.0	76.5	53.4
Isobutyl	$CH^*CH(CH^*)^2$	120.6	67.5	53.1
Trimethyl-carbinyl	$C(CH^*)^3$	98.5	46	52.5

(Linnemann, *Ann. Ch. Pharm.* clxii. 3).

BUTYLENE, C^*H^* . The number of possible modifications of this and other olefines will be greater or smaller, according as we suppose, on the one hand that their molecules contain either dyad carbon, or free combining units, or on the other hand that they are saturated compounds, having two of their carbon-atoms linked together by two combining units. Thus if butylene be supposed to contain only tetrad carbon-atoms, each pair being united by only one unit of affinity, nine modifications of it may be conceived to exist, four saturated and five unsaturated, viz. those figured in the *First Supplement* (p. 375); and three of these latter, viz. the second, fifth, and eighth, might also be regarded as saturated molecules containing dyad carbon; but if the butylenes are saturated molecules containing only tetrad carbon and having two of these carbon-atoms united by two combining units, then only three modifications are possible, viz.:

These are in fact the only modifications actually known, the first and second being produced by abstraction of HI (action of alcoholic potash) from normal primary butyl iodide, $CH^*_2-CH^*-CH^*_2-CH^*_2I$, or from secondary butyl iodide, $CH^*_2CH^*-CHI-CH^*_2$, and the third in like manner from isobutyl iodide $CH(CH^*)^2-CHI$ or from trimethyl-carbinyl iodide $CI(CH^*)^3$. The preparation of this third modification (isobutylene) from isobutyl iodide and its conversion into trimethyl carbinol have been already described (p. 210).

Isobutylene has the same properties whether it be prepared from isobutyl iodide or from trimethyl-carbinyl iodide; that obtained by Butlerow from the former source boiled at -6° , that from the latter at -7° to -8° ; but it was obtained in very small quantity only, and Butlerow regards -6° as the true boiling point. The butylene

obtained by electrolysis of isovaleric (ordinary valeric) acid, $\text{CH}^2\text{CH}(\text{CH}^3)\text{COOH}$, is likewise isobutylene, inasmuch as the butyl iodide obtained by combining it with HI, is converted, by treatment with silver oxide and water, into trimethyl carbinol, which, could not be produced from either of the other modifications of butylene (Butlerow *Zeitschr. f. Chem.* [2] vi. 236).

By combining a butylene with 2 atoms of bromine and treating the compound $\text{C}^4\text{H}^2\text{Br}^2$ with alcoholic potash, it might be expected that a hydrocarbon C^4H^4 would be produced, viz. crotonylene; and Caventou indeed states that crotonylene is thus obtained from the butylene produced by exposing the vapour of fusel-oil to heat, (ii.

196) which, as Butlerow has shown, is isobutylene. But isobutylene $\text{H}^2\text{C} - \text{C} \begin{smallmatrix} \text{CH}^3 \\ \text{CH}^3 \end{smallmatrix}$ cannot yield a crotonylene, except by transposition of the atoms, or by the formation of a closed chain, viz. $\text{H}^2\text{C} = \text{C} \begin{smallmatrix} \text{CH}^2 \\ | \\ \text{CH}^2 \end{smallmatrix}$. It is more probable, therefore, that

Caventou's butylene was one of the other modifications above mentioned (p. 223), the dibromide of either of which might yield a crotonylene:

Recent experiments by Prunier (*Compt. rend.* lxxvi, 1410) have shown that the first of these formulae, which is that of ethyl-acetylene, is the true representation of the constitution of crotonylene.

Butlerow, by heating isobutylene dibromide with alcoholic potash, obtains, not crotonylene but isocrotyl bromide $\text{C}^4\text{H}^3\text{Br}$:

This compound is a colourless, heavy, aromatic liquid, insoluble or nearly so, in water, boiling at $88^\circ\text{--}92^\circ$. Heated in sealed tubes to 150° with concentrated alcoholic potash or crystallised sodium ethylate, it is converted, by exchange of Br for OC^2H^3 , into ethyl-isocrotyl ether:

(Butlerow, *Zeitschr. f. Chem.* [2] vi. 523).

According to Prunier (*Bull. Soc. Chim.* [2] xix. 109) butylene bromide may be obtained, together with some of its homologues, by passing the vapours of light petroleum oils through red-hot tubes, and leading the resulting gases through bottles containing bromine. The results vary with the kind of petroleum employed, the temperature of the tube, the pressure, and the rate of distillation. Petroleum oils boiling below 50° yield much ethylene and but little butylene; whilst oils boiling at $50^\circ\text{--}80^\circ$ yield butylene and even amylene, together with a considerable quantity of propylene and ethylene.

The most advantageous method of obtaining the propylene and butylene compounds consists in decomposing the vapours of petroleum oils boiling at $60^\circ\text{--}90^\circ$, by passing them through a red-hot tube, and conducting the gases thereby produced through a second tube heated to dull redness, and afterwards through bottles containing bromine. The products are separated by fractional distillation, and decolorised by contact with quicklime. There remain in the retort, together with carbonaceous matters, a crystalline body easily extracted by alcohol and ether, and having all the properties of Caventou's tetrabromide of crotonylene, $\text{C}^4\text{H}^2\text{Br}^4$, and another body which appears to have the formula $\text{C}^4\text{H}^2\text{Br}^4$.

BUTYLENE GLYCOL, $\text{C}^4\text{H}^{10}\text{O}^2 = \text{C}^4\text{H}^8(\text{OH})^2$.—Ordinary butylene glycol (described in vol. v. p. 789, as tetraenylic alcohol), is obtained from the bromide of

isobutylene (produced by direct combination, or by the action of bromine on secondary butyl iodide), and has the constitution $\text{CH} \begin{cases} \text{CH}^2\text{OH} \\ \text{CH}^2 \\ \text{CH}^2\text{OH} \end{cases}$; when slowly oxidised by dilute nitric acid, it is converted chiefly into butylactic or oxy-isobutyric acid $\text{C}^4\text{H}^8\text{O}^3$:

Another modification is produced by the action of sodium-amalgam on acetic aldehyde, the change, which consists in a duplication of the molecule with addition of hydrogen: $2\text{C}^2\text{H}^3\text{O} + \text{H}^2 = \text{C}^4\text{H}^6\text{O}^2$, being analogous to that by which benzoic aldehyde $\text{C}^7\text{H}^5\text{O}$ is converted into benzoin $\text{C}^9\text{H}^{10}\text{O}^2$.

To prepare it, sodium-amalgam is added to an acidulated dilute aqueous solution of aldehyde, and the filtrate is neutralised and distilled, to separate the ethyl alcohol formed at the same time; other by-products are removed by agitation with ether; the aqueous liquid is evaporated almost to dryness, mixed with alcohol, filtered from sodium chloride, and distilled; and the butylene glycol is finally obtained from the portion of higher boiling point by repeated fractional distillation. The product is, however, very small, even under the most favourable conditions.

Butylene glycol thus prepared is a clear syrupy liquid having a sweet but slightly pungent taste; easily soluble in water and alcohol, insoluble in ether; boils at 203.5° – 204° . When oxidised by nitric acid, it yields acetic, oxalic, and carbonic acids; with aqueous chromic acid, only acetic and carbonic acids, the oxalic acid undergoing further oxidation. In both cases, also, crotonic aldehyde is formed, together with small quantities of acetic aldehyde.

The formation of crotonic aldehyde by oxidation of this butylene glycol shows that the formula of the latter is $\text{CH}^2\text{—CH}^2\text{OH—CH—CH}^2\text{OH}$. Probably the elements of water are first separated, giving rise to crotonic alcohol $\text{CH}^2\text{—CH=CH—CH}^2\text{OH}$, which is then oxidised to crotonic aldehyde $\text{CH}^2\text{—CH=CH—COH}$. This aldehyde yields the same oxidation-products as the butylene glycol (Kekulé, *Deut. Chem. Ges. Ber.* v. 56).

BUTYRIC ACID. Linnemann a. von Zotta (*Ann. Ch. Pharm.* clxi. 175) have prepared normal butyric acid, $\text{CH}^3\text{CH}^2\text{CH}^2\text{—COOH}$, from pure fermentation propyl alcohol, by converting this alcohol into iodide, the latter into cyanide by heating it for 30 hours with alcoholic potassium cyanide, and decomposing the cyanide with caustic potash. From the potassium butyrate thus obtained, the acid was separated by neutralisation with hydrochloric acid, evaporation to dryness, and treatment with dry hydrochloric acid gas, and finally purified by distillation over phosphoric anhydride.

Normal butyric acid thus prepared is identical with that which is produced by the fermentation of sugar, as the following comparison will show:—

	Butyric acid prepared by Synthesis	Butyric acid obtained by fermentation of Sugar
Boiling point (corrected)	162° – 163°	162.32°
Specific gravity at 14°	0.9601	0.9580
Solubility of silver salt $\text{AgC}^4\text{H}^7\text{O}^2$ in water	in 200 parts at 14°	in 202 parts at 14°
Solubility of calcium salt $\text{Ca}(\text{C}^4\text{H}^7\text{O}^2)_2 + 2\text{H}^2\text{O}$	in 3.2 parts at 15°	in 3.5 parts at 14°
Solubility of barium salt $\text{Ba}(\text{C}^4\text{H}^7\text{O}^2)_2$ (at 100°)	in 2.4 parts at 14°	in 2.43 parts at 14°
Ethyl ether		
Boiling point	121.05°	121.07°
Specific gravity at 18°	0.8953	0.9003

Pure normal butyric acid solidifies in a mixture of salt and snow, and is optically inactive.

2nd Sup.

According to Grünzweig (*Ann. Ch. Pharm.* clxii. 193) it boils at 157° – 160° under a barometric pressure of 716 mm., and its salts exhibit the following solubilities:

100 parts of water dissolve of the

Silver salt	Ag C ⁴ H ⁷ O ²	0.413 part at 16°
Calcium salt	{ unhydr. Ca(C ⁴ H ⁷ O ²) ²	18.1 parts, " 22°
	{ cryst. Ca(C ⁴ H ⁷ O ²) ² + H ² O	19.61 " 22°
Strontium salt (cryst.)	Sr(C ⁴ H ⁷ O ²) ² + H ² O	39.2 " 20°
		40.2 " 22°
Zinc salt (cryst.)	Zn(C ⁴ H ⁷ O ²) ² + 2H ² O	10.7 " 16°

Isobutylic Normal Butyrate, CH³CH²COOH

alcohol with sulphuric acid and normal butyric acid, boils at 150° – 155° (uncorrected) under a pressure of 722 mm. and has a specific gravity of 0.08798 at 0°, 0.86635 at 16°, 0.81838 at 98.44° (Grünzweig).

Isobutyric acid, CH(CH³)².COOH, is prepared by oxidising isobutyl alcohol with chromic acid mixture. Linnemann and v. Zotta, (*Ann. Chem. Pharm.* clxii. 7), purify it by converting the product into a calcium salt and decomposing this salt with dry hydrochloric acid gas. Pierre a. Puchot (*Ann. Chim. Phys.* [4] xxviii. 363) convert the alcohol by partial oxidation into isobutylic isobutyrate; decompose this ether with potash; distil the resulting potassium isobutyrate with dilute sulphuric acid; and subject the distillate of aqueous butyric acid to a series of fractional distillations, whereby pure isobutyric acid C⁴H⁸O² is obtained.

Isobutyric acid boils at 154.11° (Linnemann and v. Zotta), at 155.5° (Pierre a. Puchot) under a pressure of 760 mm.; at 149° – 151° under a pressure of 716 mm. (Grünzweig). Its sp. gr. is 0.9503 at 20°, (L. and Z.) 0.9697 at 0°, 0.916 at 52.6°, 0.8665 at 99.8°, 0.822 at 139.8° (Pierre a. Puchot). These determinations agree very nearly with those obtained by Markownikoff in 1865 (*1st Suppl.* 378), and show that isobutyric acid is quite distinct in its physical properties from the normal acid; nevertheless, Pierre a. Puchot do not appear to consider the existence of two modifications of butyric acid as distinctly proved* (see p. 379 of their memoir); and as their acid agrees nearly in physical properties with the butyric acid obtained by fermentation of sugar, which was examined several years ago by Kopp and by Delffs (i. 692), and found to boil at 156° , they appear to regard this latter as the pure butyric acid, and the acid of higher boiling point obtained in the same manner, as an impure product. As, however, the butyric acid of fermentation boiling at 164° agrees in its properties and those of its derivatives with the acid obtained by oxidation of normal butyric alcohol, it is much more probable that the fermentation acid boiling at 156° examined by Kopp and by Delffs was an impure product contaminated with lower homologues.

The metallic isobutyrrates are more soluble than the corresponding normal butyrrates, as may be seen from the following determinations by Grünzweig:

100 parts of water dissolve of the

Silver salt	AgC ⁴ H ⁷ O ²	0.928 parts at 16°
Calcium salt	Ca(C ⁴ H ⁷ O ²) ² + 5H ² O	36.0 " 16°
Strontium salt	Sr(C ⁴ H ⁷ O ²) ² + 5H ² O	44.1 " 17°
Zinc salt	Zn(C ⁴ H ⁷ O ²) ² + H ² O	17.3 " 19.6°

Isobutyric Ethers.—The boiling points and specific gravities of methyl and ethyl isobutyrate have been determined by Pierre a. Puchot; those of isobutyl isobutyrate by Grünzweig:

	Methylic	Ethyllic	Isobutylic
Boiling point.	93° bar. at 760 mm.	113° bar. at 760 mm.	144°–147° bar. at 722 mm.
Specific gravity.	0.9056 " 0°	0.890 " 0°	0.87670 " 0°
"	0.8625 " 38.65°	0.871 " 18.8°	0.86064 " 50°
"	0.805 " 78.6°	0.831 " 55.6°	0.81192 " 95.4°
"	—	0.7794 " 100.1°	—

* The same disregard of the difference between normal and iso-compounds is exhibited by Pierre a. Puchot in all their researches on the alcohols and acids of the fatty group (see *Compt. Rend.* 1440, 1864; *Chem. Soc. J.* [2] x. 267).

Oxidation-products of Normal Butyric and Isobutyric Acid.—Isobutyric acid is oxidised by chromic acid mixture to acetic and carbonic acids:

(Erlenmeyer, *Zeitschr. f. Chem.* [2] vii. 57).

Now Voel has shown (1st Suppl. 587), that normal butyric acid treated in a similar manner yields propyl butyrate and ethyl butyrate, but no acid containing a smaller number of carbon-atoms. These reactions appear therefore to afford an easy mode of distinguishing the two modifications of butyric acid one from the other.

According to Grünzweig, however, the only difference existing between normal butyric acid and isobutyric acid as to the products of their oxidation by chromic acid lies in the fact that the normal acid is much less readily acted on: the actual products, however, are the same in each case, viz. acetic and carbonic acids; in two experiments with the iso-acid, 98·4 and 100·4 per cent. of the theoretical quantity of carbonic acid were obtained, whilst in three experiments with the normal acid 71, 75, and 106 per cent. were respectively obtained.

Butyric Acid from various Natural Sources.—The butyric acid from ordinary butter, and that produced by oxidation of conine (ii. 3) consist of the normal acid, whereas that which exists in the carob bean, or St. John's bread, the fruit of *Ceratonía Siliqua*, is isobutyric acid. When, however, the portion of this fruit left behind on distillation with water is fermented with chalk and cheese, normal butyric acid is produced. The acid in each case was identified by the properties of its silver and calcium salts as given above (Grünzweig, *Ann. Ch. Pharm.* clviii. 117; clxii. 193). Gorup-Besanez found butyric acid in old fruit of the soap-tree (*Sapinda saponaria*), and considers it probable that this acid exists in old tamarinds. Grünzweig found only acetic acid in the latter.

Crude Butyric Acid of Fermentation.—Grillone (*Ann. Ch. Pharm.* clxv. 127) has examined the composition of the acid obtained by leaving a mixture of malt, milk, chalk, and minced meat to stand for several weeks. On heating the product to 80°, filtering, precipitating with sodium carbonate, filtering again, evaporating the filtrate to a small bulk, and mixing it with sulphuric acid, a considerable layer of crude fatty acid was obtained, the greater part of which distilled between 156° and 164°, a portion also below 125°, another between 125° and 155°, and another as high as 215°.

The portion boiling below 125° consisted almost wholly of acetic acid; that which distilled between 125° to 155°, of acetic and butyric acids, which were separated by fractional saturation with sodium carbonate and distillation, the butyric acid then passing over, while sodium acetate remained behind. No propionic acid could be detected: a result which agrees with the statement of Linnemann (*Ann. Ch. Pharm.* clx. 224) as to the non-occurrence of propionic acid in crude fermentation butyric acid.

Of the portion distilling above the boiling point of butyric acid, a large fraction went over between 155° and 174°, which seemed to indicate the presence of valeric acid; but this acid was not found. By repeatedly washing the distillate with water, a considerable portion of it was dissolved, and this portion saturated with lime yielded a calcium salt exhibiting very nearly the composition of calcium butyrate, only the traces of the salts of higher acids being present.

The portion insoluble in water distilled between 200° and 205°, and exhibited the composition of caproic acid, the presence of which in crude butyric acid had previously been demonstrated by Stich (*Jahresb.* 1868, 522). The caproic acid thus isolated, yielded an anhydrous barium salt, 100 parts of a saturated solution of which contained at 21°–22°, 8·3 parts of dry salt. Now normal barium caproate is anhydrous, and 100 parts of its solution at 18·5° contain 8·4 parts of dry salt, whereas the caproic acid obtained from fermentation amyl cyanide forms a barium salt which contains 2H²O, and dissolves at 18·5° to the amount of 34·65 parts of dry salt in 100 parts of water. The calcium salt of the caproic acid separated as above, contains 1 mol. H²O, corresponding therefore with the normal caproate, and not with that of ordinary caproic acid, which contains 3H²O. 100 parts of its solution at 21°–22° contain 4·4 parts of dry salt, the solution of normal calcium caproate at 18·5° containing 2·7 parts, and that of the ordinary caproate, 11·3 parts of dry salt. These properties show that the caproic acid contained in crude butyric acid of fermentation is normal caproic acid. No acid was found boiling at a higher temperature than caproic acid.

BUTYRIC ALDEHYDE, C⁴H⁸O = C⁴H⁷.CHO. The preparation of normal butyric aldehyde, its physical properties, and its conversion into normal butyl alcohol have been already described in connection with that alcohol (p. 214).

Isobutyric Aldehyde, CH(CH³)².CHO, may be prepared by distilling calcium isobutyrate with calcium formate, or by oxidation of isobutyl alcohol. By the former process Linnemann and v. Zotta (*Ann. Ch. Pharm.* clxii. 7) obtained isobutyric

aldehyde having a sp. gr. of 0.803 at 20°, and a corrected boiling point of 60°–82°; it dissolved in 9 volumes of water at 20°, and gave crystals with sodium bisulphite, from which it was separated by potash without alteration. By the action of water and sodium-amalgam it is reduced to isobutyl alcohol (p. 214).

A. Pinner (*Deut. Chem. Ges. Ber.* v. 699) prepares isobutyric aldehyde by cautiously oxidising isobutyl alcohol with chromic acid solution mixed with sulphuric acid, to dissolve the chromic hydrate produced; 100 grams of the alcohol, $\frac{3}{4}$ litre of water, 95 grams of chromic acid, and about 90 c.c. of strong sulphuric acid being employed, and the mixture being only gently warmed. On re-distillation of the distillate in the water-bath, isobutylic isobutyrate is left, and the aldehyde distils over. After treatment with sodium bisulphite (whereby crystals are formed), and drying over calcium chloride, the aldehyde boils constantly at 61°. It forms a difficultly crystallisable compound with ammonia. Potash appears to polymerize the aldehyde, forming a yellow liquid of peculiar aromatic odour, boiling for the most part at 145°–155°.

Sulphuretted hydrogen forms with isobutyric aldehyde an uncrystallisable oil having an abominable alliaceous odour. With an aqueous solution of isobutyl-aldehyde-ammonia, sulphuretted hydrogen yields isobutyraldine, $C^{12}H^{12}NS_2$, as an amorphous mass, very difficult to crystallise. This compound forms with mercuric chloride a compound nearly insoluble in water, amorphous to the naked eye, but crystalline under the microscope. Isobutyric aldehyde shaken with carbon bisulphide, after saturation with concentrated ammonia, forms carboisobutyraldine, $C^8H^{16}NS_2$, which is crystallisable and soluble in alcohol and ether, but not in water, and melts at 91°.

Para-isobutyric Aldehyde. Barlaglia (*Deut. Chem. Ges. Ber.* v. 105, 2) obtained a polymeric modification of isobutyric aldehyde by passing chlorine into the aldehyde kept at a low temperature. A white crystalline body was thereby produced, insoluble in water, but soluble in alcohol and more freely in ether; melting at 59°–60°, and solidifying at 50°–51°; volatile with vapour of water, and subliming easily without decomposition. It contained no chlorine, and gave by analysis numbers agreeing with the formula C^4H^6O . Its vapour-density however (105.55 and 103.76 in two determinations) showed that its true formula is $C^{12}H^{20}O_3$, the calculated vapour-density for which is 108. This modification is therefore para-isobutyric aldehyde; but the circumstances under which it is formed have not yet been ascertained, as on repeating the experiment, the same body was not produced.

BUTYRONE. $C^4H^6O = CO(C^3H^7)^2$. *Dipropyl Ketone* (Kurtz, *Ann. Ch. Pharm.* clxi. 205. E. Schmidt, *Deut. Chem. Ges. Ber.* v. 597). Kurtz prepares this body by Chancel's method (1st *Suppl.* 697) namely by distilling pure calcium butyrate in small portions at a time, and submitting the crude distillate to fractional distillation. Agitation with alkaline bisulphites did not separate any of the butyrene, but apparently a mixture of methyl-ethyl ketone and methyl-propyl ketone (1st *Suppl.* 592).

Schmidt heats calcium butyrate mixed with calcium carbonate, to prevent fusion, in a wide iron tube placed in a combustion-furnace, the heat being gradually carried from the back to the front. By operating in this manner in the preparation of butyrene and of other ketones, a much larger product is obtained than when a retort is used, the formation of secondary products being in great part prevented. Calcium carbonate is a more convenient addition, to prevent fluxing, than quicklime, as the latter gives rise to the formation of aldehydes. The crude product is dehydrated by calcium chloride and purified by fractional distillation.

Butyrene boils at 144° and has a sp. gr. of 0.819 at 20° (Schmidt); 0.83 (Chancel). It is converted by nitric acid into nitropropionic acid $C^3H^5(NO_2)O_2$, and by oxidation with chromic acid mixture into propionic and butyric acids.

Chlorine acts on butyrene, with evolution of hydrogen chloride, producing a liquid which decomposes on distillation or when left to itself. A similar product is obtained with potassium chlorate and hydrochloric acid. Phosphorus pentachloride also acts readily on butyrene, but the product is not easily separated from phosphorus oxychloride (Kurtz).

On adding sodium in small pieces to butyrene mixed with a very small quantity of water, a strong reaction takes place, and a product is formed containing butyrosapinacene $C^{14}H^{20}O_2$, and a secondary heptyl alcohol, $C^7H^{14}O$, having the constitution of d propyl carbinol.

This alcohol boils at 140° – 150° , or about 24° lower than normal heptyl alcohol or hexyl carbinol $C^6H^{13}.CH^2OH$, and about 12° lower than the secondary methyl-pentyl carbinol $CH^3.CHOH.C^3H^{11}$, both of which have been obtained by Schorlemmer from petroleum oil (see **HEPTYL ALCOHOLS**).

By oxidation with chromic acid mixture, dipropyl carbinol is reconverted into butyrene (Kurtz).

BUTYRONE-PINACONE, $C^{14}H^{20}O^2 = 2C^7H^{10}O + H^2$, is a crystalline body of sp. gr. 0.87 at 20° , melting at 68° , resolidifying at 57° , and distilling at about 260° . It smells and tastes like camphor, dissolves in alcohol and ether, sparingly in water, but does not appear to form a definite hydrate, as is the case with the pinacone of common acetone. By oxidation with potassium dichromate and sulphuric acid, it is reconverted into butyrene (Kurtz).

C

CABBAGE. Analyses of the ashes of the winter cabbage (*Brassica oleracea*, var. *acephala*) have been made by Hofmann (*Landwirthschaftliche Versuchs-Stationen*, xiii. 255). The plant was examined at two stages of its development, as young plants gathered in July, and as mature plants taken in the following January. The young plants averaged 20 cm. in height, and 4.8 grams in weight. The full-grown cabbages were 40–50 cm. in height, and their average weight, after removing the lesser roots, was 236 grams. Of this weight the leaves of the cabbage contributed 188 grams, and the stalk 48 grams. Analysis showed 100 parts in the fresh state to contain:

	Young plant	Winter cabbage	
		Leaves	Stalk
Water	85.167	20.634	22.458
Dry Substance	14.833	79.366	77.542
Ash	4.257	1.820	1.456
Nitrogen688	3.064	1.661

The composition of the ash in 100 parts was as follows:—

	Young plant	Winter cabbage	
		Leaves	Stalk
Potash	30.959	31.728	39.416
Soda	—	2.015	3.517
Lime	17.710	14.426	12.355
Magnesia	4.099	2.845	4.887
Ferric oxide	1.565	8.108	1.347
Phosphoric acid	7.750	10.093	12.263
Sulphuric acid	8.616	6.087	9.203
Silica	1.231	1.198	.845
Chlorine	8.189	7.640	6.805
Carbonic acid	15.175	13.114	7.878
Sand and charcoal	6.420	2.692	1.325
	101.714	99.946	99.840

CADMIUM. According to Schön (Zeitschr. anal. Chem. x. 391), the action of this metal on nitric acid, which is rapid under ordinary circumstances, is arrested when the cadmium is placed in contact with a sufficiently large quantity of platinum.

When a plate of cadmium and a plate of copper are immersed in a solution of cad-

mium sulphate deprived of air and covered with a layer of oil, only a slight disengagement of hydrogen is observed on the surface of the cadmium, so long as the two plates do not touch, the cadmium being at the same time feebly attacked; but as soon as the plates are made to touch, a deposition of cadmium takes place on the copper plate (Raoult, *Compt. rend.* lxxv. 1103).

CÆSIUM. *Occurrence.* The hot spring of Wheal Clifford in Cornwall contains 1·71 part of cesium chloride in a million parts by weight, or 0·12 grain in a gallon, that is about 10 times the quantity contained in the Dürkheim water (Col. Yorke, *Chem. Soc. J.* [2] x. 273).

Sonstadt has detected cesium and rubidium in sea-water and in sea-weed (*Chem. News*, xxii. 25, 44).

Preparation from Lepidolite. Stolba (*Dingl. pol. J.* cxvii. 336) heats lepidolite with sulphuric acid (for the preparation of silicofluoric acid) and utilises the residue for the preparation of cesium and rubidium. The residue is boiled with 5 or 6 times its volume of water, to which potassium carbonate is added (40 parts to 100 lepidolite), and the liquid is filtered at the boiling heat. On cooling it deposits a large quantity of potassium-alum containing rubidium and cesium, which may be separated either by Redtenbacher's method (v. 129) or by dissolving the alums in hot strong hydrochloric acid, precipitating the cesium with stannic chloride (1st *Suppl.* 382), and after evaporating the excess of hydrochloric acid from the filtrate, separating the rubidium by silicofluoric acid. The lithium remains in the mother-liquor of the alums.

According to Lecoq de Boisbaudran (*Bull. Soc. Chim.* [2] xvii. 551) a solution containing nothing but alkaline salts may be obtained from lepidolite, more rapidly than by the usual methods, by acting on that mineral with hydrofluoric acid, adding excess of chalk, filtering, precipitating with sodium carbonate and sodium sulphide, and again filtering.

In separating the rubidium and cesium by Bunsen's method, it is better, instead of washing the mixed bitartrates, to dissolve them in just enough hot water, and to stir the solution till it is cold. When the resulting precipitate of rubidium bitartrate is treated in the same way two or three times, it is obtained quite free from cesium.

Cæsio-stannic chloride, $2\text{CsCl} \cdot \text{SnCl}_4$, crystallises in octahedrons or cubo-octahedrons, and has a sp. gr. of 3·308 at 20·5° (referred to water at the same temperature). Before precipitating cesium with stannic chloride, it is necessary to expel ammoniacal salts, inasmuch as ammonio-stannic chloride is insoluble in strong hydrochloric acid. To decompose the cæsio-stannic chloride, it is mixed with powdered sal-ammoniac and ignited, whereupon the stannic chloride volatilises (Stolba, *Dingl. pol. J.* cxviii. 255).

CAFFEINE, $\text{C}_8\text{H}_{10}\text{N}_4\text{O}_2$. *Extraction from Coffee.*—According to H. Aubert (*Pfäuger's Archiv. f. Physiologie*, v. 589) the largest amount of caffeine is obtained by exhausting the coffee with water, either by percolation or by decoction, evaporating to a syrup, and treating the syrup from five to eight times with chloroform at a temperature near 60°.

Raw beans of the yellow Java kind yielded by this method 0·709–0·849 p.c. while they gave only 0·474 by Garot's method of precipitation with basic lead acetate. When much roasted, coffee loses a certain quantity of caffeine, which sublimates, whereas it loses none by slight roasting. Notwithstanding this, the coffee made in the usual way by percolation from strongly roasted coffee contains rather more caffeine than that made from an equal weight of slightly roasted coffee, as the roasting renders it more easy to extract.

When coffee is prepared by pouring six to ten times its weight of boiling water three or four times over ground coffee, nearly the whole of the caffeine is extracted, hardly one-fifth of it remaining in the grounds. The quantity of caffeine in a cup of coffee prepared from 16½ grams of coffee is about 0·1 to 0·12 gram. A cup of tea prepared in the ordinary way from 5–6 grams of Pekoe tea contains also about 0·1 to 0·12 gram of caffeine.

Physiological action.—Caffeine acts upon the spinal cord and causes tetanus in doses of 0·005 gram for a frog, injected subcutaneously; for a rabbit, 0·120 gram (injected into the jugular vein); for cats, 0·200, injected in the same way; and the same quantity for dogs. It has a peculiar action on the muscles of frogs, especially when directly applied to them, causing them to become rigid and white, apparently from coagulation of the myosin. It does not exert this action on the muscles of mammalia. The tetanus is removed by artificial respiration, and if this process is kept up for about a quarter of an hour, no recurrence of the tetanus takes place, even though the respiration is then discontinued, showing that the caffeine is quickly eliminated or destroyed in the organism. Occasionally it produces a paralysis of the hind legs in rabbits. The action of caffeine does not explain the stimulating and reviving action of coffee (Aubert).

Estimation of Caffeine in Tea-leaves.—The finely powdered tea-leaves are heated for a few minutes with three times their quantity of chloroform, and the liquid, when cold, is filtered off. The chloroform is then removed by distillation, and the residue is well washed with hot water and filtered; the filtrate, on evaporation, leaves a crystalline mass of caffeine. By this means sufficient caffeine may be extracted from 20 grams of tea to give the characteristic reaction with chlorine-water and ammonia (E. Lioventhal, *Chem. Centralblatt*, 1872, 631).

Action of Baryta-water on Caffeine and Caffeidine.—The base $C^8H^7NO^2$, obtained, together with formic acid, by the prolonged action of baryta-water on caffeine, was regarded by Schultzen, who discovered it, as different both from sarcosine and from alanine, inasmuch as it did not appear to form double salts with auric chloride or platinum chloride (1st *Suppl.* 383). Rosengarten a. Strecker, however (*Ann. Ch. Pharm.* clvii. 1), have succeeded in preparing both the auro-chloride and the platinum-chloride of this base, and find that they are identical in composition and properties with the corresponding salts of sarcosine or methyl-glycocine, $CH^3(NHCH^3).COOH$. The base obtained from caffeine also dissolves cupric oxide on boiling, and the liquid on cooling yields well-defined rhombic crystals of the compound $(C^8H^7NO^2)_2Cu + H^2O$, identical with those obtained in like manner from sarcosine prepared from creatine (v. 107). Moreover, when its aqueous solution is mixed with cyanamide and a little ammonia, it is converted into creatine.

A further proof of the identity of this base with sarcosine is afforded by the fact, noticed by Schultzen, that when treated with nitrous acid it yields a nitroso-compound, the calcium salt of which is represented by the formula $[C^8H^7(NO)NO^2]Ca + H^2O$, inasmuch as compounds which contain the group NH^2 are usually converted by nitrous acid into oxy-compounds (e.g. alanine into lactic acid), whereas those which contain the methylamine residuum $NH(CH^3)$ yield nitroso-compounds; thus:—

The equation representing the decomposition of caffeine by baryta-water is

Creotino similarly treated yields sarcosine, carbon dioxide, and ammonia, but neither formic acid nor methylamine.

CAJUPUT OIL. The presence of copper in cajuput oil was first observed by Guibourt, who found, on examination of a certain specimen, as much as 0.0274 p.c. (1st *Suppl.* 710); at the present day, however, the actual occurrence of copper in well-authenticated samples has been much doubted, more especially since the investigations of later chemists, have, as a rule, failed to corroborate the experiments of Guibourt. On the other hand, E. Histed, having carefully examined numerous specimens of cajuput oil from various commercial sources, has obtained in every instance abundant indications of the presence of copper. He finds, moreover, that cajuput oil, though naturally possessing a green colour, becomes perfectly colourless when redistilled. This colourless oil acts readily upon metallic copper, and in a few days re-acquires a green colour; the quantity of copper dissolved is, however, too small to render the oil unfit for medicinal use (*Pharm. J. Trans.* [3] ii. 804).

CALAMUS OIL. When the volatile oil obtained from the root of *Acorus Calamus* is submitted to fractional distillation, the boiling point rises from 140° to 280° , and the fraction passing over at 170° yields, on careful redistillation, a considerable quantity of product boiling at 158° – 159° . The oil thus obtained is a hydrocarbon (calamone) having the composition $C^{10}H^{16}$. It smells like turpentine, is transparent, soluble in alcohol and ether, and has a specific gravity of 0.8793 at 0° . It unites with hydrochloric acid, forming a crystalline mass which melts at about 65° .

The oils of higher boiling point yield by rectification a bluish liquid boiling at 250° – 255° . The colour disappears on boiling with sodium, and the hydrocarbon then boils at 255° – 258° . This hydrocarbon has also the composition $C^{10}H^{16}$; it dissolves slightly in alcohol, easily in ether, and does not combine with hydrochloric acid (Kurbatow, *Deut. Chem. Ges. Ber.* vi. 1210).

CALCEPAR. See CARBONATES, (p. 267).

CALCIUM CHLORIDE. *Supersaturated solution.*—A solution of 350–400 grams of crystallised calcium chloride in 50 c.c. of water, or of 200 grams of the anhydrous salt in 260 c.c. of water, prepared warm, may be shaken after cooling, either alone or with fragments of glass, without crystallising, but solidifies as soon as it is touched with a crystal of calcium chloride. The same solution when cooled to 5.8° begins to crystallise, the temperature then rising to 25° – 30° . A solution con-

taining 55 p.c. CaCl_2 deposits at about 15° large plates of $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$, which do not induce the crystallisation of the supernatant liquid. This solution in passing from the liquid to the solid state undergoes at 70° a contraction amounting to 0.0832 of its volume (E. Lefebvre, *Compt. rend.* lxx. 684).

CAMPHIC ACID. $\text{C}^{10}\text{H}^{16}\text{O}_2$.—An acid produced, together with borneol, by heating camphor with alcoholic potash in sealed tubes to 180° – 200° :

When separated by acids from the potassium salt, it forms a more or less coloured, nearly solid resin, and the solutions of its salts when evaporated leave only uncrystallisable syrups or amorphous masses (Berthelot, *Ann. Ch. Phys.* [3] lvi. 94). Wheeler (*Ann. Ch. Pharm.* cxlvi. 84) obtained the lead salt as a white insoluble powder which gave by analysis 38.77 p.c. lead, the formula $\text{Pb}(\text{C}^{10}\text{H}^{15}\text{O}_2)_2$ requiring 38.27 p.c. The *oxycamphor*, which Wheeler obtained by heating monochlorocamphor with alcoholic potash, has the same composition as camphic acid (1st Suppl. 387).

Kachler (*Ann. Ch. Pharm.* clxii. 268) denies the existence of camphic acid as a distinct compound. By boiling camphor ($\frac{1}{2}$ lb.) with alcoholic potash in a flask fitted with a condensing tube for 250 hours, treating the cooled mass with water, and straining the liquid through a cloth, he obtained a milky liquid containing potassium camphate and unaltered camphor; the latter was removed by ether, and a clear solution thereby obtained from which sulphuric acid threw down a flocculent resinous mass of crude camphic acid. This, when subjected to prolonged boiling with water, yielded a distillate containing campholic acid, and as residue, a hard, brittle, slightly acid resin, which, when heated with potassium hydrate, gave off a large quantity of camphor vapour, leaving a difficultly oxidisable residue. Hence Kachler concludes that the so-called camphic acid is nothing but a mixture of campholic acid with an acid resin, probably formed by condensation and oxidation of several molecules of camphor. To this Berthelot replies (*Bull. Soc. Chim.* [2] xvii. 390) that Kachler's failure in obtaining a definite product by the action of alcoholic potash on camphor probably arose from his having operated in an open vessel, whereas Berthelot himself obtained camphic acid by heating the materials in sealed tubes. J. Montgolfier (*ibid.* xviii. 114) heated some of the camphic acid prepared by Berthelot with water, without obtaining a trace of campholic acid; neither did the camphic acid when treated with nitric acid, yield any camphoric acid, as it should have done had it contained campholic acid. The question as to the existence of camphic acid as a definite compound must therefore be regarded as at present undecided. According to Montgolfier, camphic acid is almost insoluble in cold, slightly soluble in boiling water, and has a specific rotatory power of $+15.8^\circ$.

CAMPHOLIC ACID, $\text{C}^{10}\text{H}^{18}\text{O}_2$. This monobasic acid, originally obtained by Delalande by passing camphor-vapour over red-hot potash-lime (1st Suppl. 728), is best prepared by Malin's process (1st Suppl. 386), namely by the action of potassium on a hot solution of camphor in petroleum boiling at about 130° . The potassium campholate thus produced yields, when decomposed by sulphuric acid, a quantity of campholic acid amounting to 20–22 p. c. of the camphor employed.

Campholic acid crystallises from ether-alcohol in soft nodular groups of irregular-shaped laminae. It is nearly insoluble in cold water, melts below the boiling point of water, then dissolves to a slight extent, and separates in crystalline flocks on cooling. It volatilises with vapour of water, becomes buttery at 80° , and melts in capillary tubes at 96° , (Delalande gives 80° as the melting point). Nitric acid converts it, first into camphoric, then into camphoronic acid:

and

With bromine and water, campholic acid yields, first camphoric acid, then bromo-camphoric anhydride, $\text{C}^{10}\text{H}^{14}\text{BrO}_2$, and lastly oxy-camphoric anhydride $\text{C}^{10}\text{H}^{12}\text{O}_4$ (p. 236). Phosphorus pentachloride converts it into campholic chloride $\text{C}^{10}\text{H}^{17}\text{OCl}$, which is an oil decomposed by water. The calcium salt when distilled yields campholene $\text{C}^{10}\text{H}^{16}$. The substance called *campholone* obtained by this process by Delalande, who assigned to it the formula $\text{C}^{10}\text{H}^{16}\text{O}$, was probably campholene mixed with some oxidised body (Kachler, *Ann. Ch. Pharm.* clxii. 259).

Most of the campholates are crystallisable. The potassium salt $\text{C}^{10}\text{H}^{17}\text{KO}_2$ and the sodium salt $\text{C}^{10}\text{H}^{17}\text{NaO}_2$ obtained by dissolving the acid in the dilute alkalis are precipitated, as flocculent or sandy crystalline powders, on mixing their mother-liquors.

dilute solutions with strong caustic alkali. The other salts are formed from the ammonium salt by double decomposition; the *barium, calcium, zinc, and magnesium salts* separate in microscopic needles; the *copper salt* as an amorphous light-green precipitate; the *silver salt*, $C^{10}H^{17}AgO_2$, as a white precipitate not much affected by exposure to light. Ethyl campholate is not formed by the action of hydrogen chloride on an alcoholic solution of the acid.

CAMPHOR, $C^{10}H^{16}O$. Artificial Formation. When cymene (prepared from turpentine-oil or from citrene) is oxidised with potassium chromate and sulphuric acid, in a flask provided with an upright condensing tube, a small quantity of a white crystalline substance sublimes in the tube, having the appearance, odour, and composition of ordinary camphor. The substance thus obtained was found to boil at 162° , common camphor boiling at 175° ; the difference was probably due to impurity, as the quantity of substance obtained was too small to admit of purification (Oppenheim, *Deut. Chem. Ges. Ber.* v. 631).

Action of Nitric Acid. When camphor is heated in a retort with nitric acid of sp. gr. 1.37, there is formed, besides camphoric and camphretic (camphoronic) acids, a volatile liquid which floats on top of the acid liquid condensed in the receiver. This substance is more or less decomposed by washing with water or by distillation, and can therefore be purified from absorbed nitrous vapours only by passing through it a stream of dry air or carbonic acid gas. It has the composition of a *nitrate of camphor* $2C^{10}H^{16}O.N^2O^2$, analogous to that of cinnamic aldehyde $2C^9H^8O.N^2O^2$. Water immediately decomposes it, forming camphor and nitric acid. Caustic potash, on the other hand, does not affect it (Kachler, *ibid.* iv. 380).

The mother-liquors obtained in the preparation of camphoric acid deposit, after long standing, a crystalline body, which by recrystallisation from water, is obtained in thin transparent rhombs having the composition of tetranitro-camphor $C^{10}H^{12}(NO^2)^4O$. It volatilises by slow evaporation, and explodes when quickly heated. It dissolves sparingly in cold water, easily in alcohol, ether, and ammonia, and forms with the latter a salt which is precipitated by lead acetate and silver nitrate (Schlebusch, *ibid.* iii. 591).

Action of Ammonium Sulphide.—Camphor heated for eight or ten hours to 130° with alcoholic ammonium sulphide, yields a product which crystallises from hot alcohol in feathery crystals and appears to have the composition $C^{10}H^{18}S$. (Schlebusch).

Constitution of Camphor and its Derivatives.

As camphor, by abstraction of water, yields a homologue of benzene, viz. cymene, it probably contains a 6-carbon nucleus to which the remaining four carbon-atoms are attached in lateral chains. V. Meyer, however (*Deut. Chem. Ges. Ber.* iii. 116), supposes that the carbon-atoms in this nucleus do not form a closed chain, and that in the oxidation of camphor it is not the lateral chains which are attacked (as in that case hydrogen would be removed); but that the oxidation appears to be wholly confined to two of the six carbon-atoms of the nucleus. Moreover, he considers that the carbon-atoms which yield carboxyl by oxidation, cannot be attached to the same carbon-atom of the camphor-molecule, as in that case the camphor could not be converted by dehydration into a homologue of benzene. On this view then, there remain only three formulæ by which the constitution of camphor may be expressed:

The nucleus C^6H^{14} (which includes the 4 carbon-atoms present as lateral chains) is in these formulæ quadrivalent; in camphoric acid, on the other hand, it is bivalent, two of its units of affinity neutralising one another (*vid. infra*).

The first of these formulæ represents camphor as an aldehyde, which is the view proposed some time ago by Berthelot; but as Tollens and Fittig have shown that it does not exhibit any of the properties of an aldehyde (*1st Suppl.* 386) this formulæ must be rejected. According to the second formula, camphor contains the group OH, and should therefore exhibit alcoholic characters. It differs, however, from the alcohols by its complete indifference to acids; indeed Berthelot has shown that it may be separated from borneol, which is a decided alcohol, by its indifference to stearic acid and other acids. Moreover, it is not altered in the slightest degree by prolonged heating with acetyl chloride, and when its alcoholic solution saturated with hydrogen

chloride is left for weeks in sealed tubes, not a trace of ethylated camphor is produced. From these results it may be inferred that camphor does not contain the group OH, and therefore that it cannot be represented by the second of the above formulae.

There remains then only the third formula $O \begin{array}{c} \diagup CH \\ || C^6H^{14} \\ \diagdown CH \end{array}$ as the representative of its

constitution. The constitution of the nucleus C^6H^{14} may be inferred from that of cymene, which, according to the experiments of Fittig, Köbsch and Jilke, has the constitution of methyl-propyl- (or isopropyl-) benzene (1st Suppl. 302). This hydrocarbon, together with camphor and camphoric acid, may accordingly be represented by the following formulae:

Borneol and campholic acid may be represented by the following formulae:

Hlasiwetz (*ibid.* 539) agrees with Meyer as to the position of the oxygen-atom in camphor, but represents the group $C^{10}H^{16}$ in a different manner, thus:

On the other hand, Kachler (*Ann. Ch. Pharm.* clxix. 185) regards camphor as a ketonic body, containing the group CO and formed on the closed ring of the benzene nucleus. The ketonic character is inferred from its conversion into borneol $C^{10}H^{16}O$, by the action of nascent hydrogen, which is similar to that of acetone into isopropyl alcohol, and by its reaction with bromine, chlorine, phosphorus pentachloride, and hydriodic acid, which are exactly analogous to those of acetone.

Kachler represents camphor and camphoric acid by the following formulae, the formation of the latter by oxidation of camphor being supposed to consist in the conversion of the group CO into COOH and of the propyl group C^3H^7 into C^3H^7COOH :

Wredon (*Deut. Chem. Ges. Ber.* v. 1106) finds that the hydrocarbon C^8H^{14} obtained from camphoric acid is converted by fuming nitric acid into trinitro-isoxylene; whence it would appear that camphoric acid is tetrahydro-isoxylene-bicarbonic acid:

Borneol is related to camphor in the same manner as isopropyl alcohol to acetone; and campholic acid may be represented as the mono-carbonic acid of a propyl-hexylene.

CAMPHORIC ACID, $C^{10}H^{16}O^4 = C^8H^{14} \begin{Bmatrix} COOH \\ COOH \end{Bmatrix}$ Wredon (*Ann. Ch. Pharm.*

clxiii. 323) prepares this acid by dissolving 160 grams of camphor in 2 litres of nitric acid, sp. gr. 1.27 (2 vols. of the strong commercial acid to 1 vol. of water) and heats the solution for 50 hours in a large flask standing in a water-bath and having cemented to its mouth a long condensing tube, bent at right angles and leading into the chimney. Camphor thus treated yields more than half its weight of purified camphoric acid.

Camphoric acid melts at 174° – 176° , not 60° and 70° , as commonly stated (V. Moyer, *Deut. Chem. Ges. Ber.* iii. 116).

Camphoric acid heated with hydriodic acid (sp. gr. 1.7) to 200° for not more than eight hours—the gases formed (CO and CO_2) being allowed to escape from time to time—yields a heavy iodised oil of variable boiling point, from which, by distillation over quicklime and subsequent treatment with sodium, the hydrocarbon C^8H^{14} is obtained. The decomposition is represented by the equation:

By further heating the iodised oil ($C^8H^{14}.HI?$) with hydriodic acid to 200° for nine hours, the hydrocarbon C^8H^{14} is produced (Wredon, *Zeitschr. f. Chem.* [2] vii. 120).

Camphoric acid distilled with excess of lime, splits up into water and camphoric anhydride $C^{10}H^{14}O^3$, which at a higher temperature is further decomposed by the lime yielding phorone:

Cupric camphorate when strongly heated gives off carbon dioxide and the hydrocarbon C^8H^{14} , as first observed by Moitissier (*Jahresb.* 1866, 428):

(V. Moyer, *Zeitschr. f. Chem.* iii. 498).

Meso-camphoric acid. Camphoric acid has hitherto been known in four isomeric modifications: viz. dextro-camphoric acid (the ordinary acid); levo-camphoric acid, an optically inactive acid (para-camphoric acid) obtained by mixing equivalent quantities of these two active acids; and an insoluble modification, also optically inactive, which is formed by decomposing para-camphoric ether with boiling potash-ley (1st Suppl. 389).

A new inactive modification—meso-camphoric acid—related to dextro-camphoric acid in the same manner as meso-tartaric acid to dextro-tartaric acid—is formed by the regulated action of concentrated hydriodic or hydrochloric acid on the ordinary dextro-acid, e.g. when this acid is heated to 140° in portions of 5 grams each with 20 c.c. of fuming hydrochloric acid (at 200° the hydrocarbon C^8H^{14} is obtained).

Meso-camphoric acid crystallises from water in felted needles or nodules. It crystallises unaltered from solution in strong sulphuric acid, whereas ordinary camphoric acid is converted thereby into the anhydride. By prolonged action of sulphuric acid a sulpho-acid is formed exhibiting all the properties of Walter's sulpho-camphoric acid.

Meso-camphoric acid when heated yields a sublimate of camphoric anhydride. Its ammonium salt forms an amorphous transparent mass, the calcium salt has been obtained only in pellicles.

When meso-camphoric acid is repeatedly crystallised from water, or, better, from dilute alcohol, or when its aqueous solution is boiled for a fortnight with hydrochloric acid, it is converted into a new modification, having all the properties of common camphoric acid, with the exception of being inactive. By treating it with an excess of concentrated hydriodic acid, the hydrocarbons $C^{10}H^{14}$, $C^{10}H^{16}$, $C^{10}H^{18}$ are formed, (Wreden, *Zeitschr. f. Chem.* [2] vii. 419).

Substitution-products of Camphoric Anhydride $C^{10}H^{14}O^2$.

Bromo-camphoric Anhydride, $C^{10}H^{12}BrO^2$.—When 1 mol. bromine is heated with 1 mol. camphoric acid in presence of water to 170° and the mixture is left to cool, long prismatic crystals, probably having the composition $C^{10}H^{16}O^2Br^2$, are obtained, which when exposed to the air are slowly resolved into bromine and camphoric acid. In the absence of water the reaction takes a different course, bromocamphoric anhydride being formed:

To prepare this body, a mixture of 12 grams camphoric anhydride and 18 grams dry bromine is heated in a sealed tube for about three hours at 130° — 140° . The contents of the tube are then washed out with ether, and the white powder so obtained is re-crystallised from chloroform. It is less soluble in ether than camphoric anhydride; crystallises from strong boiling alcohol in small needles, but with partial decomposition. It dissolves undecomposed in 60 per cent. spirit at a temperature of 60° , and is readily soluble in chloroform, from which it may be obtained in transparent prismatic crystals. It blackens when heated to 100° , and is not attacked by phosphorus pentachloride under the ordinary atmospheric pressure. It does not exhibit the usual behaviour with water characteristic of anhydrides; for on treatment with water or alcohol, the bromine becomes replaced by the OH or OC^2H^5 group. More highly brominated products of camphoric anhydride have not been obtained (Wreden, *Ann. Ch. Pharm.* clixiii. 330; *Zeitschr. f. Chem.* [2] vii. 97).

Oxycamphoric Anhydride, $C^{10}H^{14}O^4 = C^{10}H^{12}(OH)O^2$ (also called *Camphanic acid*) is prepared by heating bromocamphoric anhydride with water in a flask connected with an inverted condenser. If the bromanhydride contains camphoric anhydride, the product will also contain camphoric acid. To remove this, it is converted into the lead salt, whereupon insoluble lead camphorate is formed, which may be filtered off, and the oxyacid then set free by sulphuric acid (Wreden). It is also produced by the action of bromine and water on campholic acid (Kuchler, *ibid.* lxxii. 264):

Oxycamphoric anhydride melts at 201° , and if heated for some time at 200° begins to decompose; it is soluble in ether and alcohol, also in water, but in this case it first melts; it also separates as an oil on cooling from a hot saturated aqueous solution. It crystallises with one or two molecules of water, but becomes anhydrous on standing over sulphuric acid in a vacuum.

Oxycamphoric anhydride forms salts, all of which with the exception of the sodium salt, are crystalline and soluble in water. The lead salt is difficultly soluble even in boiling water; the barium and silver salts decompose when heated with water; a volatile oil escapes while barium carbonate or silver remains. The cadmium salt, $Cd(C^{10}H^{12}O^4)^2 + 3aq.$, crystallises in transparent prisms which lose their water at 100° . The ether $C^{10}H^{12}(C^2H^5O)^2$, produced by passing hydrochloric acid gas into a solution of oxycamphoric anhydride in absolute alcohol, or by heating bromocamphoric anhydride with alcohol to 150° in sealed tubes, forms prismatic needles, which melt at 63° and sublime below 100° ; it dissolves readily in alcohol, ether, chloroform, and carbon sulphide, slightly in boiling water, which is without action on it. It is saponified by heating with potash-solution.

Phosphorus pentachloride converts oxycamphoric anhydride into the corresponding chloranhydride from which water regenerates oxycamphoric anhydride.

On heating the calcium salt of oxycamphoric anhydride, an oil is obtained, which

after heating with sodium in a sealed tube to 100° , boils at 118° — 120° , has the composition C^6H^{10} , and the vapour-density 3.75 (calculated 3.8):

The same body is formed by heating oxycamphoric anhydride with water to 180° , carbonic anhydride and carbonic oxide being evolved; probably also by heating the anhydride to 150° with strong hydriodic acid (Wreden).

It will be seen from the results above described that oxycamphoric anhydride exhibits the characters of an acid, hence the name *camphonic acid*; it is the first representative of a new class of acids not containing carboxyl (Wreden, *loc. cit.*).

Amidecamphoric Anhydride and acid, $C^6H^{10}(NH^2)O^3$, is formed by dissolving bromocamphoric anhydride, $C^6H^{10}BrO^3$, in aqueous ammonia at 150° . It crystallises in needles, is sparingly soluble in boiling water and cold alcohol, but dissolves readily in boiling alcohol. When heated it begins to sublime at 150° , and melts at 208° . Nitrous acid converts it into oxycamphoric anhydride, $C^6H^{10}(HO)O^3$. The same compound is formed by boiling it with concentrated alkalis, whilst dilute alkalis produce *amidecamphoric acid*, $C^6H^{10}(NH^2)O^4 + H^2O$, which is more soluble in alcohol than the anhydride, and crystallises in small shining prisms. It loses its water at 85° , and between 85° — 160° is changed into the anhydride, which is also formed by the action of nitrous, or of concentrated hydrochloric and sulphuric acids. The *calcium salt* $Ca(C^6H^{10}NH^2O^4)^2 + 2H^2O$ forms transparent prisms, and dissolves readily in water; a normal calcium salt could not be obtained. The *copper salt* crystallises from water in blue shining needles; the *cadmium salt* in iridescent pellicles.

CAMPHORONIC ACID, $C^6H^{10}O^3$ (Kachler, *Ann. Ch. Pharm.* clix. 281). This acid is formed, together with camphoric acid, by the action of nitric acid on camphor. The syrupy concentrated mother-liquor from which the camphoric acid has separated deposits crystals, after standing for some months, the mass finally becoming semi-solid; and, on subjecting this mass to strong pressure, and recrystallising the solid portion from water, after decoloration with animal charcoal, camphoronic acid is obtained in minute pearly crystals, very soluble in water, alcohol and ether, but almost insoluble in benzene and carbon sulphide. The aqueous solution has an acid taste and reaction and decomposes carbonates, forming two classes of salts, in which 2 and 3 atoms of hydrogen are replaced by metals. The acid itself, when air-dry, has the composition $C^6H^{10}O^3$ or $C^6H^{10}O^4.H^2O$. It does not give off water at 100° , but when heated to 110° it begins to fuse and loses water, giving an anhydrous compound which melts at 115° , and distils unaltered at a slightly higher temperature; both the distilled product and the substance melting at 115° have the composition $C^6H^{10}O^3$.

Camphoronic acid is not precipitated in the cold by any metallic salt, except lead-salts, which give a white precipitate. On heating it with solution of *cupric acetate*, a copious light green precipitate is formed, which redissolves completely as the liquid cools.

The *bibasic ammonium salt* gives off both water and ammonia at 100° ; dried *in vacuo* it contains $C^6H^{10}(NH^2)O^3 + H^2O$. The *bibasic barium* and *zinc salts* are obtained by treating the acid with the carbonates of these metals; dried at 170° they contain $C^6H^{10}BaO^3$ and $C^6H^{10}ZnO^3 + H^2O$, the latter not losing its water even at 200° .

By boiling a solution of the acid saturated with ammonia with *barium chloride*, an insoluble sandy crystalline powder is precipitated which will bear washing with water; this is a tribasic salt, and has the composition $Ba^2(C^6H^{10}O^3)^2 + 2H^2O$, the water of crystallisation being lost at 185° ; the formation of this sandy precipitate on boiling serves as a qualitative test for the acid, and also as a means of preparing the pure acid from the syrupy mother-liquors in the first instance, by decomposition of the salt with dilute sulphuric acid and exhaustion with ether.

A *tricalcio salt* $Ca^3(C^6H^{10}O^3)^2 + 4H^2O$ is obtained in needle-shaped crystals by saturating the acid with calcium carbonate.

A *tricupric salt* is formed, as above mentioned, by heating the solution of camphoronic acid with cupric oxide, and separates as a light green powder, which redissolves on cooling, but may be washed with hot water; its composition is $Cu^3(C^6H^{10}O^3)^2 + 4H^2O$. The liquid filtered from this and concentrated, deposits after some time a bluish green salt of darker colour than the preceding, and having, when dried, the composition $Cu^3(C^6H^{10}O^3)^2 + 2H^2O$.

The *lead* and *silver salts*, which are obtained by precipitation, the latter from the ammonium salt, are decomposed by washing; the silver salt appears to be tribasic. The *potassium* and *sodium salts* are extremely soluble, and have not been obtained in definite forms.

An alcoholic solution of camphoronic acid saturated with gaseous hydrogen chloride,

deposits an oil which yields by distillation, a *mono-ethylic ether* $C^6H^{11}(C^2H^5)O^2$, boiling at 302° .

The calcium salt, mixed with quicklime and distilled, gives a thick product, from which, by rectification, a clear and perfectly volatile substance $C^6H^{12}O$, may be isolated, formed by the reaction, $C^6H^{12}O^2 = 2CO^2 + C^6H^{12}O$. This formula requires a vapour-density = 3.86; the numbers found in two determinations were 3.69 and 3.74.

Camphoronic acid, heated with three times its weight of caustic potash, is completely decomposed; and by distillation of the product with dilute sulphuric acid, a distillate containing *butyric acid* is obtained, the reaction being, $C^6H^{12}O^2 + 12H + H^2O = 2C^4H^8O^2 + CO^2$.

Camphoronic acid is a product of the oxidation of camphoric acid, and is always formed when the latter is boiled with nitric acid till camphoric acid no longer crystallises out on cooling. If the liquid be then evaporated, an acid syrup is obtained, exhibiting all the properties of Schwannert's camphrotic acid (1st Suppl. 390). The acid so called appears, however, to be nothing but a mixture of camphoronic and camphoric acids, the former of which may be separated as a barium salt in the manner above described; and if the filtrate be then acidulated with sulphuric acid and agitated with ether, and the ethereal solution evaporated, a syrupy liquid resembling the so-called camphrotic acid is obtained, which, sometimes merely on standing, but more frequently after dilution with water, deposits crystals of camphoric acid. The mother-liquors, if again treated with ammonia and barium chloride, yield an additional quantity of camphoronic acid.

Oxycamphoronic acid $C^6H^{12}O^6$ is formed when a mixture of 1 mol. air-dried camphoric acid, $C^6H^{12}O^5.H^2O$, and 2 atoms of bromine is heated to 130° for two hours in sealed tubes: $C^6H^{12}O^5 + Br^2 = 2HBr + C^6H^{12}O^6$. On opening the tubes a large quantity of hydrogen bromide escapes, and a syrupy liquid is left, which dissolves almost wholly in water, forming a solution which, after concentration, deposits hydrated oxycamphoronic acid, $C^6H^{12}O^6.H^2O$, in large crystals which give off their water at 100° .

The crystals, which are obtained particularly large and fine by redissolving the acid in water, decolorising the solution with animal charcoal, and leaving it to evaporate over sulphuric acid, are monoclinic, having their axes $a : b : c = 1.4918 : 1 : 0.98075$, and the angle $ac = 86.50$. Observed faces $\infty P \infty . 0P . +P \infty . \alpha P . (\infty P \infty) . -\frac{1}{2}P \infty$.

Oxycamphoronic acid has a pure and pleasant sour taste: it dissolves easily in water, alcohol, and ether. The dehydrated acid begins to melt at 210° , solidifies in the crystalline form on cooling, and may be distilled without alteration. It is a strong acid, decomposing carbonates with facility, and forming salts in which 2 or 3 atoms of hydrogen are replaced by metals. Like camphoronic acid, it is not directly precipitated by any metallic salts, excepting basic lead acetate. It does not exhibit the reaction of camphoronic acid with cupric acetate, but behaves in a similar manner to that acid, when its solution saturated with ammonia is heated with barium chloride, excepting that the precipitated barium salt is bibasic instead of tribasic, as in the case of camphoronic acid.

An *acid potassium salt* $C^6H^{11}KO^4 + H^2O$ is obtained in small shining crystals by saturating the half of a solution of the acid with potassium carbonate, then adding the other half, and concentrating. The *neutral salt* $C^6H^{10}K^2O^6$, obtained by complete saturation, dries up in a vacuum to a gummy very hygroscopic mass. The *barium salt* $C^6H^{10}BaO^6$, prepared as above, forms nacreous laminae. The *calcium salt* $C^6H^{10}CaO^6$ dries up in a vacuum to a fissured mass which may be triturated to a chalky powder. The *lead salt* formed by precipitation has, when dried at 120° , the composition $Pb(C^6H^9O^6)^2 + 2H^2O$; it is the only trimetallic oxycamphoronate yet obtained. The *silver salt* $C^6H^{10}Ag^2O^6$ is obtained by precipitation in white flocks; it is moderately soluble in water, and decomposes partially during washing and drying.

Oxycamphoronic acid is not formed from anhydrous camphoronic acid by the action of bromine; neither is any bromine substitution-compound obtainable from either acid. Fused caustic potash acts on both acids alike; both are but little attacked by nitric acid, and are unaltered by treatment with sodium-amalgam.

CAMPHERENE.—This name was given by Schwannert to a product isomeric with phorone, $C^6H^{14}O$, which he obtained by the action of sulphuric acid upon camphor (1st Suppl. 290). According to Kachler, however (*Ann. Ch. Pharm.* cxlvi. 79), the substance thus obtained is not a definite compound, but a mixture of phorone with a hydrocarbon which raises its boiling point to 230° – 235° (pure phorone from camphoric acid boiling at 208°). Camphrene prepared according to Schwannert's directions gave by analysis 1 p.c. less carbon than that required by the formula $C^6H^{14}O$, and was resolved by fractional distillation into a portion boiling at a considerably lower temperature.

perature, and a liquid which boiled at 242° – 247° , and contained only 6.9 p.c. oxygen, instead of 11.59 as required by the same formula. By oxidation with chromic acid mixture the camphrene prepared as above yielded acetic and adipic acids—which acids are likewise obtained by oxidation of phorone from camphoric acid—together with a crystalline acid having the composition $C^{12}H^{10}O^4$ —apparently identical with Schwanert's camphrenic acid—and exhibiting all the properties of Hofmann's insolinic acid (v. 725), of the acid which Hirzel a. Beilstein obtained by oxidation of xylic acid, and therefore having the formula $C^8H^4(CH^3) \begin{cases} COOH \\ COOH \end{cases}$, and of the xylidic acid of Fittig a. Laubinger.

Hence it appears probable that these several products are one and the same homologue of terephthalic acid, and that Schwanert's camphrenic acid is produced by oxidation, not of phorone, but of the hydrocarbon with which the phorone is mixed in the so-called camphrene.

Schwanert obtained from his camphrene, by the action of phosphoric anhydride, a hydrocarbon $C^{12}H^{12}$ which boiled at 170° – 175° , and was therefore regarded by him as only isomeric with cumene, which boils at 150° – 160° . As, however, Schwanert's analysis of this hydrocarbon exhibits a deficiency of 1 to 1.5 p.c. in the carbon, it is probable that this hydrocarbon still contained a portion of the so-called camphrene, which would raise its boiling point.

Schwanert's camphrenic anhydride, which sublimed in white feathery crystals when camphrenic acid was heated to 250° , was perhaps benzoic acid, which, according to Hofmann, is produced, together with benzene and carbon dioxide, by distillation of insolinic acid.

CANDLE-NUTS.—These nuts, so called from their property of taking fire and burning with a bright flame, like ordinary candles, are the fruit of *Aleurites triloba*, Forst. (*A. Ambinua*, Pers.; *A. moluccana*, Willd; *Croton moluccanum*, Linn.); a shrub belonging to the order *Euphorbiaceæ*, tribe *Acalifæ*, indigenous in the Moluccas and in some of the islands of the Pacific. They are also known by the name of *Bancoul* nuts, and in Tahiti by that of *Tiili*.

The fruit of *Aleurites triloba* is formed of two large fleshy drupes, adhering laterally, and divided internally into two cells, each of which contains a single indehiscent seed of the size of a common nut, and is covered, especially in the furrows, with a thin whitish skin of earthy aspect, beneath which is the husk, of blackish colour, and very hard. The almond is white, and formed of a large oleaginous albumen, surrounding the homotropous embryo, which is provided with thin membranous cotyledons rather narrower than the albumen.

The seeds are usually sent to Europe deprived of their husks, which are used as fuel. The imperfect combustion of these husks serves in Tahiti for the preparation of a kind of lampblack, used by the natives in tattooing. In the same locality the bark of the shrub is used for the manufacture of various textile fabrics.

The fresh almonds have a not unpleasant taste, but are difficult to digest, and exert a purgative action even in moderate doses. In the islands of the Pacific they are eaten only after slight torrefaction, which renders them innocuous. They are, however, chiefly used by the natives for the extraction of oil for burning. The shelled almonds quickly turn rancid, acquiring a yellow-brown colour and a disagreeable taste. The fat extracted from them is subject to similar alterations. This fat is used in Europe solely for soap-making. The oil-cake forms an excellent manure.

The average weight of the husks is 6.5 grams; of the almonds, 3.3 grams.

Phosphoric anhydride	29.30	0.82

The fatty matter extracted from the almonds by carbon sulphide at ordinary temperatures forms a transparent, amber-yellow, syrupy liquid. When cooled to -10° it becomes viscous, but neither loses its transparency nor changes colour (Nallino, *Gazzetta chimica italiana*, ii. 257).

CAOUTCHOUC. The sulphur in vulcanised caoutchouc is easily oxidised by ozone. A. M. Wright (*Syll. Am. J.* [3] iv. 29) observed that the ebonite insulators belonging to Holtz's electrical machine, and the ebonite jackets of some induction-coils, became unusually hygroscopic soon after the instruments had been used for the production of ozone, to such an extent, indeed, that the accumulated liquid was sometimes so abundant as to trickle down in drops. An examination of this liquid showed that it contained a considerable amount of free sulphuric acid, the presence of which was attributed to the action of the ozone upon the sulphur of the vulcanised caoutchouc. Experiments were made which confirmed this supposition. Air, strongly ozonised, was passed through a vulcanised rubber tube, and then bubbled through water. In a short time the water acquired the odour of sulphurous acid, and ultimately gave a white precipitate with barium chloride.

In a similar manner a thin dry slip of ebonite placed in a small bottle into which ozone was driven became in a short time bedewed with moisture having an acid reaction, and exhibiting the same properties as that formed on the insulators of the machine. An attempt to oxidise free sulphur by means of ozone was unsuccessful.

The caoutchouc of Borneo yields a saccharine substance called bornesite, having the composition $C^4H^{14}O^6$ (p. 206).

CAPILLARITY. *Constants of Capillarity* (G. Quincke, *Pogg. Ann.* cxxiv. 356; cxxv. 621; cxxviii. 141; cxxix. 1). The great tenacity exhibited by fused substances, like glass or cement, which, while in the fused state, have been able to form a surface of equilibrium, leads to the idea that the phenomena of capillarity are developed not only in liquids, but likewise in solid bodies, the smallest particles of these bodies being indeed not absolutely fixed, but susceptible of a certain amount of displacement. Many phenomena may, according to Quincke, be explained on the assumption of a tension existing on the surface of solid bodies, whether this surface is free, that is, bounded by the air, or the surface of separation between the body in question and another body, solid or liquid. If the free surface of a body is the same as that of a liquid acted upon by the same external forces, this free surface must possess a certain degree of tenacity measured by the tension exerted on a linear unit of the surface. The tenacity of round metallic wires may therefore be expressed by two members, the first of which is proportional to the transverse section, the second to the periphery of the wire.

The law for the tenacity of metallic wires has also been deduced empirically from numerous experiments by Karmarsch (*Dingl. polyt. J.* cliv. 45), who represents the tenacity (in half-kilograms) by the formula,

$$\tau = a D^2 + b D$$

where D is the diameter of the wire in millimeters, and a and b are constants.

Quincke replaces this equation by the following:

$$t = \alpha \cdot 2\pi r + \beta \cdot \pi r^2$$

where t is the tenacity in grams, r the radius of the wire in millimeters, and α , β are constants related to a and b as follows:

$$\alpha = \frac{b}{\pi} 500; \quad \beta = a \cdot \frac{1}{\pi} 500$$

The quantity α , called the constant or coefficient of capillarity, denotes the weight in grams of the tension exerted on 1 mm. of the surface (periphery) of the wire; in other words, it is the measure of the surface-tension of the wire.

In liquids the same constant is the weight of the liquid column raised by capillarity in a tube of given diameter.

The following Table contains the results deduced from Karmarsch's experiments.

Capillarity-constants, α of Solid Metals.

	Hard-drawn	Annealed
	grams	grams
Iron	5731	1592
Platinum	3025	2388
Copper	2388	0
Silver	2388	478
Gold	1592	478
Zinc	557	—
Steel	6685	955
Nickel-silver	6685	1114
Silver	5253	2547
Gold (14 carats)	3661	2228
Brass (wire)	2547	1751
" (threads)	1751	687

The order of the metals in this table is the same as that which they assume when arranged with regard to their hardness, as determined by the experiments of Calvert & Johnson (*Phil. Mag.* [4] xvii. 114).

Capillarity-Constants of Fused Bodies.—To determine these constants, the noble metals, in the form of thin vertical wires, and glass in the form of threads, were melted in a flame of the lowest possible temperature, till the drop hanging to the end fell down. Neglecting the small weight of the fused mass remaining attached to the thin wire or thread, the weight W of the fallen drop is the greatest weight that the fused vertical mass is capable of sustaining. The constant of capillarity α of the fused metal is therefore determined by the relation,

$$W = \alpha \cdot 2\pi r$$

where $2r$ is the diameter of the wire in millimeters.

Base metals and other bodies, as zinc, tin and selenium, were fused in glass tubes, the funnel-shaped extremities of which were inserted into narrow vertical tubes. For easily oxidizable bodies, such as phosphorus, cadmium, lead, antimony and bismuth, the drops were formed (by means of a peculiar apparatus) in an atmosphere of carbonic anhydride. Sodium and potassium were made to drop into rock-oil; the number obtained for potassium is however regarded as uncertain.

The capillarity-constants of gold, cast iron, silver and copper were determined by another method, which will be described hereafter.

The capillarity-constants of salts were estimated by fusing beads of them on a horizontal platinum wire of known diameter, and adding or removing portions of the salt by means of another thin platinum wire, till the quantity of salt was found which would just hang, or just drop, from the end of the wire when placed vertically. The falling drops were received on platinum foil and weighed, hygroscopic salts between watch-glasses.

The capillary coefficients of water, mercury and bromine were determined by the more exact method of measuring the heights of these liquids in capillary tubes. That of sulphur is calculated from the experiments of Frankenheim (*Jahresb. f. Chem.* 1847-48, 4); that of wax from the experiments of Wertheim (*Zamminer's Jahresb. f. Phys.* 1857, 5).

The mean values of the several capillarity-constants are given in the following table, the substances being arranged in the order of magnitude of these constants. The values of $\alpha^2 = \frac{2\alpha}{\sigma}$ and of α are also given, σ being the specific gravity of the fused body. The specific gravities σ_0 at 0° were determined directly, excepting in the case marked with asterisks, and thence the specific gravities for the melting points were calculated. These calculations are, however, liable to some uncertainty, for want of exact data as to the coefficient of expansion, the melting point, and the expansion or contraction which takes place in fusion:—

In another series of experiments (*Pogg. Ann.* cxxxviii. 141) Quincke has determined the capillarity-constants of salts by a method which he regards as more exact, especially in the case of compounds which are liable to be decomposed by contact with flame-gases. The substance, melted in a platinum crucible, was poured on a horizontal plate of platinum or porcelain, where it usually formed a drop having its upper surface

FIG. 7.

horizontal; and it is shown, by a process of mathematical analysis for which we must refer to the original paper, that the square of the vertical distance between this upper surface and the vertical element of the meridional curve of the drop (Kk , in fig. 7) is equal to the constant α^2 in the preceding table (called the *specific cohesion* of the liquid), which, when multiplied into half the specific gravity, gives the capillarity-constant α (the superficial tension). This relation is altogether independent of the nature of the surface on which the drop is poured.

The specific gravities at the melting points were determined by the loss of weight which a platinum ball weighing 1.8 gram, fused before the oxy-hydrogen blow-pipe, sustained when thrown into water or into the fused substance; these determinations are all too small, as the temperatures were above the melting point. Under σ_0 are given the specific gravities determined at ordinary temperatures by other observers. The numbers for certain sugars and fats are also given.

The most important result deducible from this and the preceding table is that the values of the constants α^2 for metals and other substances may be arranged in groups of nearly equal magnitude, the numbers in which are entire multiples of 4·3. Hence it follows that when different substances in the melted state, and at temperatures a little above their respective melting points, are dropped from tubes of the same diameter, the volumes of the drops are to one another as the numbers 1, 2, 3, &c.; or more generally, that the specific cohesions of all fused bodies at temperatures near their melting points are to one another nearly as the numbers 1, 2, 3, &c.

The second table shows that fused bodies of similar chemical composition have, at temperatures near their melting points, nearly the same specific cohesion α^2 . Water, carbonates and sulphates (probably also phosphates), in the fused state have a specific cohesion twice as great as that of mercury; nitrates, chlorides, sugars and fats, the same; bromides and iodides half as great specific cohesion as mercury. Among the metals, lead, bismuth, and antimony have the same specific cohesion as mercury; platinum, gold, silver, cadmium, tin and copper, twice as great; zinc, iron, palladium, three times as great; sodium six times as great a specific cohesion as mercury. From experiments with borax in the oxidising blowpipe-flame, according to the first method, Quinke believes also that this body should also be included in the mercury group.

Capillarity of Saline Solutions.—Buliginisky (*Pogg. Ann.* cxxxiv. 440) has determined the capillarity-constants of saline solutions at different degrees of concentration, by measuring the height to which the several solutions are raised in capillary tubes at different temperatures. For the description of the apparatus used and the method of observing, we must refer to the original memoir. In the case of potassium nitrate observations on solutions of four different strengths were made in three groups: the first at temperatures varying from 9° to 12°; the second from 15° to 18°; the third from 22·5° to 24·5°. By comparison of these observations, the differences of height in the columns corresponding to the degree of temperature were determined, and by means of those differences the observed heights of the columns were reduced to the standard temperature of 15°. The mean of all the heights for each solution (for which the observed heights reduced as above deviated but little) was then calculated proportionally to the capillary height of water = 100; and by multiplying the values thus determined into the corresponding densities of the solutions, and reducing these products to water = 100, the capillarity-constants were determined, as in the following Table:—

CAPILLARITY.

Capillarity-Constants of Saline Solution.

	Potassium Nitrate in 100 parts by weight of solution	Density at 15° referred to water at 4°	Mean Capillary Height	Capillarity-Constant
Distilled water . . .	—	0.99918	100.00	100.00
Solution I.	4.630	1.0270	98.00	100.73
Solution II.	7.572	1.0465	96.69	101.27
Solution III.	10.405	1.0657	95.33	101.68
Solution IV.	13.218	1.0862	93.98	102.17

If G denote the capillarity-constant of a solution, A that of distilled water; g the weight of the salt in 1 gram of the solution; p that of water in 1 gram of the solution; and k a coefficient to be determined from the observations, the connection between the observed capillarity-constants appears to be expressed with sufficient approximation by the formula:

$$G = A(p + qk.)$$

Thus for $k = 1.1628$, we have the following values:

calculated:	100.00	100.75	101.23	101.69	102.15
observed:	100.00	100.73	100.27	101.68	102.17

Experiments with aqueous solutions of ammonium chloride of four different strengths, made at temperatures varying from 15.0° to 16.6° gave results, from which, by calculating as above, the following values were obtained:—

	Ammonium Chloride in 100 parts by weight of solution	Density at 15° referred to water at 4°	Mean Capillary Height	Mean Temperature	Capillarity-Constant
Distilled water . . .	0	0.99918	100.00	16.0	100.00
Solution I.	5.247	1.0156	100.41	16.3	102.06
Solution II.	13.645	1.0406	100.97	16.2	105.16
Solution III.	20.449	1.0587	101.86	16.6	107.93
Solution IV.	25.242	1.0721	102.57	16.0	110.06

It is remarkable that the heights of the columns for solutions of sal-ammoniac are greater than those for water, whereas comparative experiments with solutions of sugar, sodium chloride, ammonium iodide, potassium chloride, calcium chloride, magnesium chloride, and ammonia always gave heights smaller than for water.

Calculating the capillarity-constants of the preceding sal-ammoniac solutions according to the formula $G = A(p + qk)$ and making $k = 1.3895$, we find

calculated:	100.00	102.04	105.31	107.96	109.83
observed:	100.00	102.06	105.16	107.93	110.06

The relations between the capillarity and density of saline solutions have also been examined by C. A. Valson (*Compt. rend.* lxxiv. 103), whose method consists in determining the densities and the capillary heights in tubes of $\frac{1}{2}$ mm. diameter of a series of solutions containing equivalent quantities (in grams) of the salts in a litre of water: these he calls normal solutions:—

The results are given in the following Table, in which E denotes the equivalents of the several metals; H the capillary heights of the several solutions, at the temperature of 15°; D the density of the normal solutions at the same temperature; DH the products of the capillary heights into the densities, that is to say the capillary contents:

The product of the height and density is very nearly constant, and, with two or three exceptions, lies between the numbers 61.5 and 62.0. It follows therefore that the weight of a normal saline solution raised in a capillary tube of given diameter may be regarded as constant; for a tube of $\frac{1}{2}$ mm. diameter, this weight is 12.1 milligrams.

The numbers in the following table are also connected by the relation

$$H = 118.5 - 56.8 D,$$

which shows that in passing from one normal solution to another, the increase of capillary height is proportional to the diminution of the density.

In a previous series of experiments (*Compt. rend.* lxx. 1040) Valson examined

Relations between Capillarity and Density in Saline Solutions.

[illegible]

especially the increase or decrease produced in the height of the capillary column of a normal solution by a change in one or both of the radicles contained in it, and concluded that the capillary action of each metallic and each chlorous radicle is constant and independent of that with which it is associated; and consequently that when both radicles change together, the change in the height of the capillary column is equal to the sum of the changes which would be produced by a change in each radicle separately. The change in the height of the column of a standard solution (ammonium chloride) produced by the substitution of any other radicle for the basylous or chlorous element of that solution, is called the capillary modulus of the corresponding radicle. The following table contains the moduli of a number of radicles—for a tube 5 millimeters in diameter, and for a temperature of 15°.

Moduli of Capillarity.

Metallic Radicle	Modulus	Chlorous Radicle	Modulus
	mm.		mm.
Ammonium, NH^+	0.0	Chlorides (Cl^-)	0.0
Lithium	0.05	Carbonates (CO_3^-)	0.5
Sodium	1.2	Nitrates (NO_3^-)	1.0
Magnesium	1.4	Bicarbonates (C^2O_6^-)	1.1
Calcium	1.4	Sulphates (SO_4^-)	1.2
Potassium	1.5	Sulphites (SO_3^-)	1.3
Manganese	2.5	Thiosulphates (S^2O_3^-)	1.4
Iron	2.5	Bromides (Br^-)	2.1
Zinc	2.7	Iodides (I^-)	3.9
Copper	2.9		
Strontium	2.9		
Barium	3.9		
Cadmium	4.3		
Silver	5.5		
Lead	5.9		
Thallium	7.9		

To find, by means of this table, the capillary height of the normal solution of any salt, barium nitrate for example, in a tube of the diameter above mentioned, from the known height, (60.9 mm.) of that of a normal solution of ammonium chloride, we must subtract from this height the number 4.9, that is to say, the sum of the moduli of the two radicles of barium nitrate, the result being 5.6; direct observation gives 5.9.

The chlorides of lithium and ammonium are the only salts in the above table whose capillary height is greater than that of water.

Sphere of Action of the Molecular Forces of Capillarity (Quincke, *Pogg. Ann.* cxxviii. 402). The phenomena of capillarity are usually ascribed to molecular forces acting only at insensible distances. Nevertheless, it appears from the experiments of several observers (*Jahresb. f. Chem.* 1861, 2; 1862, 2; *Zamminer's Jahresb. f. Physik.* 1857, 5; *Pogg. Ann.* cxix. 199), that the capillarity-constant of a given liquid varies according to the curvature of the solid wall on which the elevation of the liquid is observed. This appears to be explicable only on the supposition that the greatest distance at which the molecular forces are still effective, or in other words, the so-called radius of the sphere of action, l , is not immeasurably small. Quincke has endeavoured to determine the magnitude, or rather the lower limit of the magnitude, of this radius by the following method. A plate of glass having a clean homogeneous surface is covered with a wedge-shaped layer of another substance, the thickness of which is very small at the edge of the wedge, and then gradually increases. Now when this wedge-shaped layer is brought in contact with a liquid which does not wet it, the angle at which the last element of the surface of the liquid cuts the solid wall will depend upon the mutual attractions of the particles of the solid wall and the liquid, and will become constant only where the thickness of the wedge-shaped layer is greater than that is to say, greater than the radius of the sphere of action, since at smaller thicknesses the underlying glass plate will act upon the particles of the liquid and modify the angle. The results obtained by this method are the following:

- $l > 0.000542$ mm. for Water, Silver, Glass.
- $= 0.000483$ mm. for Mercury, Silver sulphide, Glass.
- $= 0.000059$ mm. for Mercury, Silver iodide, Glass.
- < 0.000080 mm. for Mercury, Collodion, Glass.

According to these determinations, the radius of the sphere of action amounts to 50 millionths of a millimeter, which is about the tenth of the breadth of a medium light-wave, or more. Quincke is further of opinion that other molecular forces, as those which determine elasticity and the optical properties of bodies, are likewise effective at finite distances: a view which, if established, would considerably modify the prevailing theoretical views respecting these forces.

Surface-tension of Liquids, and Spreading of one Liquid on the Surface of another.

—The following propositions relating to the surface-tension of liquids have been deduced by Plateau (*Pogg. Ann.* cxli. 44), from a comparison of the results obtained by different observers: 1. Tension exists over the whole surface of a liquid, and therefore in every liquid film. 2. This tension is independent of the curvature of the surface or film; it is of the same magnitude throughout the surface or film, and the same at each point, in all tangential directions. 3. It is independent of the thickness of the film, so long at least as this thickness is not less than twice the radius of molecular attraction. 4. It varies according to the nature of the liquid. 5. In the same liquid it varies in inverse direction to the temperature; at ordinary temperatures however, the variation is but small.

The following proposition is regarded by Plateau as established by his own experiments. The superficial layer of a liquid possesses a peculiar viscosity independent of that of the interior of the mass: in certain liquids, as water, and especially in solution of saponin, this superficial tension is much stronger than the internal; in others, on the contrary, as turpentine, oil, and alcohol, it is weaker and often much weaker than the internal viscosity. In the formation and persistence of large films the part played by cohesion is as secondary as that of the internal viscosity.

On the Surface-tension of Liquids and the Formation of Drops, see also Duclaux (*Ann. Ch. Phys.* [4] xxi. 378; *Compt. rend.* lxx. 933; *Jahresb.* 1870, 31).

On Capillary Action in the Evolution of Gases, see J. C. d'Almeida (*Compt. rend.* lviii. 533; *Jahresb.* 1869, 37).

R. Ludtgo (*Pogg. Ann.* cxxxix. 620) has endeavoured to determine by experiment the limit up to which it is allowable to regard the tension of liquid films as independent of their thickness, and secondly in what manner beyond this limit, the tension is affected by the thickness of the film. He infers: 1. That a liquid film, immediately after its formation, has a thickness less than twice the radius of the sphere of action of the molecular forces (namely of a millimeter, according to Quincke), and consequently that the tension of a film is not constant, but a function of the thickness. 2. That the tension of a film increases as its thickness decreases. This second proposition is at variation with the results obtained by Monsbrugghe (*Pogg. Ann.* cxli. 608), who found that films of various thickness exhibited equal tensions, and that in the same film the greatest tension did not occur at the thinnest parts.

Ludtgo (*Pogg. Ann.* cxxvii. 362) has also made experiments on the spreading of one liquid on the surface of another, from which the following conclusions are deduced: 1. If a drop of one liquid spreads itself out on the surface of a second, the second never diffuses itself over the surface of the first. 2. If there be two liquids whose mutual adhesion is greater than the cohesion of the less coherent of the two, a drop of the less coherent liquid will spread itself out on the surface of the other. 3. On the contrary, a drop of the more coherent liquid placed on the surface of the less coherent retains its drop-like form, and becomes covered with a thin layer of the other liquid. 4. All liquids which satisfy the preceding condition as to the force of their mutual adhesion may therefore be arranged in a series, in which each liquid spreads itself out on the surface of the following one, never the contrary. 5. This series is the same as that which is obtained when the same liquids are arranged according to their constants of capillarity, beginning with the smallest, as in the following table:—

Ethyl Oxide	1.89	} Frankenheim	Glycerin	4	Plateau
Ethyl Acetate	2.292		Nitric acid	6.026	} Frankenheim
Alcohol	2.406		Sulphuric acid	6.623	
Benzene	2.78		Hydrochloric acid	7.026	
Turpentine-oil	2.78		Ammonia	—	
Plateau's Soap	2.8	Plateau	Cupric Sulphate	—	
Acetic acid	2.884	Bède	Water	7.58	Frankenheim
Poppy-oil	3.05	} Guthrie	Solution of Sal-ammoniac	—	
Carbon Sulphide	3.31		Solution of Ferric Chloride	—	
Potash solution	—				

6. The spreading takes place more distinctly in proportion as the two liquids are

less miscible and as the difference of their cohesion is greater. 7. The spreading of a liquid on its own surface may be produced by placing a drop raised to a higher temperature on the surface of the same liquid at a lower temperature. 8. The greater the cohesion of any liquid, the greater is the difficulty of keeping its surface clean. See also G. van der Mensbrugghe (*Pogg. Ann.* cxxviii. 323; *Jahresb.* 1869, 39).

The following propositions relating to the capillary phenomena developed at the surface of contact of two liquids are deduced from an elaborate series of experiments by Quincke (*Pogg. Ann.* cxxxix. 1-89):—1. At the common surface of two liquids, 1 and 2, a surface-tension is developed similar to that which exists at the free surface of a liquid bounded by the air. 2. The surface-tension or capillarity-constant $\alpha_{1,2}$ at the common boundary-surface of two liquids, multiplied into the sum of the reciprocals of the principal radii of curvature at any point of that surface, gives the capillary pressure in the direction of the normal to the surface at that point. 3. The magnitude of this capillarity-constant $\alpha_{1,2}$ cannot be directly determined from the capillarity-constants α_1 and α_2 of the free surfaces of the two liquids, but must be determined by special experiments. It may have all values between 0 and $\alpha_1 - \alpha_2$. If $\alpha_{1,2} = 0$, the liquids 1 and 2 are miscible in all proportions, and no drops or bubbles of either liquid can form within the mass of the other. For the rest, $\alpha_{1,2}$ appears to be smaller, the more miscible the liquids are, and always less than $\alpha_1 - \alpha_2$. 4. If three capillary surfaces meet in the same point, the dihedral angles formed by the intersection of the three surfaces are equal to the three external angles of a triangle whose sides are proportional to the capillarity-constants of the three surfaces. 5. A liquid 3 spreads out on the common surface of two liquids 1 and 2, whenever $\alpha_{1,2} < \alpha_{3,1} - \alpha_{2,3}$. 6. A liquid 2 spreads out on the free surface of a liquid 1, whenever $\alpha_{1,2} < \alpha_1 - \alpha_2$. 7. If liquids which are miscible in all proportions, so that $\alpha_{1,2} = 0$, be so arranged in a series that each successive liquid is capable of spreading on the surface of that which precedes it, the series thus obtained is identical with that on which the liquids are arranged according to the magnitudes of the capillarity-constants of their free surfaces. 8. If a lenticular drop of a liquid 2 remains on the free surface of a liquid 1, without spreading out, then certainly in most cases, and probably in all, the free surface of the liquid 1 is contaminated with a thin film of a foreign liquid 3. The action of this foreign liquid film increases with its thickness up to a certain limit, which is equal to twice the radius of the sphere of action. 9. If a liquid 2 spreads in a thin film on a flat drop of a liquid 1 in air, or on a flat air-bubble in the interior of the same liquid, the vertical distance $K-k$ (fig. 7, p. 244) between the horizontal and vertical portions of the capillary surface diminishes. The new form of the flat drops or bubbles may be calculated as soon as $\alpha_{1,2}$ and α_2 are known. 10. When a liquid 3 spreads out on the surface of a flat drop of a liquid 2 within a liquid 1, all that can be predicted is that the depth $K-k$ of the drop will diminish; the alteration of form in this case cannot always be determined by calculation. 11. The capillarity-constants of free liquid surfaces determined on flat drops or bubbles are larger than when they are calculated from the heights of the columns in fresh-drawn capillary tubes. The dihedral angle which a liquid makes with a clean glass surface is but rarely = 0. 12. When two liquids rest one above the other in a capillary tube, the weight of liquid raised above the general level depends upon the form of the free surface of the upper liquid v , and that of the contact-surface of the upper and lower liquids v and u . 13. The weight of liquid raised above the general level is never determined, as stated by Poisson, by the lower liquid alone; but in many cases when the two liquids are miscible in all proportions, it is determined by the upper liquid alone. 14. The mean height of the liquid v and u may be calculated from the values of the constants α_v and $\alpha_{v,u}$ measured as flat drops or bubbles when the dihedral angle made by the free surface and that of the contact-surface of the two liquids with the wall of the tube is known; this angle is only in a few cases equal to 0° or 180° . 15. Observations on the heights of liquid columns in capillary tubes, or on flat drops of a liquid, or on drops falling from vertical tubes into the air, are apt to give too small a value of the capillarity-constant, inasmuch as foreign bodies diffused through the air in the form of vapours condense on the curved capillary surface, and the resulting film of liquid spread out on that surface diminishes the superficial tension of the free surface. This source of error is greater at ordinary than at high temperatures, greater also in liquids with large than in those with small capillarity-constants, and explains the too small values of the capillarity-constants of certain liquids, as mercury and water found by former observers. 16. This condensation of vapours on the surface of liquids, exhibits the varying forms of lenticular water-drops on mercury and the so-called *Wasserbilder*.

The part played by capillarity in the diffusion of one liquid on the surface of another has also been studied by Du Bois-Reymond (*Pogg. Ann.* cxxxix. 262). When the free surface of a liquid A is covered with a thin layer of another liquid B—while

may either be totally different from the former, or a mixture of another substance with the liquid A, as when the vapours of certain liquids fall on the surface of certain others, or thirdly, a warmer film of the liquid A, brisk movements are often observed on the surface and in the interior of A, indicating that the superficial layer is striving, from some unknown cause, to extend in all directions the area of surface which it covers, and carrying with it centrifugally the covered liquid, wherever the two are in contact. The visible effect is, therefore, as if the covering liquid were actuated by a repulsive force tending to tear it asunder. The existence of such a force has been admitted by some observers, whereas others attribute the phenomena in question to capillarity or some similar force. Du Bois-Reymond regards these phenomena as due partly to capillarity, partly to manifestations of hitherto unknown forces, having their seat in sufficiently thin films of certain liquids. He points out that the meridian curve of a drop floating in equilibrium can have no point of contrary flexure either at its free or at its lower surface. The horizontal diameter of a drop of given small mass must therefore be greater as the angle at which its upper and lower surfaces meet is smaller. If this angle vanishes, the diameter of the drop becomes infinitely great, that is to say, the drop spreads itself out. He regards as vague and unsatisfactory the tension hypothesis, according to which the surface of a liquid is compared with a membrane tending to contract with a certain force depending on the nature of the liquid; and refers to the stationary diffusion of alcohol upon oil, observed simultaneously by himself and by Plateau, in which, notwithstanding the uniform centrifugal flow of the alcohol, the entire surface assumes a fixed form. Finally, he regards the existence of a repulsive force in thin films of certain liquids as established with a degree of probability equal to that which is attainable in the case of physical forces in general.

CAPRIC or RUTIC ACID, $C^{10}H^{20}O_2 = C^9H^{19}.COOH$ (F. Grimm, *Ann. Ch. Pharm.* clvii. 264). This acid has been found, together with caprylic acid, in the fusel-oil of Hungarian wines. The liquid, freed by distillation from water, ethyl alcohol and amyl alcohol, was boiled with strong caustic soda, and the lower layer containing the sodium salts of the fatty acids was treated with dilute sulphuric acid, whereby a brown disagreeably smelling oil was separated. This oil was dissolved in dilute ammonia; the liquid freed from an undissolved fatty substance was precipitated by barium chloride; and the precipitate was collected on a linen cloth and pressed between filter paper. To remove the fatty substance which still adhered to it, the barium salt was decomposed by hydrochloric acid, and the fatty acids were saponified with a dilute solution of sodium carbonate. After repeating this operation twice, a mixture of fatty acids was obtained, which solidified at $+20^\circ$. On distillation, it began to boil at 225° , the temperature rising gradually to 280° , when a thick brown residue was left in the retort. A small portion of the distillate was precipitated in fractions by a hot concentrated solution of caustic baryta. The analysis of the different fractions showed that the acids consisted chiefly of capric acid with a little caprylic and perhaps a small quantity of ananthylic acid. The same acids were found by Fischer in crude ananthic ether, excepting that he obtained more caprylic acid.

To obtain pure capric acid, the mixture of acids was subjected to fractional distillation, and the portion boiling above 260° pressed between filter-paper, first at a very low, and afterwards at the common temperature.

Pure capric acid melts at 30° to a clear oil, which begins to solidify again at 29.5° , and boils with partial decomposition at 268° – 270° .

Methyl caprate, $C^{10}H^{19}(OH)O_2$, was obtained by saturating a solution of the acid in methyl alcohol with dry hydrochloric acid gas. It is a colourless liquid, boiling at 222° – 225° , and having a pleasant fruit-like smell. **Ethyl caprate**, which has been prepared by Fischer and Rowney, boils at 243° .

Amyl caprate, $C^{10}H^{19}(C^5H^{11})O_2$, prepared by acting with hydrochloric acid on a solution of the acid in amyl alcohol, is a light colourless liquid, which has only a faint smell. The small quantity obtained distilled between 275° – 290° with partial decomposition. This ether is contained in large quantity in the Hungarian fusel-oil, which contains neither propyl nor butyl alcohol.

Capric chloride, $C^{10}H^{19}.OCl$, corresponding with the preceding acid, is best prepared by the action of phosphorus pentachloride on the acid. It has not however been obtained in the pure state, as it is decomposed by distillation and by contact with water. It is a heavy liquid, boiling at a temperature above 200° , and having a faint aromatic, not pungent odour.

The action of phosphorus pentachloride on the acid likewise gives rise to a small quantity of a white crystalline body, which is not acted upon by boiling water, by potash solution, and therefore does not appear to consist of capric anhydride (Grimm, *loc. cit.*).

The capric acid above described is doubtless identical with that which was obtained some years ago by Rowney from Scotch fusel-oil. It is probably an iso-acid.

Another modification, liquid even at low temperatures, has been prepared by Borodin (*Zeitschr. f. Chem.* vi. 416), by oxidation of the decyl alcohol $C^{10}H^{22}O$, which he obtained in 1864 by the action of sodium on valeral (v. 972). This alcohol, heated with a dilute mixture of potassium dichromate and sulphuric acid, is converted into capric aldehyde $C^{10}H^{20}O$, and capric acid, which may be separated by potash-ley, the acid alone dissolving therein; the aldehyde is also converted into the acid by further oxidation.

The capric acid precipitated from the potash-solution by hydrochloric acid may be freed from admixed lower homologues by converting into the calcium or cadmium salt, both of which are crystallisable. It boils at 241.5° , becomes a syrupy at -20° , but does not solidify even at -37° . It has a faint odour and a disagreeable rancid taste, is insoluble in water, but dissolves readily in alcohol and ether.

The potassium, sodium, and ammonium salts are obtained by neutralisation; the rest by precipitation. The *potassium salt* $K(C^{10}H^{19}O_2)$ is an amorphous very soluble mass, the concentrated aqueous solution of which is decomposed by water, with formation of an acid salt. The *sodium salt* $Na(C^{10}H^{19}O_2)$ is very much like the potassium salt. The *silver salt* $Ag(C^{10}H^{19}O_2)$ is a white precipitate somewhat soluble in hot alcohol, from which it separates in flocks on cooling. The *cadmium salt* $Cd(C^{10}H^{19}O_2)_2$ is also a white precipitate soluble in alcohol, from which it separates easily in needle-shaped crystals. The *calcium salt* $Ca(C^{10}H^{19}O_2)_2$ is a white precipitate sparingly soluble in water and in alcohol, easily in ether, from which it crystallises in needles. The *strontium salt* resembles the calcium salt; the *barium salt* is oily or waxy and seldom crystallises; the *magnesium salt* is soluble. The *zinc, manganese, iron, chromium, aluminium, cobalt, nickel, copper, mercury, and lead salts* are all insoluble or slightly soluble, glutinous precipitates.

Borodin regards this modification of capric acid as an amyliated valeric acid $C^{11}(C^{10}H^{19})_2COOH$.

CAPROIC ACID, $C^6H^{12}O_2$.—*Normal Caproic acid*, $(CH_2)^4CH^3.COOH$, is prepared by heating normal amyl cyanide $(CH_2)^4CH^3.CN$ with alcoholic potash, and decomposing the resulting potassium salt with sulphuric acid. The acid then separates as an oily layer, which may be purified by washing and distillation. It is a colourless liquid, which does not mix with water, has an odour fainter and somewhat less disagreeable than that of ordinary caproic acid, and a strongly acid taste. It boils at 204.5° – 205° (bar. at 0.7385 met.); ordinary caproic acid boils at 199.7° . Its specific gravity at different temperatures is as follows:—

Temperature . . .	0°	20°	40°	99.1°
Specific gravity . . .	0.9149	0.9294	0.9172	0.8947

(Lieben a. Rossi, *Gazzetta chimica italiana*, i. 314).

The following table exhibits the composition and solubility of the calcium and barium salts of this acid, and of ordinary caproic acid prepared from fermentation amyl alcohol, by converting it into the chloride, this into the cyanide, &c. The numbers denote the quantities of *anhydrous* salt dissolved in 100 parts of water at 185° :—

	Normal	Ordinary
Calcium Salts . . .	$Ca(C^6H^{11}O_2)_2 + H_2O$ 2.6676–2.707 parts at 18.5° ; a little more in boiling water.	$Ca(C^6H^{11}O_2)_2 + 3H_2O$ 4.4 parts at 18.5° ; more soluble in hot water.
Barium Salts . . .	$Ba(C^6H^{11}O_2)_2$ 8.496 parts at 18.5° ; much more soluble in hot water.	$Ba(C^6H^{11}O_2)_2 + 2H_2O$ 34.65 parts at 18.5° ; less soluble in hot water.

The normal barium salt contained a little water, probably hygroscopic.

Normal ethyl caproate, $C^6H^{13}.C^6H^{11}O_2$, prepared by treating 10 grams of the normal acid with 10 grams alcohol of 99 p.c. and 6 grams of sulphuric acid, boils at 166.5° under a pressure of 735.8 mm., and has a sp. gr. of 0.8898 at 0° , 0.8732 at 20° , 0.8594 at 40° .

Ordinary ethyl caproate, prepared in like manner, boils at 160.4° (corr.) under a pressure of 737 mm. and has a sp. gr. of 0.887 at 0° , 0.8705 at 20° , 0.8568 at 40° .

The *ordinary* caproic acid, from which the preceding compounds were prepared, and a very feeble optical rotatory power: hence the statements made respecting it are not

necessarily true for every specimen of caproic acid prepared from fermentation amyl alcohol (Lieben & Rossi, *Ann. Ch. Pharm.* clxv. 118).

Normal caproic acid is contained in the less volatile portions of the crude acid obtained by the butyric fermentation of sugar. A mixture of rice, malt, milk, chopped meat and chalk, left to ferment for several weeks, yielded a mixture of acetic, butyric, and caproic acids (no propionic or valeric acid). The portion which passed over on fractional distillation between 164° and 175° consisted of butyric and caproic acids, from which the former was removed by repeated washing with water. The caproic acid which remained boiled at 200° – 205° , yielded an anhydrous barium salt, 100 parts of a saturated solution of which at 21° – 22° contained 8.3 parts of salt, and a calcium salt, $\text{Ca}(\text{C}^6\text{H}^{11}\text{O}_2)^2 + \text{H}_2\text{O}$, containing in 100 parts of solution saturated at 21° – 22° , 4.4 parts of anhydrous salt (Grillone, *Ann. Ch. Pharm.* clxv. 127).

According to A. Freund (*J. p. Chem.* [2] iii. 224) ordinary caproic acid is formed, together with formic, acetic, and butyric acids (but no valeric acid), by the fermentation of wheat-bran in contact with leather-cuttings (the process recommended by Keller for the preparation of propionic acid).

This caproic acid added to a solution of cupric acetate throws down cupric caproate in bluish-green, heavy, oily drops, which after a short time become crystalline. The salt is nearly insoluble in water, and may therefore be readily obtained pure by washing; it is readily soluble in alcohol, and is obtained by spontaneous evaporation in small, dark green, anhydrous rhombohedrons (Freund).

Zinc caproate is formed in like manner by the action of caproic acid on zinc acetate, as a difficultly soluble crystalline precipitate, which redissolves partly on warming in the mother-liquor, and is deposited in small plates on cooling. The crystals separated from the mother-liquor are but slightly soluble in water, but readily soluble in warm alcohol, from which the salt separates in anhydrous crystalline needles having a mother-of-pearl lustre and a soapy feel. The formation of this salt may be employed as a method of distinguishing caproic acid from valeric and butyric acid, neither of which forms a precipitate when added to an aqueous solution of zinc acetate. The same salt is produced by acting on zinc oxide with an alcoholic solution of caproic acid (Freund).

CAPRONE or DINONYL KETONE, $\text{C}^{10}\text{H}^{20}\text{O} = \text{CO}(\text{C}^5\text{H}^{10})^2$, is obtained in large quantities by distilling the calcium salt of capric acid from Hungarian fusel-oil (p. 249). It crystallises in white pearly scales, which are insoluble in water, readily soluble in ether and boiling alcohol; it melts at 58° , solidifies again at 56° , and boils above 350° . It is not acted upon by a boiling mixture of 8 parts of potassium dichromate, 3 parts of sulphuric acid, and 10 parts of water; neither is it changed by dilute nitric acid; when it is heated with concentrated nitric acid, a violent action takes place, and, amongst other products, capric acid, and perhaps also caprylic acid, are formed (Grimm, *loc. cit.*).

CAPROONE or DIAMYL KETONE, $\text{C}^{11}\text{H}^{22}\text{O} = \text{CO}(\text{C}^5\text{H}^{11})^2$. E. Schmidt (*Deut. Chem. Ges. Ber.* v. 597) prepares this compound (and other ketones in like manner) by heating calcium caproate, mixed with chalk to prevent fusion, in a wide iron tube placed in a combustion furnace. After dehydration by calcium chloride and repeated fractional distillation, it has a sp. gr. of 0.822 at 20° , and boils at 220° – 221° (at 165° according to Brazier & Gosleth). Nitric acid acts violently on it, forming caproic and nitrovaleric acids:

Methyl-caproone, $\text{CO} \begin{smallmatrix} \text{CH}_3 \\ | \\ \text{C}^5\text{H}^{11} \end{smallmatrix}$, prepared in like manner by heating a mixture of the calcium salts of caproic and acetic acids, has a sp. gr. of 0.813 at 20° (0.828 at 0° according to Popoff), and boils at 155° – 156° (at 144° according to Popoff; at 152° , according to Schorlemmer's 'Lehrbuch'). With nitric acid it yields caproic and acetic acid, but no nitro-acid. With sodium bisulphite it forms an abundant crop of crystals (Schmidt).

CAPRYL CHLORIDE, $\text{C}^{10}\text{H}^{19}\text{OCl}$, see CAPRIC ACID, (p. 249).

CARBAMATES.—*Ammonium Carbamate*, $\text{CO}^*\text{N}^*\text{H}_4 = \text{NH}_4^+\text{COONH}_4^-$, splits up completely, when volatilised, into ammonia and carbon dioxide. A. Nauman (*Deut. Chem. Ges. Ber.* iv. 779), in five determinations of the vapour-density made with Hofmann's apparatus (1st Suppl. 1127), at temperatures ranging between 37° and 100° , obtained numbers between 0.855 and 0.891, the density calculated for $2\text{NH}_3 + \text{CO}_2$ (4 vols.) being 0.898. The apparatus has to be heated for an hour before the tension becomes constant, and at low temperatures the tension reaches its maximum with extreme slowness, both when the point of saturation has not been previously attained, and when it has been passed over by cooling, after long continued exposure of the

substance to a higher temperature. Bodies which volatilise without decomposition, as naphthalene and carbon sesquichloride, behave differently.

From a great number of experiments, the following Table has been calculated:—

Decomposition-Tensions of Ammonium Carbamate.

Temp.	Tension	Temp.	Tension	Temp.	Tension	Temp.	Tension
	mm.		mm.		mm.		mm.
—15°	2·8	10°	29·8	26°	97·5	42°	278
—10	4·8	12	34	28	110	44	316
—5	7·5	14	39	30	124	46	354
0	12·4	16	46·5	32	143	48	402
2	15·7	18	53·7	34	166	50	470
4	19	20	62·4	36	191	55	600
6	22	22	72	38	219	60	770
8	25·7	24	84·8	40	248		

This table shows that the decomposition-tension of ammonium carbamate increases by increase of temperature similarly to the tensions of other substances.

The time required for this decomposition depends partly on the quantity of undecomposed salt present, and becomes shorter the larger the surface of the latter. Both during decomposition and during reproduction, the tension increases or decreases more slowly, the nearer it comes to the point of equilibrium.

The long time required for the decomposition by heat, or for the reproduction, of this compound, shows that it is an atomic and not a molecular combination. In this respect it resembles formic metaldehyde, $C^2H^4O^2$, which, as Hofmann has shown, splits up when heated into three molecules of formic aldehyde CH^2O , this gas on cooling being slowly reconverted into the solid polymeric compound (Naumann, *Deut. Chem. Ges. Ber.* v. 815).

Benzyl Carbamate, $CO.NH^2.OC^2H^5$, is produced, together with benzyl chloride, by the action of cyanogen chloride, gaseous or solid, on benzyl alcohol. See BENZYL-COMPOUNDS (p. 178).

Phenyl Carbamate, $CO.NH^2.OC^6H^5$, is formed, together with ammonium chloride, by the action of dry ammonia gas on a solution of phenyl chlorocarbonate in absolute ether:

The solution filtered from the sal-ammoniac and left to evaporate, yields phenyl carbamate in beautiful laminae melting at 141° , soluble in alcohol and water, as well as in ether. When evaporated with strong soda-solution, it gives off a large quantity of ammonia, and forms sodium carbonate and sodium phenate. Heated to 140° – 150° with saturated aqueous ammonia, it forms phenol and urea:

(Kempf, *Deut. Chem. Ges. Ber.* iii. 253).

Ethyl Phenylcarbamate, **Ethyllic Carbanilate**, **Phenylcarbamie Ether**, or **Phenyl-urethane**, $C^6H^5NO^2 = CO \begin{Bmatrix} NH.C^2H^5 \\ OC^6H^5 \end{Bmatrix}$. This ether is formed when 1 mol. ethyl chlorocarbonate is allowed to flow upon 2 mol. aniline contained in a flask connected with an inverted condenser. The whole solidifies to a crystalline mass, which, when heated in a water-bath and freed from excess of aniline by washing it, first with water containing hydrochloric acid, and then several times with cold water, yields crystals of ethyl carbanilate:

The ether may be purified either by boiling it with a large quantity of water and filtering quickly, or better, by distilling it after drying. It is nearly insoluble in cold, somewhat soluble in boiling water, easily soluble in alcohol and ether; passes over abundantly with aqueous vapour; melts at 51° – 52° ; volatilises without decomposition, and boils at 237° – 238° . It is decomposed by baryta-water and hydriodic acid, and carbanilic acid cannot be prepared from it. It reacts like the urethanes and appears to be only isomeric with the ethylic ether of anthranilic or meta-amidobenzoic acid (obtained by the action of boiling potash on indigo, *1st Suppl.* 751), but probably identical.

with the body which Hofmann obtained in 1849 by the action of ethyl alcohol on phenyl cyanate or carbanil (ii. 197). When treated with potash-ley, it yields at first alcohol, carbon dioxide and aniline, the last of which acts further on the undecomposed ethyl carbanilate, converting it into diphenyl-urea, $\text{CON}^{\text{H}}\text{H}(\text{C}^6\text{H}_5)_2$. The diphenyl-urea obtained in this manner, or directly by heating ethyl carbanilate with aniline to 160° , differs from Hofmann's carbanilide (i. 756) only by boiling at 225° instead of 205° , and by its smaller solubility in alcohol. Ethyl carbanilate heated with ammonia yields aniline and urea (Wilm a. Wischin, *Chem. Soc. J.* [2] vi. 192).

H. Schiff (*Deut. Chem. Ges. Ber.* vi. 649) has obtained an ethyl carbanilate differing in properties from that above described, by the action of aniline on ethyl chlorocarbonate in ethereal solution. 1 part of ethyl chlorocarbonate dissolved in 10 to 15 times its volume of absolute ether was added by drops to 2 parts of aniline; the liquid filtered from the aniline hydrochloride and evaporated; and the residue washed, first with acidulated, then with pure water, dried over calcium chloride, again dissolved in ether, and evaporated.

The product thus obtained has the composition of ethyl carbanilate, but does not crystallise. It is not volatile without decomposition, but decomposes when heated above 200° , giving off vapour of ether, and between 230° and 235° a colourless liquid which begins to boil in the receiver, giving off ether-vapour and an odour of phenyl cyanate, and finally solidifying to a white crystalline mass. After some time more crystals are formed, the odour of phenyl cyanate is no longer emitted, and the mass, which then contains alcohol, may be freed from the uncrystallisable portion by treatment with ether or benzene.

The crystallised mass thus obtained contains three compounds which may be separated by means of alcohol; all three, when fused with potash, yield aniline and carbonic anhydride, and when fused alone, emit the odour of phenyl cyanate. These compounds are: 1. *Triphenyl Cyanurate*, $\text{C}^6\text{H}_5\text{N}(\text{OC}^6\text{H}_5)_3$; small colourless prisms, insoluble in water and in ether, nearly insoluble in cold, very slightly soluble in hot alcohol, moderately soluble in hot benzene and in the alcoholic solutions of the compounds 2 and 3. It melts at 214° – 216° (corr. 222°) and is identical with the compound which Hofmann obtained by heating ethyl carbanilate with phosphoric anhydride (*Deut. Chem. Ges. Ber.* iii. 765), and by the action of cyanogen chloride on potassium phenate (*ibid.* 269). 2. *Diphenyl-carbamide* or *Carbanilide*, $\text{N}^{\text{H}}\text{CO}(\text{C}^6\text{H}_5)_2$, identical with that obtained in various other ways (i. 756; 1st *Suppl.* 398). It forms long shining needles, melting at 200° – 203° , easily soluble in hot alcohol, more soluble in cold alcohol than the preceding compound. It forms the principal part of the product obtained by the decomposition of the carbanilic ether. 3. *Triphenyl-bisret*,

$\text{N} \begin{pmatrix} \text{CONHC}^6\text{H}_5 \\ \text{C}^6\text{H}_5 \\ \text{CONHO}^{\text{H}} \end{pmatrix}$. This constitutes the portion of the product easily soluble in alcohol;

it is best precipitated from the alcoholic solution by water, whereby an indistinctly crystalline mass is obtained which melts at 105° , and may be distilled but decomposes at the same time, yielding triphenyl cyanurate and diphenyl-carbamide.

Ethyl-aniline acts on ethyl chlorocarbonate less strongly than aniline, forming a compound which distils without decomposition between 245° and 250° (Schiff).

Ethyl Tolylocarbamate or Toly-urethane, $\text{CO} \begin{pmatrix} \text{NH.C}^6\text{H}_4 \\ \text{OC}^6\text{H}_5 \end{pmatrix}$, is obtained by the action of chlorocarbonic ether upon toluidine; the reaction is very violent, and is best conducted in presence of ether. The solution filtered from the toluidine hydrochloride and evaporated leaves the tolyl-urethane as an aromatic oil, which, when cooled by a freezing mixture, solidifies with difficulty. It is insoluble in water; crystallises from alcohol in long prisms melting at 32° . By distillation with phosphoric anhydride it yields tolyl isocyanate or tolyl-carbimide, $\text{N} \begin{pmatrix} \text{CO} \\ \text{C}^6\text{H}_4 \end{pmatrix}$ (Hofmann, *Proc. Roy. Soc.* xix. 108).

Ethyl Xylylocarbamate or Xylyl-urethane, $\text{CO} \begin{pmatrix} \text{NH.C}^6\text{H}_3 \\ \text{OC}^6\text{H}_5 \end{pmatrix}$, obtained in like manner from chlorocarbonic ether and toluidine, crystallises in slender needles melting at 65° (Hofmann).

Ethyl Naphthylcarbamate or Naphthyl-urethane, $\text{CO} \begin{pmatrix} \text{NH.O}^6\text{H} \\ \text{OC}^6\text{H}_5 \end{pmatrix}$, obtained by treating naphthylamine with chlorocarbonic ether, crystallises from alcohol in needles which melt at 79° (Hofmann).

CARBAZOL, $\text{C}^{12}\text{H}_8\text{N}$. (Graebe a. Glaser, *Deut. Chem. Ges. Ber.* v. 12; Graebe, *ibid.* 976, also *Ann. Ch. Pharm.* cxlii. 256, cxlvii. 126).—A compound obtained in the purification of crude anthracene on the large scale, under conditions not yet precisely

specified. For purification it is distilled once or twice, then dissolved, together with an equal weight of picric acid, in tar-oil of high boiling point. The solution on cooling deposits fine red crystals of a compound of carbazol and picric acid, which when treated with ammonia, yields the carbazol. It is also produced, together with hydrogen, ammonia and ammonium cyanide, by passing aniline-vapour through a porcelain tube heated to bright redness:

and more readily by decomposition of diphenylamine, $\text{C}^{12}\text{H}^{14}\text{N} = \text{C}^{12}\text{H}^{14}\text{N} + \text{H}^2$. Hence it may be supposed to have the composition of imido-diphenyl

$\begin{array}{c} \text{C}^6\text{H}^5 \\ | \\ \text{C}^6\text{H}^5 \end{array} \text{NH}$. Three determinations of its vapour-density (in sulphur-vapour) gave the numbers 5.97, 5.96 and 6.01, the calculated number for $\text{C}^{12}\text{H}^{14}\text{N}$ being 5.85.

By sublimation or crystallisation, carbazol is obtained in beautiful white laminae or tables. It is insoluble in water, but dissolves in alcohol, ether, and benzene, sparingly at ordinary, more freely at higher temperatures. It melts at 238° and boils at 338° . It is not decomposed by passing through a red-hot tube or by distillation over red-hot zinc-dust or soda-lime. It dissolves in cold sulphuric acid, ordinary or fuming, and separates out unaltered on addition of water; but when heated to 100° with ordinary sulphuric acid, it is converted into carbazol-disulphonic acid. Nitric acid, according to its degree of concentration, converts carbazol into a mono- or di-nitro-compound. Fuming nitric acid acts upon it with great violence. The same nitro-derivatives are formed by the action of nitrous acid on carbazol dissolved in alcohol. Carbazol is not decomposed by hydrochloric acid, by fusion with potassium hydrate, or by heating to 200° with alcoholic potash-solution. Neither is it reduced by sodium-amalgam in alcoholic solution, or by hydriodic acid at 200° , but when heated to 200° – 220° with strong hydriodic acid and amorphous phosphorus, it takes up 6 at. hydrogen and is converted into carbazoline. Carbazol is strongly attacked by oxidising agents; when dissolved in glacial acetic acid, it is readily oxidised by chromic acid, but does not yield any well-defined product. With chlorine and bromine it forms substitution-products.

The compound of carbazol with picric acid $\text{C}^{12}\text{H}^9\text{N} \cdot \text{C}^6\text{H}_2(\text{NO}^2)_3\text{O}$ forms beautiful red needles slightly soluble in cold benzene, more freely in hot benzene and in ether. It is decomposed by water and by alcohol like the corresponding anthraceno-compound, from which indeed it is distinguishable only by the form of its crystals and by its inferior solubility in benzene. By careful heating it may be sublimed in needles, with only slight decomposition.

In the characters of its picric acid compound, as well as in not combining with mineral acids, and indeed in all the characters above described, carbazol resembles a hydrocarbon much more closely than a nitrogenised organic base.

CARBAZOLINE, $\text{C}^{12}\text{H}^{14}\text{N}$.—A base formed, as already mentioned, by the action of hydriodic acid on carbazol in presence of amorphous phosphorus. To prepare it, carbazol is heated for some hours to 200° – 230° with 4 parts of hydriodic acid (b. p. 127°) and $\frac{1}{4}$ part of amorphous phosphorus; the contents of the tube when cold are mixed with water; and the solution is warmed, and filtered from a brown unctuous mass formed at the same time. The filtrate, on addition of ammonia, deposits carbazoline, which may be purified by crystallisation from alcohol.

Carbazoline crystallises from alcohol in large white needles; it melts at 96° , and distils at 286° (uncorrected); its vapour-density is 8.13, 6.99 being the calculated density for $\text{C}^{12}\text{H}^{14}\text{N}$. It sublimes in needles, and volatilises with water-vapour. It is readily soluble in alcohol, ether, and benzene, and forms salts with acids very soluble in water and alcohol; its hydrochloride is $\text{C}^{12}\text{H}^{14}\text{N} \cdot \text{HCl}$. Platonic chloride, ferric chloride, potassium dichromate, and potassium permanganate, readily oxidise its solutions, even in the cold, with formation of a brown amorphous mass; nitric acid of sp. gr. 1.2, forms a resinous body; red-hot soda-lime and melting potash are without action on it (Graebe u. Glaser, *loc. cit.*).

CARBOGLYCOLLIC ETHERS (Heintz, *Ann. Ch. Pharm.* cliv. 257).

1. *Ethyl Carbodiglycollate*, $\text{C}^6\text{H}^{10}\text{O}^2 = \text{CO} \begin{array}{l} \text{OCH}^2\text{COOC}^2\text{H}^5 \\ \text{OCH}^2\text{COOC}^2\text{H}^5 \end{array}$ is formed,

together with ethyl chlorocarbonate and glycolide, when gaseous carbonyl chloride (phosgene) is continuously passed through ethyl glycolate. On leaving the liquid to itself for some time, glycolide $\text{C}^2\text{H}^4\text{O}^2$ separates out; and on washing this substance with ether, mixing the ethereal washings with the liquid from which the glycolide has separated, and agitating the ethereal solution with water, hydrochloric acid and ethyl

glycollate dissolve, and the remaining ethereal liquid dehydrated with calcium chloride, and evaporated, leaves a liquid which by fractional distillation yields ethyl chlorocarbonate, ethyl glycollate, and ethyl carbodiglycollate.

The formation of carbodiglycollic ether in the above reaction is represented by the equation:

the simultaneous formation of glycollide and chlorocarbonic ether probably by the equations:

Carbodiglycollic ether is a viscid liquid of yellowish colour (probably colourless in the pure state), sinking in water, having a somewhat ethereal, not altogether pleasant odour, and a peculiar burning taste; easily soluble in alcohol and ether. It boils with partial decomposition at about 280° . Under the influence of bases, it decomposes, readily yielding carbonate and glycollate; probably, however, a carbodiglycollate is formed as an intermediate product, for the ether dissolves in lime- or baryta-water without immediate deposition of carbonate; but decomposition ensues on heating the liquid, and partially even when it is left to evaporate at ordinary temperatures, so that it has not yet been found possible to prepare a pure metallic carbodiglycollate.

2. *Ethyl Carboglycollate*, $\text{C}^2\text{H}^2\text{O}^3 = \text{CO} \begin{array}{l} \text{OC}^2\text{H}^3 \\ \text{OCH}^2\text{COOC}^2\text{H}^3 \end{array}$, is produced

by the action of ethyl chlorocarbonate on ethyl glycollate:

A mixture of the two ethers is heated to 100° in a sealed tube till hydrochloric acid no longer escapes on opening the tube; and by subjecting the product to repeated fractional distillation, carboglycollic ether is at length obtained in the form of a somewhat viscid colourless liquid boiling at about 240° . It has a pleasant though faint ethereal odour, and a disagreeable burning taste; sinks in water; dissolves in alcohol and ether; also, without turbidity, in cold lime- and baryta-water. Hence metallic carboglycollates appear to be producible, but they are very easily resolved into carbonates and glycollates.

In the preparation of this ether, glycollide and ethyl carbonate are formed at the same time by a simple decomposition of the ethyl carboglycollate:

CARBON. *Allotropic Modifications.*—Döbereiner found, several years ago, that all kinds of carbon heated in the electric arc of a battery of 500 to 600 Bunsen's elements, soften and are ultimately converted into graphite. According to Bettendorf (*Arch. Pharm.* [2] xlv. 79), gas-coke may be thus transformed by a battery of only 24 elements. When wood (of box, ash, hornbeam, elder, lilac or cork), or flax, hemp, cotton, paper, or silk is placed in a porcelain tube, vapour of carbon sulphide passed over it at ordinary temperatures till all the air is driven out, and the tube then slowly and gradually heated to redness for about an hour, the organic substance is found, after cooling, to be converted into a kind of coke, having the ring of steel, silver, &c., and a great power of conducting heat and electricity. When heated it gradually becomes incandescent throughout its whole mass, without taking fire at any particular part, and cools down as soon as the source of heat is removed; it might, perhaps, be used to form the carbon cylinders of Bunsen's battery. It exhibits metallic lustre on its surface, is denser than wood-charcoal, and does not sensibly absorb gases. A kind of carbon, which is a good conductor of heat and electricity, and does not absorb gases, is likewise obtained by strongly heating wood in a crucible filled with charcoal powder. Wood-spirit, hydrocarbons, &c., likewise act like carbon sulphide in converting wood into elastic and conducting carbon.

time, whereby the interior of the tube becomes coated with silver white threads of carbon about a centimeter long (Sidot, *Compt. rend.* lxx. 605).

Carbon in Meteorites. Certain meteorites contain carbon, both in the free and in the combined state, that is, in the form of hydrocarbons; the combined carbon is completely dissolved out by free acids. In two samples of meteoric iron from Cailla, Boussingault (*Compt. rend.* lxxiv. 1287) found 0.12 p.c. combined carbon. Three specimens of meteoric iron from Orivvak, in Greenland, were found by Daubrée (*ibid.* 240) to contain:

Combined Carbon	3.00	2.6	3.6 p.c.
Free Carbon	1.64	0.3	1.1 „

The meteorite found at Cranbourne near Melbourne contains fragments of pyrites and a certain quantity of amorphous carbon. On treating the amorphous carbon, first with nitric acid, to remove admixed pyrites, and then with a mixture of fuming nitric acid and potassium chlorate, a greenish graphitic oxide is obtained, identical in all respects with the oxide from the graphite which crystallises from molten cast-iron, but different from the oxide obtained from plumbago. From its association with pyrites in the meteorite, the carbon may have arisen from the action of carbon sulphide on the incandescent iron; at any rate, it has been formed under the influence of a very high temperature (Berthelot, *Compt. rend.* lxxiii. 494).

Carbon from the decomposition of Carbonic Oxide by Iron.—In the decomposition of carbonic oxide by iron and oxide of iron, at a comparatively low temperature, a large quantity of amorphous carbon is produced. By repeated treatment with nitric acid and potassium chlorate, this carbon dissolves almost completely, in the same way as the combined carbon in carburetted iron and manganese, a trace only of graphitic oxide being formed (Berthelot).

CARBON BROMIDE (TETRA-), CBr_4 (Bolås a. Groves, *Chem. Soc. J.* [2] ix. 773). The formation of this compound by the action of bromine in presence of iodine bromide or antimonious bromide on carbon sulphide, bromopierin or bromoform, has been already noticed (1st Suppl. 400. See also Bromoform, in this volume). Subsequent experiments have shown: (1). That this compound is formed in small quantity when carbon sulphide is heated with pure bromine alone to 180° – 200° for several hundred hours; (2). that the quantity produced is greatly increased by the presence of the bromides of bismuth, arsenic, gold, platinum, cadmium, zinc, or nickel, whereas the bromides of iron, tin, phosphorus and sulphur have but little influence on the result. Bismuth heated with carbon sulphide and excess of bromine for a considerable time, converts a large proportion of carbon sulphide into tetrabromide, apparently yielding a result as good as that obtained with antimony; arsenious bromide under similar circumstances also transforms the greater portion of the carbon sulphide. On the whole, however, iodine bromide in presence of excess of bromine appears to be the most convenient agent for effecting the conversion. Carbon tetrabromide is also produced in the following reactions.

a. By decomposition of Bromopierin, $\text{CBr}_3(\text{NO}^*)$. When this liquid, in quantities of 200 to 300 grams, is gently heated for thirty or forty hours in a flask connected with a condensing apparatus, nitrogen oxides and carbon dioxide are given off, a dark red liquid having nearly the composition NOBr collects in the receiver, and the liquid remaining in the flask deposits after some time large crystals of carbon tetrabromide. To obtain this compound in the pure state, the liquid is mixed with water, caustic soda added to neutralise excess of bromine, and the solution is heated till the carbon tetrabromide melts into a cake. The product thus obtained contains a small quantity of an oily substance, which may be removed by strong pressure between bibulous paper before crystallisation. Traces of bromopierin which remain undecomposed, unless the heating has been continued for a somewhat longer time than that above specified, may be removed by heating the product with aqueous potassium cyanide. The action of heat on bromopierin affords an easy and expeditious method of preparing small quantities of carbon tetrabromide, the yield being about 30 p.c. In operating on small quantities, however, care must be taken that the liquid does not dry up on the sides of the vessel, and become strongly heated, as in that case the whole is apt to decompose with explosive violence.

b. By the action of Bromine on Iodoform, CHI_3 . At ordinary temperatures this reaction gives rise to bromoform, CBBr_3 ; but an excess of bromine at high temperatures removes the whole of the iodine, producing carbon tetrabromide. When one part of iodoform was introduced into a tube, and six times its weight of bromine added to it, the mixture became watery, and much iodine was liberated. The tube was then sealed and heated to about 180° for 70 hours, and on opening it at the expiration of that time, a considerable quantity of hydrobromic acid

escaped. The contents were then neutralised with sodium hydrate, and distilled in the usual way. The semi-solid crystalline mass, after being separated from the water, and having the greater portion of the oily matter removed by pressure, was examined, and found to be carbon tetrabromide contaminated with a minute quantity of the above-mentioned oil, which was, however, easily removed by crystallisation from spirit. In this experiment bromiodoform was undoubtedly first produced, the liberated iodine combining with the excess of bromine; and the bromide of iodine thus formed, acting upon the bromiodoform, transformed it into tetrabromide of carbon.

γ. *By the action of Iodine Bromide and Bromine on Chloroform.*—This reaction yields the compounds CBr^4 and CBr^3Cl , together with other products. When dry chloroform was heated to 150° in sealed tubes with one part of iodine and 3 parts of bromine till the tubes on being opened no longer emitted gas, the contents when submitted to fractional distillation yielded several fractions, the lowest of which (100° – 130°) was liquid at ordinary temperatures, while the intermediate fractions deposited large colourless crystals when cooled, and the highest (180° – 200°) solidified at once to a crystalline mass, which when recrystallised from alcohol had nearly the composition of tribromochloromethane CBr^3Cl . Another rectification of the higher fraction yielded a substance, which, after crystallisation from spirit, melted at 76° and gave by analysis 92.91 p.c. bromine and 3 p.c. chlorine. Now as carbon tetrabromide contains 96.4 p.c. bromine, it would appear that the substance in question was simply carbon tetrabromide contaminated with a small quantity of tribromomethane.

Boiling point and Specific gravity.—The following table gives the results of two parallel series of experiments made with the tetrabromide prepared from carbon sulphide and from bromopierin. Column I. represents the pressure in millimeters; column II. the boiling point of the tetrabromide derived from carbon bisulphide; column III. the boiling point of that from bromopierin:—

I.	II.	III.
mm.	CBr^4 from CS^2 .	CBr^4 from ON^2Br^2 .
50	101.75	101.75
100	120.50	121.00
228	143.00	143.50
280	150.00	150.50
380	160.25	161.00
430	—	165.50
482	—	169.50
558	—	175.00

Tetrabromide of carbon under the ordinary pressure (760 mm.) boils at 189.5° , but at the same time it undergoes a slight decomposition, bromine being liberated. It can, however, be distilled without change in a vacuum, but, when the pressure is increased to about 360 mm., a very slight decomposition commences.

The specific gravity of carbon tetrabromide was found to be 3.42 at 14° ; but the result is perhaps rather too low, as the substance is very apt to form cavities in crystallising.

Reactions. 1. Carbon tetrabromide heated to 200° in a sealed tube, undergoes partial decomposition, a small quantity of bromine being liberated. The same phenomenon takes place when the tetrabromide is exposed to bright sunshine, the substance at the same time showing a strong tendency to crystallise on the side of the tube nearest the light, in well-formed and very brilliant crystals.

2. Carbon tetrabromide heated to 100° with alcohol in a sealed tube, yields hydrogen bromide, aldehyde and bromoform:

3. Heated with alcoholic ammonia to 100° in a sealed tube for several hours, it likewise yields bromoform, produced as above, together with a small quantity of guanidine.

4. When 1 part of carbon tetrabromide is heated with 2 parts of aniline, the mixture turns red, and in a few seconds a powerful reaction sets in, which completes itself without further application of heat, and the mixture on cooling solidifies to a crystalline mass, consisting of the hydrobromides of aniline and carbatriphenylamine or triphenylguanidine:

The reaction is exactly similar to that which Lehmann obtained with the tetrafluorides (i. 786), but takes place much more readily.

2nd Sup.

6. The tetrachloride heated with *antimony* gives up part of its bromine, and yields a carbonaceous mass. 5. When it was heated with *silver oxalate* to 100° in a sealed tube, a violent explosion took place.

CARBON CHLORIDES. The trichloride C^2Cl^3 is produced by the action of chlorine on acetylene tetrachloride C^2HCl^4 . Acetylene tetrachloride heated in a sealed tube to 300° for fifteen hours splits up into chloroacetylene dichloride and hydrogen chloride. The action is:

Carbon trichloride is also formed, when hydrogen, mixed with the vapour of the tetrachloride, is passed through a red-hot glass tube filled with fragments of glass:

The reaction takes place at a temperature at which no perceptible resolution of the tetrachloride into the trichloride and chlorine takes place (Städeler, *Ann. Ch. Pharm. Suppl.* vii. 168).

Thirdly, carbon trichloride is formed by the action of phosphorus pentachloride on acetyl chloride CH^3COCl , the oxygen-atom and the three hydrogen-atoms being replaced by equivalent quantities of chlorine. When acetyl-chloride is heated for some hours in a sealed tube to 180° with rather more than 4 mol. PCl^5 , the tube being opened now and then to allow the escape of hydrochloric acid, and finally heated for 56 hours to 210° – 220° , and the contents then slowly poured into cold water, carbon trichloride separates as a white mass, which may be crystallised from boiling alcohol in feathery crystals, or by slower separation in thick square plates. The crystals melt at 182° – 183° , not at 160° as commonly stated (1st *Suppl.* 766).

The formation of the trichloride is accompanied by that of a small quantity of the compound $\text{C}^2\text{H}^2\text{Cl}^3$ or CH^3CCl^3 (H. Hübner u. F. C. G. Müller, *Zeitschr. f. Chem.* vi. 328).

Tetrachloride, CCl^4 . When 1 mol. phosphorus pentoxide is heated with 2.3 mol. carbon tetrachloride to 200° – 220° , the following reaction takes place:—

The quantity of phosgene produced is about three-fourths of the theoretical amount, and a portion of carbon tetrachloride always remains unchanged. By diminishing the quantity of the latter, the yield of phosgene always diminishes while that of carbon dioxide is increased. On employing equal numbers of molecules, the reaction is—

The residue in the tubes is a viscid liquid, consisting of phosphorus oxychloride, and a compound formed by the action of phosphorus oxychloride on the pentoxide (Gustavson, *Zeitschr. f. Chem.* [2] vii. 615).

Phosphorus pentasulphide has no action on carbon tetrachloride, even when the two are heated together to 200° – 220° in a sealed tube for a week (Thorpe, *Chem. Soc. J.* [2] x. 453).

Chlorobromides. The trichlorobromide CCl^3Br is obtained by heating chloroform with bromine to 200° for six or eight hours, washing the product, and submitting it to fractional distillation. It is a mobile colourless liquid, which becomes coloured on exposure to light, has a pleasant ethereal odour, dissolves in alcohol and ether, and boils at 104.3° under a pressure of 757.9 mm. A small quantity of the dichloro-dibromide $\text{C}^2\text{Cl}^2\text{Br}^2$, which is a liquid boiling at a higher temperature, is likewise obtained in this reaction (Paternò, *Gazzetta chimica italiana*, i. 593).

The tetrachloro-dibromide, or tetrachloro-dibromethane $\text{C}^2\text{Cl}^4\text{Br}^2$, is produced, by heating pentachloroethane C^2HCl^5 with bromine to 200° , as a crystalline body, which may be purified by washing with dilute potash and crystallisation from alcohol or ether, in which it is very soluble. It has a characteristic camphor-like odour, similar to that of carbon trichloride, which it closely resembles in appearance. When heated, it decomposes, with liberation of bromine, but without melting or volatilising. It has the constitution $\begin{Bmatrix} \text{CCl}^4 \\ \text{CCl}^3\text{Br} \end{Bmatrix}$, and is isomeric with the compound $\begin{Bmatrix} \text{CCl}^4\text{Br} \\ \text{CCl}^3\text{Br}^2 \end{Bmatrix}$ which Malaguti obtained (1st *Suppl.* 768), by the direct union of bromine and carbon dichloride (Paternò).

Chloroacetylenes. Carbon dichloride, or tetrachloroethylene C^2Cl^4 , when

directly with nitrogen tetroxide, forming crystalline tetrachloro-dinitroethane $C^2Cl^4(NO^2)^2$. This compound is violently attacked by alcoholic potash; but if the liquid be diluted with water, and the nitro-compound gradually added to it, the formation of by-products may be avoided, and an alkaline liquid is obtained, which by evaporation yields potassium chloride, together with long prisms agreeing in

composition with the formula, $\left. \begin{matrix} CCl^3 \\ NO^2 \\ NO^2 \end{matrix} \right\} C.O.K.$ This compound may be regarded as the

potassium salt of trichloroacetic acid in which the oxygen of the group CO is replaced by two atoms of nitryl; or as the potassium derivative of trichloro-dinitro-ethyl alcohol (Hoch u. Kolbe, *J. pr. Chem.* [2] iv. 60).

Carbon dichloride gradually added to a well-cooled mixture of concentrated sulphuric and red fuming nitric acid, forms nitryl chloride and nitrotrichloroethylene. This compound, which has not been obtained in the pure state, owing to its instability, is a yellow liquid, having an extremely intense and unpleasant odour, and causing headache and tears; it is decomposed by water and alkalis. By heating with bromine for some hours to 140° – 150° it is converted into $C^2Cl^2(NO^2)Br^2$, a crystalline substance, melting at about 120° , with decomposition (separation of bromine), easily soluble in ether, less soluble in alcohol. By heating with liquid nitrogen tetroxide in sealed tubes to 115° , it is converted into trinitrotrichloroethane, $C^2Cl^3(NO^2)^3$, which crystallises in feathery forms; this body is not explosive, but gives up nitrogen tetroxide when heated (K. Hoch, *J. pr. Chem.* [2] vi. 95).

CARBON OXIDES. 1. *Monoxide. Carbonic Oxide.* CO. This gas is oxidised to CO^2 by chromic acid. The oxidation may be slowly but completely accomplished by introducing a ball of gypsum soaked with solution of chromic acid into carbonic oxide standing over mercury (E. Ludwig, *Ann. Ch. Pharm.* clxii. 47).

Decomposition by Iron and its Oxides.—When pure and dry carbonic oxide is passed over metallic iron at 300° – 400° , scarcely any deposition of carbon takes place; but when it is passed over ferrous oxide, this oxide is reduced at the surface to metallic iron and a deposit of carbon is formed. Carbonic oxide mixed with a small quantity of carbonic anhydride or oxygen, and passed over metallic iron at the same temperature, deposits pulverulent carbon on the surface of the iron. These reactions may be represented by the equations:

If in the experiments which yield carbon, the temperature be raised to redness, the deposition of carbon immediately stops, and any ferrous oxide that may be present is again burnt.

The carbon which is deposited in these reactions contains metallic iron, sometimes amounting to between 5 and 7 p. c., and some oxides of iron, for the most part magnetic. The presence of iron in the deposited carbon suggests the idea that natural graphite containing iron may have originated in a similar manner (Grüner, *Compt. rend.* lxxiii. 281).

Action of Electricity on Carbon Monoxide alone and in presence of Hydrogen.—When a mixture of hydrogen and carbon monoxide was submitted to the action of electricity in an induction tube, a contraction of the mixed gases was observed; and after the fifth hour they were found to contain about 6 p. c. of marsh-gas, which had thus been synthetically produced:

In a similar experiment, made with a mixture of hydrogen and carbon dioxide, the resultant gas was found to contain carbon monoxide, and at the same time minute drops of an oily liquid appeared in the tube. These were found to give the characteristic reactions of formic acid:

When pure and dry carbon monoxide is circulated through the induction tube, and then submitted to the action of electricity, a decomposition of the gas occurs, attended with a gradual and regular contraction, carbon dioxide being formed, whilst a transparent film of a reddish-brown colour is deposited on the sides of the tube. This film, which is entirely soluble in water, and yields a coloured solution possessing an intensely acid reaction, is an oxide of carbon, but in different experiments it does not present the same composition. Two of these 'oxycarbons,' have however been identified, namely, C^2O^2 , and C^2O^4 , which may be regarded as corresponding with

crotonylene, C^4H^4 , and valerylene, C^4H^4 , in the analogous hydrocarbon system of which acetylene is the first term (Brodie, *Proc. Roy. Soc.* xxi. 245).

2. Dioxide or Carbonic Anhydride.—Cailletet (*Compt. rend.* lxxv. 1271) has examined the properties of liquid carbon dioxide, which he condenses by mechanical pressure; but his experiments do not add much to the information previously furnished by those of Gore (*1st Suppl.* 402), with which he does not appear to be acquainted. It is a colourless mobile liquid, which does not conduct electricity. When the ends of the wires of a powerful induction-coil are brought near each other in this liquid, a brilliant white light is produced, unaccompanied by any deposit of carbon. It does not dissolve sodium chloride, sodium sulphate, calcium chloride, calcium carbonate, sulphur, phosphorus, stearin, or paraffin. It converts neutral sodium carbonate into acid sodium carbonate, which is insoluble in the liquid. Iodine dissolves in it sparingly, giving the tint produced by 5 milligrams of iodine in 10 c. c. of carbon bisulphide. The liquid fats are slightly soluble in liquid carbon dioxide; tallow is bleached by the abstraction of its liquid fats. Petroleum oil dissolves 5 or 6 times its volume of the liquid dioxide. It appears to be miscible with ether in all proportions. Carbon sulphide takes up a small proportion only. Liquid carbon dioxide is not reduced by sodium.

The liquid bubbles enclosed in certain minerals, as rock-crystal, topaz, amethyst and quartz appear to consist in many cases of liquid carbon dioxide, sometimes enclosing a small bubble of water. The liquefied carbon dioxide does not fill the cavities completely, and does not adhere to their sides, but moves freely about, like mercury in glass. On heating the mineral, the liquid carbon dioxide expands strongly, and condenses the enclosed water-bubble. When, however, the water predominates, the bubble does not disappear on heating (Vogelsang u. Geissler, *Pogg. Ann.* cxxxvii. 56).

Respecting the amount of carbon dioxide contained in the air near the Baltic Sea; see ATMOSPHERE (pp. 112, 113).

Decomposition by the Electric Discharge.—A. Thénard (*Compt. rend.* lxxiv. 1280) by passing gaseous carbon dioxide through a tube similar to those used by Houzeau for the preparation of ozone, finds that from 4 to 8 p.c. of the gas is decomposed, yielding, after absorption of the undecomposed portion by potash, a mixture of 1 vol. carbon monoxide and $\frac{1}{2}$ vol. oxygen, 255 c.c. of which were obtained in thirty hours. Ozone was likewise formed, but its quantity was extremely small, indicating that the energy of the electric discharge was almost exclusively consumed in decomposing the carbon dioxide.

Action of Carbon and Iron on Carbon Dioxide at a red heat.—It has been lately asserted by Dubrunfaut (*Compt. rend.* lxxiv. 125) that carbon dioxide cannot be reduced to monoxide by ignited charcoal, unless hydrogen gas or water-vapour is present. To test the truth of this assertion, Dumas (*ibid.* lxxv. 511) has undertaken a series of very careful experiments, in which charcoal, completely deprived of hydrogen and aqueous vapour by ignition in a current of chlorine, was afterwards heated to redness in a current of dry carbon dioxide. The gas collected at four different stages of the operation exhibited the following composition:—

	I.	II.	III.	IV.
Carbon dioxide . . .	0.0	0.0	4.6	0.9
Carbon monoxide . .	99.9	188.0	95.4	90.1
Gas, non-absorbable by potash or cuprous chloride	0.1	Inappreciable traces.	Inappreciable traces.	Inappreciable traces.
	100.0	188.0	100.0	100.0

These results show that, at the commencement of the operation, a trace of gas is disengaged which is not absorbed by potash or cuprous chloride, and that this gas finally disappears. Also that, towards the termination of the experiment, carbon dioxide makes its appearance in increasing quantity, having escaped decomposition because of the deficiency of carbon. The two following points may be regarded as definitely settled by the experiments: first, that charcoal absolutely deprived of hydrogen and water by the action of chlorine, will transform carbon dioxide into monoxide; secondly, that the conversion is total when the conditions are favourable, that is to say, when there is an excess of carbon, and when the current is slow.

In order to ascertain whether metallic iron exerts a similar decomposing action upon carbon dioxide, the foregoing experiments were repeated, the tube being filled with clean iron turnings, instead of charcoal. It was found that a very slow current of

carbon dioxide passing over iron at a temperature approaching nearly to whiteness, was not entirely converted into monoxide, 30 vol. and sometimes 50 vol. p.c. escaping decomposition. The difference between the action of iron and that of carbon is explained by the fact that the iron oxide formed at first, tends to reproduce carbon dioxide by acting upon the monoxide, and thus gives rise to varying mixtures of the two gases.

Reduction of Carbonic to Formic Acid.—When a stream of carbon dioxide is passed continuously for several days into the porous cell of a Grove's battery, formic acid is found both in the porous cell and in the outer vessel. The quantity formed in a given time is greater with unamalgamated than with amalgamated zinc, provided a little dilute sulphuric acid be added from time to time to the liquid in the outer vessel (E. Royer, *Compt. rend.* lxx. 731).

Estimation of Carbon dioxide in Sea-water.—Hinly (*Chem. Soc. J.* [2] x. 455) points out that the amount of carbon dioxide in sea-water cannot be correctly determined by the ordinary gasometric method, since the gas is never completely expelled by boiling the sea-water, either in a vacuum or at 100° under the ordinary atmospheric pressure, even when a stream of pure air free from carbon dioxide is simultaneously passed through the liquid. The presence of magnesium chloride in the sea-water has doubtless an essential influence on the retention of the carbon dioxide.

The total amount of the carbon dioxide may be estimated by the use either of baryta-water or of aqueous ammonia saturated with a suitable barium salt, and an ammonium salt. The following method of conducting the estimation is very simple, free from errors that might arise from the carbon dioxide of the air, and very exact, inasmuch as it depends only upon two barium determinations:—

The precipitation of the sulphuric and carbonic acid of the sea-water is performed in a graduated litre cylinder, with a quantity of the reagent which need not be exactly known, but should be slightly in excess of that which is actually required. The liquid having been set aside, out of contact with the air, till the precipitate has completely settled down, an aliquot part, $\frac{1}{10}$ ths for example, of the clear liquid is decanted; the barium contained in it is determined as sulphate; and from this the quantity of barium which remains dissolved in the last $\frac{1}{10}$ th of the liquid may be determined by calculation.

The barium carbonate is then dissolved by dilute acid, the liquid is filtered, and the total quantity of barium determined as sulphate. The difference gives the quantity of barium contained in the solution as carbonate, and from this the quantity of carbon dioxide may be calculated.

To avoid loss of carbon dioxide and other gases during and after the collection of the sea-water, Hinly proposes to add the reagent below the surface of the sea; and for this he has devised an apparatus consisting of a cylinder open at both ends, and capable of being closed when sunk to the required depth. For this purpose it is provided at each end with a large stopcock, which can be closed by a powerful spring, released at the proper moment by means of an electro-magnet set in action in the usual way.

On the solubility of calcium carbonate and of bone phosphate in water containing carbonic acid, see CARBONATES and PHOSPHATES.

CARBON OXYCHLORIDE, COCl_2 . *Phosgene.*—This compound is very soluble in benzene, glacial acetic acid, and most liquid hydrocarbons. It may be expelled from these liquids by boiling, but never in a state of perfect purity; for not only does the smallest trace of water contained in the solvent decompose an equivalent quantity of the oxychloride on boiling, into carbon dioxide and hydrogen chloride, but the escaping oxychloride is likewise contaminated with the vapour of the solvent.

Cold water dissolves about an equal, or at most a double volume of phosgene gas, and decomposes it very slowly, whereas alcohol decomposes it immediately, into hydrogen chloride and ethyl chloro-carbonate, $\text{CO}.\text{Cl}.\text{OC}_2\text{H}_5$. Aqueous potash and ammonia absorb it immediately. Very characteristic of carbon oxychloride is the fact that, when brought in contact with slightly moistened potassium bicarbonate, it triples its volume and the gas then becomes completely absorbable by water:

No other gas reacts in this manner (Berthelot, *Bull. Soc. Chim.* [2] xiii. 14).

Action of Liquid Phosgene on Organic compounds.—Liquid phosgene acts on acetic acid at 110°–120°, forming, acetyl chloride:

Heated to 110°–120° for some days with *acetone*, it yields a small quantity of a liquid boiling at 120°–135°, probably dichloroacetone.

When 2 parts of liquid phosgene are heated with 3 parts of *phenol* to 140°–150°, and the contents of the tube are subsequently treated with dilute soda-ley, phenyl carbonate $(C^6H^5)_2CO^2$ is obtained, as a solid substance which crystallises from alcohol in needles. If the heating be continued for some time and the product then distilled by itself, a pungent-smelling liquid distillate is obtained, which contains phenyl chlorocarbonate $CO.Cl.OC^6H^5$, and when dissolved in anhydrous ether and saturated with ammonia gas, yields phenyl carbamate $CO.NH^2.OC^6H^5$ (T. Kempf, *Deut. Chem. Ges. Ber.* iii. 632, 740).

Cresol reacts with liquid phosgene similarly to phenol; so likewise does *thymol*, though with much greater difficulty. With *benzoic aldehyde* at 120°–130°, liquid phosgene forms chlorobenzyl chloride: $C^6H^5.CHO + COCl^2 = CO^2 + C^6H^5.CCl^2$ (Kempf, *Zeitschr. f. Chem.* [2] vii. 77).

Urea heated with excess of liquid phosgene in sealed tubes to 100° for two days, is converted into carbonyl-diurea, $C^6H^4N^2O^2$:

By further action of the phosgene at 150°–160°, the carbonyl-diurea is converted into hydrochloric acid, and a crystalline mixture of dicyanic and tricyanic (cyanuric) acids.

By heating *biuret* and phosgene to 60° for twelve hours, carbonyl-dibiuret $C^6H^4N^2O^3$ is formed:

and by further action, this compound is resolved into two molecules of cyanuric acid:

Benzamide and liquid phosgene heated together to 160°–170° yield carbon dioxide, benzyl chloride, benzonitril and carbonyl-dibenzamide, $C^{13}H^{12}N^2O^2$, the latter being formed according to the equation:

With *acetamide*, in like manner, carbonyl-diacetamide, $C^8H^8N^2O^4$, is produced (E. Schmidt, *J. pr. Chem.* [2] v. 35; *Chem. Soc. J.* [2] x. 718).

Butlerow has shown that phosgene gas is slowly absorbed by *zinc-methyl*, forming the crystalline compound $2Zn(CH^3)_2.C^2H^2OCl$, which when acted upon by water yields trimethyl carbinol. He formerly stated also that a small quantity of acetic acid is formed at the same time (*1st Suppl.* 406). He now finds, however, that no acetic acid is formed by the action of water on this crystalline body; the small quantity formerly observed was probably due to the decomposition of the trimethyl carbinol (*Zeitschr. f. Chem.* [2] vi. 523).

On the action of phosgene on *anthracene* and *benzene*, see pp. 83, 131; on *glycollic ethers*, see CARBOGLYCOLLIC ETHERS, p. 254.

CARBON OXYSULPHIDE, COS. According to F. Salomon (*J. f. Chem.* [2] v. 476), the best mode of preparing this gas is to pass a mixture of carbon monoxide and sulphur vapour through a red-hot tube, and absorb the gas by alcoholic potash, from which it may be liberated in the pure state by hydrochloric acid.

Carbon oxy sulphide is absorbed slowly by aqueous potash, more quickly however than the vapour of the bisulphide diffused through air or any other gas. Bromine and strong sulphuric acid react with the oxy sulphide nearly in the same manner as with the bisulphide. Potassium hydrate moistened with alcohol absorbs both compounds very quickly; absolute alcohol and liquid hydrocarbons dissolve both of them in large quantity. *Ammonia* either gaseous or in solution is the best reagent for distinguishing between the two. The vapour of the bisulphide mixed with air may remain mixed with gaseous ammonia for hours without producing any distinct reaction; but when the oxy sulphide is mixed with dry ammonia gas, the sides of the vessel immediately become covered with a crystalline crust of ammonium oxy sulphide carbamate, $NH^2.COSNH^2$, formed by direct combination of COS and $2NH^3$. The

aqueous solution of this salt, heated to 100° in a sealed tube, is converted, by separation of H_2O , into ammonium sulphocyanate CNS.NH_4 . The same solution gently heated with lead carbonate, gives up H_2S and yields urea $\text{CN}^2\text{H}_4\text{O}$ (Berthelot, *Ann. Chim. Phys.* [4] xxvi. 470).

CARBON SULPHIDES. 1. *Bisulphide or Disulphide, CS_2 .* *Preparation and Purification.* In the manufacture of this compound, the yield depends mainly on the temperature employed. Sidot (*J. Pharm.* [4] xiii. 239) by passing a known weight (40 grams) of sulphur, in the form of vapour, over 10 grams of charcoal contained in a porcelain tube heated to various temperatures, has obtained the following numbers, representing the mean results of three experiments at each of the temperatures mentioned:—

1.	At a dull red heat, 5 grams of carbon gave 17 grams of carbon bisulphide.
2.	" red heat 6.3 " " 29 " "
3.	" bright-red " 7.5 " " 19 " "

These numbers show clearly that, in order to obtain the maximum yield, a red heat should be employed, but that it should by no means be exceeded. In practice the variations in the yield of carbon bisulphide are attributed to loss, to imperfections in apparatus, and chiefly to temperature, which is always considered to be too low. The above result is due to the fact already pointed out by Berthelot, that carbon bisulphide undergoes decomposition the more completely the higher the temperature to which it is exposed. It behaves, in presence of charcoal, exactly like the carbon oxide in Deville's dissociation experiments, undergoing simple decomposition, and the liberated carbon being deposited upon the heated charcoal. Sidot has made a series of comparative experiments at different temperatures, the results of which show that decomposition takes place to some extent even at a dull red heat, but that it goes on much more rapidly at higher temperatures: 150 c.c. of carbon bisulphide were completely decomposed by passing six times over 10 grams of charcoal heated to bright redness in a porcelain tube.

To purify carbon bisulphide, Sidot first distills, and then agitates it with mercury, till it ceases to blacken the brilliant surface of the metal. This latter operation is performed as follows:—500 grams of the bisulphide, and about the same weight of mercury, are introduced into a bottle of 500 c.c. capacity, which is then agitated for some time. The sulphide formed is easily removed by filtration, and the mercury separated by means of a funnel. The two liquids are then returned to the bottle, and the agitation is renewed, until the bright surface of the mercury is no longer tarnished. Carbon bisulphide thus purified is completely free from the fetid smell which it generally possesses, and has a pure ethereal odour. It is not affected by contact with mercury for any length of time.

Solubility in Water.—Carbon bisulphide is not quite insoluble in water. After several days' contact at ordinary temperatures, water takes up about 1 part in 1,000 of its weight of this compound, a very small quantity at the same time undergoing decomposition. The aqueous solution when distilled gives up the carbon bisulphide unaltered, at the commencement of the distillation. It has the odour of the compound, a slightly burning taste, and does not contain more than 0.002 gram of hydrogen sulphide in a litre (Sestini, *Gazetta chimica italiana*, i. 473).

Solubility in Alcohol.—Carbon bisulphide does not, as usually stated, mix in all proportions, with common strong spirit, which indeed takes up less of the bisulphide in proportion as it contains more water. It is only with absolute alcohol that carbon bisulphide is miscible in all proportions. These facts afford a means of testing the strength of alcohol, as the point of saturation can be very easily determined, one drop of bisulphide in excess producing a milky turbidity. The only precaution to be attended to is to work at a temperature above 15° , because below that point the solubility decreases rapidly with the temperature, whereas above it the solubility remains nearly constant. Thus when a saturated solution is cooled down from $+15^{\circ}$ to -12° , about one-half of the bisulphide separates out; at -10° one-third, and at $+10^{\circ}$ about one-fifth.

The following results were obtained: 10 c. c. of alcohol were used in each experiment, the temperature being 17° :

Percentage of Alcohol by weight.

98.5 98.15 96.95 93.54 91.37 84.12 70.02 48.40 47.90

Cub. cent. of CS_2 dissolved.

18.20 13.20 10.00 7.00 5.00 3.00 2.00 0.2 0

By inserting these values in a system of co-ordinates, a curve having the following equations is obtained:—

$$y = \frac{1}{x} \left(s - \frac{c}{x + b} \right)$$

$$x = \frac{(s - yb) + \sqrt{(s + yb)^2 + 4yc}}{2y}$$

when $s = 1.065$, $b = 0.58$, and $c = 0.592$.

On calculating from these equations, y , or the quantity of bisulphide in cbc. dissolved in 10 cbc. of alcohol of x per cent. by weight, numbers are obtained agreeing almost exactly with those found by experiment. On the other hand, x can be easily calculated when we know how much bisulphide dissolves in 10 cbc. of the alcohol to be tested. Alcohol which mixes in all proportions with bisulphide may be considered as anhydrous (Tuchschmidt & Pollenius, *Deut. Chem. Ges. Ber.* iv. 583).

Reactions. 1. *With the Hydrates of the Alkaline Earths.*—When a mixture of water, calcium hydrate, and carbon bisulphide is exposed to the action of solar light in summer, the liquid in six or eight hours acquires a fine yellowish-red colour, and during the following night deposits a few very fine prisms of an orange-red colour. The same reaction takes place in two hours when carbon bisulphide is heated to about 50° with milk of lime. The liquid filtered while hot does not deposit any crystals on cooling; but on adding calcium hydrate to the cooled filtrate, it yields the prismatic crystals above mentioned, which consist of a compound of hydrate and sulphocarbonate of calcium, represented by the formula $3\text{CaH}^2\text{O}^2, \text{CaCS}^2 \cdot 7\text{H}^2\text{O}$. The formation of the sulphocarbonate, which however is preceded by that of sulphide of calcium, is represented by the equation,

This reaction affords a test for the presence of carbon bisulphide, 0.5 c.c. of the compound is sufficient to produce it.

Hydrate of barium acts exactly like hydrate of calcium, and gives rise to a yellow compound which crystallises in short prisms. The hydrates of *strontium* and *magnesium* likewise act in the same manner (the latter but feebly), but do not yield crystallised compounds (Sestini, *loc. cit.*).

2. *With Lead Acetate.*—On mixing 10 c.c. of a saturated aqueous solution of carbon bisulphide (containing $\frac{1}{10000}$ part of CS^2) with caustic potash, heating to 50° , and adding acetate of lead, the liquid yields, after five minutes, a copious black precipitate of lead sulphide. The same reaction is still perceptible with a saturated aqueous solution of the bisulphide diluted with ten times its volume of water, containing, therefore, only $\frac{1}{100000}$ part of CS^2 (Sestini).

3. *With Phosphorus Pentachloride.*—According to Rathke (*Zeitschr. f. Chem.* vi. 57), this reaction yields phosphorus sulphochloride and carbon tetrachloride:

The statement of Carius (*Ann. Chem. Pharm.* cxii. 193), that carbon sulphochloride is formed in this reaction, is incorrect.

Solid (?) Hydrated Carbon Bisulphide.—When a strong current of dry air is passed over the surface of carbon bisulphide contained in a glass vessel, crusts of the solidified compound form, even while an immersed thermometer still stands at a few degrees above 0° ; the temperature, however, quickly falls to -17° or -18° , and white cauliflower-like masses then form on the surface, and float on the liquid; the air-delivery tube also quickly becomes stopped up by the snowy mass, and should therefore be rather wide. In a short time the whole of the liquid has disappeared, and the thermometer begins to rise, remaining constant at about -12° . When a mixture of carbon bisulphide and ether (to diminish the partial pressure) is introduced into the receiver of a Carré's air-pump, it is possible, by vigorous pumping, to obtain the bisulphide in the above-mentioned cauliflower-like masses.

Solid carbon bisulphide retains its solid form for some time at ordinary temperatures, but gives off a quite peculiar aromatic odour, and is less inflammable than in the liquid state. It affords an easy means of obtaining ice of low temperature in comparatively large quantity. It is merely necessary to add to water in a glass dish a few centimeters of the liquid bisulphide, and pass a strong current of air through it, upon (if a little more of the bisulphide be used, so that this also may solidify) temperature of the whole may sink to -13° . In all these experiments care must

taken to avoid the continuous inhalation of the vapour of the bisulphide (Wartha, *Deut. Chem. Ges. Ber.* iii. 80).

Berthelot, by rapid evaporation of moist carbon bisulphide, obtained a crystalline substance which he regarded as a hydrate of the bisulphide; and Duclaux afterwards assigned to it the composition $2\text{CS}_2 \cdot \text{H}_2\text{O}$ (*1st Suppl.* 410). Ballo (*Deut. Chem. Ges. Ber.* iv. 118) regards the solid substance obtained by Wartha also as a hydrate. He put some carbon bisulphide into a shallow vessel, and directed a current of air on it, so as to strike the surface at an acute angle; with *undried* air, the formation of a snowy solid was particularly observed at the point where the current divides the liquid like a wedge, while a general formation of flakes took place in the rest of the liquid. Air, *dried* by calcium chloride, gave no formation of snow; or at most, a very slight formation. Some of the snowy substance was freed from liquid carbon bisulphide by a current of air, and the amount of water determined by Duclaux' method. Three experiments gave 17.3, 36.14, 27.09, as the percentages of water. Ballo regards the possibility of formation of ice from excess of moist air, or of loss of carbon bisulphide during the purification, as sufficient to account for the variable numbers.

To ascertain whether water is really necessary for the formation of the solid substance, he directed the air-current on the bisulphide covered with a layer of absolute alcohol, so that the air on reaching the bisulphide was thoroughly dried; in this case the snowy substance was not formed. He concludes from this that water is necessary for the production of this body, and regards it as a solidified solution of liquid carbon bisulphide in water, or of water in carbon bisulphide.

Szjohelyi and Ballo (*ibid.* iv. 160) have tried the effect of a current of moist air directed on the surface of chloroform and ethyl iodide. The same formation of snow was observed, as in Ballo's experiments with carbon bisulphide; the chloroform snow was shown to contain water and chloroform by melting in a test-tube. In the case of chloroform the temperature fell to -13° , in that of ethyl iodide to -9° .

Wartha (*ibid.* iv. 180 and 221) regards the experiments of Ballo as inconclusive. He maintains that in his own experiments the solid bisulphide was obtained by directing a current of *dry* air on the surface of the liquid in a manner which altogether prevented the admixture of frozen atmospheric water with the solid bisulphide, and attributes the non-formation of the solid when a current of air was directed on the liquid bisulphide covered with absolute alcohol, to the fact that the temperature in this experiment fell only to -11.5° , whereas the solid bisulphide melts at -12° to -13° .

In reply to these observations, Ballo (*ibid.* iv. 294) states that he did not observe any formation of the solid substance, even when the temperature of the above liquid was lowered to -18° , which can be effected by cooling the bisulphide and alcohol with a mixture of ice and salt, and at the same time directing the air-blast on the liquid. If a layer of water be substituted for the alcohol, the formation of the hydrate of carbon bisulphide takes place at a temperature much higher than -18° .

The crystalline compound was likewise formed when air saturated with vapour of carbon bisulphide was passed through a tube cooled by a freezing mixture to -15° ; no crystals were obtained, however, when air dried by calcium chloride was employed.

Ballo further remarks, that the solid substance obtained by Wartha by the sudden evaporation of a mixture of carbon bisulphide and ether by means of the air-pump, has not been shown to be free from water.

2. Pentacarbon Bisulphide, C_5S_2 (?).—A substance having this composition is formed, according to L. Raale (*N. Repert. Pharm.* xix. 449), by the action of sodium on carbon bisulphide. The sodium becomes covered with a black easily separable crust which dissolves with red colour in water, and on treating the solution with chlorine or with an acid, a yellowish-brown, and afterwards a red-brown precipitate is formed. This precipitate dissolves in alkalis, ammonia, baryta-water, nitric acid, aqua regia, potassium cyanide, and sodium sulphate, but not in carbon bisulphide, alcohol, or ether. It begins to melt at 135° , and if then left to cool, forms an amorphous, nearly black, resinous, brittle mass, translucent with red colour on the edges. At 150° it decomposes, emitting extremely fetid yellow vapours. It gave by analysis 47.73 p.c. carbon and 62.27 sulphur, the formula C_5S_2 requiring 48.38 and 61.62.

CARBON SULPHOBROMIDE, CSBr_2 , appears to be formed as an intermediate product in the preparation of carbon tetrabromide by the action of bromine and bromide of iodine on carbon bisulphide (p. 258). On pouring the product of this reaction into water, removing the iodine and excess of bromine by cautious addition of dilute soda-solution, taking care that the liquid never became alkaline (otherwise nothing but tetrabromide would have been obtained), a slightly-coloured heavy oil separated, which, when dried by calcium chloride and submitted to fractional distilla-

tion, passed over for the most part between 150° and 160° , though with considerable decomposition. The portion boiling at 165° gave 7.81 p. c. sulphur, whereas the formula CSBr_2 requires 15.69 p. c.; hence it would appear that the oily liquid consisted of carbon sulphobromide mixed with the tetrabromide. The sulphobromide smells like the corresponding sulphochloride. Heated with excess of soda-solution, it is completely converted into the tetrabromide (Bolas & Groves, *Chem. Soc. J.* [2] x. 78).

CARBON SULPHOCHLORIDES.—*Sulphocarbonyl chloride*, CSCI_2 , the analogue of phosgene, was discovered by Kolbe, who obtained it by the action of dry chlorine on carbon bisulphide (1st Suppl. 777). Another sulphochloride CSCI_4 , which may be regarded as perchloromethyl-mercaptan CCl_3SCI , is formed, together with trichloromethyl-sulphurous chloride CCl_3SO_2 (v. 559), by the action of moist chlorine on carbon bisulphide, or by digesting the bisulphide for several days with a mixture of manganese dioxide and hydrochloric acid; the action may be considerably assisted by addition of a little iodine; it is then completed in a week. On distilling the product, a yellow oil passes over, partly with the aqueous vapour, and afterwards trichloromethyl-sulphurous chloride solidifies in the receiver. The oil dried with lime and submitted to fractional distillation, yields, below 80° , carbon bisulphide, carbon tetrachloride, and a small quantity of sulphocarbonyl chloride, and between 80° and 140° a mixture of the preceding products with an oil the greater part of which distils between 140° and 150° ; and from this by further fractionation, perchloromethyl-mercaptan CCl_3S , boiling at 147° (corr.) may be isolated. This compound has a golden yellow colour, and a pungent, tear-exciting odour like that of sulphocarbonyl chloride. In moist air, and more quickly by heating with water, it is decomposed in the manner represented by the equation:

similarly by aqueous potash or ammonia; in the latter case ammonium sulphocyanate is likewise formed, together with a small quantity of a compound not yet examined, containing sulphur and nitrogen. When left for two or three weeks in contact with nitric acid (sp. gr. 1.2) it is converted into trichloromethyl-sulphurous chloride. Solution of potassium iodide acts upon it even in the cold, with evolution of gas, separation of iodine, and formation of hydriodic acid and a yellow glutinous solid body. Heated to 200° it is resolved into carbon tetrachloride, together with small quantities of sulphocarbonyl chloride and sulphur chloride (Rathko, *Deut. Chem. Ges. Ber.* iii. 858).

CARBONATES. *Ammonium Carbonates* (Divers, *Chem. Soc. J.* [2] viii. 171). There are three, if not four, true carbonates of ammonium: the normal or diammoniac carbonate, the acid or monammoniac carbonate, the half-acid ammonium carbonate, and probably a hyper-acid carbonate which Rose obtained crystallised from aqueous solution.

The normal carbonate appears to have been obtained by Dalton, but his account of it is imperfect, and has been either ignored or discredited by other chemists. Its production in the solid state presents no difficulty. It may be prepared in large crystals by adding ammonia to a warm concentrated solution of the ordinary carbonate, provided that an excess be added and not merely the calculated quantity as directed by Dalton—the presence of the ammonia serving to diminish very considerably its solubility. Another method of preparing it, also in large crystals, is to warm some water repeatedly with fresh quantities of the ordinary carbonate, and allow the solution to cool and crystallise between the additions of the carbonate, until the cold mother-liquor from the last crop of crystals, on further standing, forms crystals of the normal carbonate. In this process the first crops of crystals consist of acid carbonate, and the later ones of the half-acid carbonate. The cold mother-liquor yielding the normal carbonate on standing has been ascertained to be a solution of carbamate; and this gradually becomes converted into the carbonate. The normal carbonate can also be obtained in several other ways.

It forms elongated plates or flattened prisms, which decompose very rapidly on exposure to ammonia, water, and the acid carbonate. Its composition is expressed by the formula $\text{CO}(\text{OH})_2(\text{NH}_4)_2 = \text{CO}(\text{NH}_4)_2\text{OH}_2$ or $\text{CO}(\text{NH}_4)_2\text{H}_2$. It is freely soluble in water, insoluble in alcohol, and only sparingly soluble in ammonia-water. Digested for some time in the most concentrated solution of ammonia at a temperature of 20° – 25° in a closed vessel, it is gradually dissolved and converted into ammonium carbamate, which separates in brilliant crystals when the solution is allowed to cool.

The half-acid carbonate contains only four atoms of water instead of six, as hitherto supposed, its formula being $(\text{CO})_2(\text{OH})_2(\text{NH}_4)_2 = \text{CO}(\text{NH}_4)_2\text{OH}_2 + \text{CO}_2(\text{OH})_2(\text{NH}_4)_2$. A new and advantageous method of preparing it is the already described of dissolving at a gentle heat successive quantities of the

carbonate in the same quantity of water until the crops of crystals obtained cease to consist of the acid carbonate. There are also other new ways of obtaining it.

There are several reasons for supposing that the formula of the acid carbonate ought to be $(\text{CO}_2)(\text{OH})^2(\text{NH})^2$ instead of the half of this—the formula usually given to it. The relations of the three carbonates are exhibited in the following table:—

Normal carbonate	$(\text{CO}_2)(\text{OH})^2(\text{NH})^2$
Half-acid "	$(\text{CO}_2)(\text{OH})(\text{NH})$
Acid "	$(\text{CO}_2)(\text{OH})^2(\text{NH})^2$

Rose's hyper-acid carbonate probably forms the fourth member of this series.

A normal orthocarbonate, $\text{CO}_2(\text{NH})^2$, appears to exist; for the commercial carbonate mother-liquor which has just deposited the half-acid carbonate, contains more than 2 mols. of ammonia to one of carbon dioxide, and must therefore, in all probability, be a solution of the half-acid (meta) carbonate and the normal orthocarbonate.

When any of the true ammonium carbonates or the commercial carbonate are distilled, not too slowly, the principal product is the substance $(\text{CO}_2)(\text{OH})^2(\text{NH})^2$ identical with the carbonate now occurring in commerce. When first obtained it is always moist from adhering water. In a day or two this moisture becomes combined with the carbamate of the salt, and often before doing so it serves to fix a little ammonia upon the acid carbonate of the salt. The per-centage numbers given by analysis, and certain of its reactions, place beyond doubt the correctness of the above formula for the commercial carbonate, although it contains 1 p. c. or so of water in excess, and often also a very little ammonia from the cause just stated. Besides the fact, that a body of this composition is formed under a variety of conditions, there is another serving to establish that the commercial carbonate is a single substance. This is that acid potassium carbonate appears to combine with ammonium carbamate and form a compound analogous to the commercial carbonate of ammonia.

When sal-ammoniac and chalk are distilled together, the products are not those stated in the text-books, namely, ammonia, water, and the carbonate of commerce, but water and ammonium carbamate. The production of the commercial carbonate occurs during the re-distillation of the crude cake. E.D.

Calcium Carbonate.—Experiments on the dimorphism of this compound have been made by H. Credner (*Jahrbuch f. Mineralogie*, 1871, 288), from which the following results are deduced:—

1. From a pure and cold solution of calcium bicarbonate, when saturated or moderately dilute, the normal carbonate separates at ordinary temperatures as calcspar, in the form of the fundamental rhombohedron; from more dilute solutions as prismatic aragonite.

2. The calcspar deposited from a cold solution of bicarbonate to which potassium silicate has been added, is remarkably transparent, well defined, and exhibits numerous faces. Credner had previously noticed that it is from association with apophyllite that certain calcspars of Andreasberg and Lake Superior derive their complex form. Similar results are obtained when sodium silicate or a mixture of the two silicates is used.

3. From a cold solution of the carbonates of calcium and strontium in carbonated water, the two being dissolved together, acicular or prismatic aragonite separates, even when the solution is moderately dilute. Calcium bicarbonate, to which strontium bicarbonate has been added, or introduced by dialysis, gives acicular and wedge-shaped aragonite, accompanied with crystals of calcspar, the latter increasing in number as the admixture of strontium is reduced. The spectroscopic shows the presence of a trace of strontium in the aragonite; in short, such results place it almost beyond doubt that a trifling proportion of strontium is of influence in the formation of aragonite.

4. The addition of a solution of gypsum to cold bicarbonate disposes a portion of the latter to take the form of aragonite.

5. In presence of a sufficient quantity of lead salt, calcium carbonate crystallises in the form of aragonite. This is seen in nature in the case of tarnovskite. If, however, the amount of lead carbonate present is small, the calcium carbonate separates as calcspar, with greater numbers of faces.

The general conclusions deducible from these observations are:—I. The addition of certain bodies to a solution of a mineral substance exerts an influence on the form and the number of faces of a crystal deposited from it. II. By the presence of certain bodies in its solution, one and the same mineral substance may receive an impulse to form totally different mineral species. III. Calcium carbonate, which separates from cold, pure, and not too dilute solutions of the acid carbonate, as calcspar, is deposited partly in the form of aragonite, on the addition of trifling quantities of lead carbonate, calcium sulphate, or strontium carbonate. IV. Differences in temperature and degree

of concentration of solution are not the only causes of the dimorphism of calcium carbonate.

Hydrated Calcium Carbonate, $\text{CaCO}_3 \cdot 5\text{H}_2\text{O}$. — Crystals of this hydrate, which Pelouze obtained from a solution of lime in sugar-water, and Salm-Horstmar observed in a water-pipe (1st Suppl. 781), have also been found attached to conifers in a pond. This hydrate is distinguished by losing its water at temperatures above 15° even when immersed in water (Rammelsberg, *Deut. Chem. Ges. Ber.* iv. 469).

On the solubility of Calcium Carbonate in Carbonic acid water, see Schloosing (*Compt. rend.* lxxiv. 1152; *Chem. Soc. J.* [2] x. 788).

Sodium Carbonate. — Efflorescences, called by the natives *Coollpa* (pronounced *Koichpa*), are deposited in dry places in the bed of the Rio de Hualfin (Argentine province Chlamarea) which flows from the Sierra de Galampaja, especially in winter when the stream is slow; they are used by the natives for washing and for making soap. A specimen which had been kept for four years in a corked bottle, gave by analysis 21.475 p.c. H_2O , 24.142 CO_2 , 25.985 Na_2O , 0.538 K_2O , 6.307 NaCl , 1.924 SO_3 , 5.788 clay and sand, and 0.554 organic matter, with traces of magnesia and lime, numbers which, neglecting the sodium chloride and other extraneous matters, lead to the formula $\text{Na}_2\text{CO}_3 + 2\text{H}_2\text{O}$. A recent specimen, on the other hand, gave 31.934 p.c. H_2O , 23.939 CO_2 , 34.647 Na_2O , 3.484 NaCl , 0.845 SO_3 , 0.264 MgO , 4.492 clay and sand, and 0.089 organic substance, leading to the formula $\text{Na}_2\text{CO}_3 + 3\text{H}_2\text{O}$ (Schickendanz, *Ann. Ch. Pharm.* clv. 359).

CARBONYL CHLOROPLATINITE. See PLATINUM COMPOUNDS.

CARBONYL-DIACETIMIDE, $\text{C}^6\text{H}^2\text{N}^2\text{O}^3$ = $\text{CO} \begin{cases} \text{NH}(\text{COCH}^3) \\ \text{NH}(\text{COCH}^3) \end{cases}$, is formed

by heating acetamide to 50° with liquid carbonyl-chloride.

It crystallises in rhombic needles; water and alcohol dissolve it, but slowly in the cold, freely at a higher temperature. It melts when heated and sublimes without decomposition. By boiling with concentrated acids it is decomposed into ammonia and acetic acid, and when boiled for a long time with potash-solution it yields carbon dioxide and acetamide (E. Schmidt, *J. pr. Chem.* [2] v. 35).

CARBONYL-DIBENZAMIDE, $\text{C}^{13}\text{H}^{12}\text{N}^2\text{O}^3$ = $\text{CO} \begin{cases} \text{NH}(\text{COC}^6\text{H}^5) \\ \text{NH}(\text{COC}^6\text{H}^5) \end{cases}$, is

formed in like manner when phosgene and benzamide are heated together to 160° – 170° . It is sparingly soluble in water, more freely in alcohol, and crystallises in fine silky needles. With concentrated acids and with alkalis, at the boiling heat, it reacts like carbonyl-diacetamide (Schmidt).

CARBONYL-DIBIURET, $\text{C}^8\text{H}^6\text{N}^6\text{O}^3$ = $\text{CO} \begin{cases} \text{NH.CO.NH.CO.NH}^2 \\ \text{NH.CO.NH.CO.NH}^2 \end{cases}$, is

formed by heating biuret with liquid phosgene to 60° for twelve hours:

Carbonyl-dibiuret is a light, white crystalline powder, which is a little more soluble in water than carbonyl-urea, but almost insoluble in alcohol. It is soluble in alkalis and strong acids. When heated on platinum-foil it decomposes into carbon dioxide, ammonia, and cyanic acid, and when it is slowly heated in a small flask, ammonia and carbon dioxide are given off, and a residue containing urea, cyanuric acid, and ammelide is left behind.

On passing nitrous acid through a warm solution containing an excess of carbonyl-dibiuret, carbon dioxide is evolved, and as the liquid cools, urea nitrate crystallises out, mixed with a little cyanuric acid and ammonium nitrate. On boiling it with concentrated hydrochloric acid or potash-solution it decomposes into ammonia, carbon dioxide, and cyanuric acid, whilst when boiled with baryta water, it yields carbon dioxide, cyanuric acid, and urea. Like carbonyl-urea it combines only with metallic oxide; the compound $\text{C}^8\text{H}^6\text{N}^6\text{O}^3 \cdot 3\text{HgO}$ is a white bulky powder.

By the further action of phosgene upon carbonyl-diuret, it is resolved into two mols. of cyanuric acid: $C^3H^4N^4O^3 + COCl^2 = 2HCl + 2C^3H^2N^4O^3$. (Schmidt).

CARBONYL-UREA, or **CARBONYL-DICARBAMIDE**, $C^3H^4N^4O = NH.CO.NH^2$, is obtained by heating urea with excess of liquid phosgene to 100° for two days:

It is a bulky white powder composed of microscopic needles, very slightly soluble in cold, more freely in boiling water, almost insoluble in cold alcohol. Heated on platinum-foil, it is resolved into ammonia and cyanic acid. When heated slowly in a test-tube, it yields ammonia and cyanuric acid. It is soluble in concentrated acids, but does not combine with them. Neither does it form compounds with salts or bases, with the exception of mercuric oxide. The compound $C^3H^4N^4O^3.HgO$ is obtained as a crystalline precipitate, which is insoluble in water, and decomposed by dilute acids.

Carbonyl-urea is further acted upon by phosgene when the two substances are heated up to 150°–160°, hydrochloric acid being formed, together with a crystalline body, which is a mixture of dicyanic and tricyanic (cyanuric) acids (Schmidt).

CARBOTHIALDINE, $C^3H^4N^4S^2$.—This compound was obtained by Liebig & Redtenbacher by the action of carbon bisulphide on aldehyde-ammonia (1st Suppl. 802). It cannot be crystallised from water or alcohol, but is deposited in magnificent crystals from solution in concentrated aqueous ammonia. It is decomposed by iodine, nitrous acid, and mercuric chloride, yielding aldehyde, carbon bisulphide, ammonia and ammonium sulphocyanate. When 1 mol. mercuric chloride is heated with 1 mol. carbothialdine in aqueous or alcoholic solution, the whole of the mercury is quickly precipitated as sulphide, while aldehyde, sal-ammoniac, hydrochloric acid and sulphocyanic acid are produced. But when a large excess of mercuric chloride is used, a white precipitate is formed which becomes crystalline on boiling, without the production of a trace of aldehyde.

CARBOXAMIDO BENZOIC ACID. See BENZOIC ACID (p. 166).

CARMINE. See COCHINEAL.

CARNINE, $C^3H^4N^4O^3$. Weidel (*Ann. Ch. Pharm.* clviii. 353).—A base obtained from extract of meat, of which it constitutes about 1 p.c. To prepare it, the extract is dissolved in 6 or 7 parts of warm water, and carefully precipitated with strong baryta-solution, avoiding excess: the mass is filtered through a linen cloth, and the filtrate precipitated by basic lead acetate. A lead-compound of carmine is thus thrown down, and being soluble in boiling water, can thus be separated from the other bodies likewise precipitated. The aqueous solution thus obtained is decomposed while boiling with hydrogen sulphide, and the filtrate from the lead sulphide is evaporated to a small bulk and separated from a crystalline mud, sometimes deposited on standing, and due to the presence of variable quantities of sodium chloride in the extract employed, whereby ultimately more or less hydrochloric acid is formed in the crude carmine solution: the liquid portion is precipitated by strong solution of silver nitrate; and from the mixed silver chloride and silver-compound of carmine thus produced, the former is dissolved out by diluted ammonia-solution, the latter being almost insoluble in that medium: finally, the silver compound is washed with boiling water, decomposed by hydrogen sulphide, and the filtrate decolorised with animal charcoal, a considerable portion of carmine being, however, absorbed by the charcoal. From the colourless aqueous solution thus obtained, carmine crystallises on cooling in chalk-white druses and friable groups of extremely small irregular crystals, containing 1 mol. water ($C^3H^4N^4O^3.H^2O$) which is given off at 100°.

The hydrochloride $C^3H^4N^4O^3.HCl$ is obtained in needles on cooling the hot solution of carmine in strong hydrochloric acid; these needles, freed from the mother-liquor and redissolved, do not again make their appearance, a mud separating, which, however, on standing, again becomes perfectly converted into needles; the salt is anhydrous. The platinochloride has the composition $2(C^3H^4N^4O^3.HCl).PtCl^4$.

Silver nitrate throws down from a carmine solution a flocculent white precipitate, which is insoluble in nitric acid and in ammonia, and when dried at 100° has the composition $2C^3H^4AgN^4O^3.AgNO^3$; theobromine, which differs from carmine by only one oxygen-atom, does not yield an analogous body, its silver compound being $C^3H^4AgN^4O^3$; sarcosine, on the other hand, yields the compound $C^3H^4N^4O^3.AgNO^3$.

Concentrated hydriodic acid does not reduce carmine to theobromine; neither does

long boiling with baryta-water produce any change (no ammonia or methylamine is evolved, and unaltered carnine is found after precipitating the baryta with carbonic acid).

With bromine-water in slight excess on the water-bath, carnine gives a slight evolution of gas; after evaporation, crystals of the hydrobromide of sarcine separate, from which alkalis precipitate the base itself, soluble in excess, but nearly insoluble in cold water. From analyses of the base and its hydrobromide, and from its properties, it appears to be identical with Strecker's sarcine (v. 196), the only observed difference being that, whereas Strecker states that his sarcine is not precipitated by basic lead acetate, the base obtained as above is precipitable by basic lead acetate, though not by neutral lead acetate, or even by the basic lead salt in presence of the neutral salt. Strecker's statement is, however, in contradiction to the fact that Städeler also has prepared sarcine from the basic lead precipitate from flesh, liver, &c.

Ordinary nitric acid, heated with carnine, gives rise to a violent action, from the product of which the nitrate of sarcine is obtained on cooling: oxalic acid and an indistinctly crystalline yellow body are also produced.

as either

and the production of sarcine from carnine by bromine appears to be in accordance with the equation

Bromacetic acid might possibly be formed at the same time; but this body was not distinguishable in the ethereal extract obtained with the product of the action of bromine.

When sarcine is heated with fresh chlorine-water and a trace of nitric acid, and the solution is evaporated on the water-bath to dryness, and placed in an ammoniacal atmosphere, a dark rose-red tint is produced; carnine gives the same reaction, sarcine being previously formed.

The barium precipitate obtained in the method of extracting carnine from meat-extract, as above described, is principally phosphate and sulphate; the portion of the lead precipitate insoluble in water contains inositol, a little lactic acid, and some succinic acid; and especially an amorphous extractive matter, part of which only is soluble in alcohol. The filtrate from the original lead precipitate yields, when evaporated, a crystalline lead lactate, and the filtrate from this, when evaporated, yields much creatine with a little creatinine, the mother-liquor of which contains considerable quantities of glutinous and dextrin-like substances.

Doses of $\frac{1}{2}$ to 2 decigrams of carnine and its hydrochloride appear to have a slight effect on the nervous system, a slackening of pulsation being the most marked symptom.

CARVOL. See OILS, VOLATILE.

CASHEIN. See PROTEIDS.

CASSIA OIL. See OILS, VOLATILE.

CASTOR OIL. This oil rotates a ray of polarised light. 10 p. c. solutions of pure Italian and Ostend castor oil in absolute alcohol gave, as a mean result, a direct deviation of 10° to the right, which gives as the specific rotatory power of castor oil, $(\alpha) = +12.15^\circ$. This behaviour of castor oil may be used as a test of its purity, although the specific rotatory power is too small to allow small quantities of adulteration to be detected. Castor oil also contains a constant quantity of nitrogen, which may be due to the presence of an alkaloid. It is possible indeed, that not only the purgative properties, but also the circular polarisation, are due, not to the oil itself, but to the presence of this alkaloid (Popp. *Arch. Pharm.* [2] cxlv. 233).

CATHARTIN. This substance, extracted from senna by Lassaigne & Berthelot (1st Suppl. 817), and by them regarded as the active principle of the plant has

lately been examined by Bourgoïn (*Compt. rend.* lxxiii. 1449), who finds that it is a mixture of three distinct substances, viz.:—

1. *Chrysophanic Acid*.—Obtained by exhausting crude cathartin with ether; it is present but in small quantity in senna, but may be at once rendered evident by the formation of a characteristic red colour on the addition of ammonia to an aqueous infusion of the leaves.

2. *A dextro-rotatory Glucose*.—Cathartin freed from the above acid yields with water a limpid solution, possessing the following properties: (1.) It ferments in contact with yeast, giving carbonic anhydride and alcohol. (2.) It reduces a cupropotassic solution. (3.) Freed from chrysophanine and colouring matter, it rotates a ray of polarised light to the right. This glucose may be isolated by precipitating with basic lead acetate, and evaporating to dryness after removing the dissolved lead.

3. *Chrysophanine*.—Obtained by adding lead acetate to a strong infusion of senna, after the removal of the mucilaginous matter by alcohol, decomposing the precipitate with hydrogen sulphide, evaporating the liquid to a syrup, treating the syrup with alcohol, dissolving the residue in water, reprecipitating with alcohol, and then drying over sulphuric acid. Thus obtained it is almost white.

CELLULOSE. The solubility of this substance in ammoniacal copper-solution has been made available for the preparation of water-proof paper, artificial wooden slabs, &c.

When linen rags or wood sawdust are fully dissolved in ammoniacal copper-solution, and the solution then allowed to evaporate to dryness, a semi-transparent, brittle glass is left. But if the action of the solvent be prevented from effecting more than a commencing superficial solution, in which the fibres maintain their original form and disposition, a very tough material is obtained. A sheet of paper, left only an instant in the ammoniacal copper-solution, and then passed between rollers and dried, becomes quite impervious to water, and does not lose its power of cohesion at the boiling heat. Two sheets of paper thus treated adhere firmly together, and form one piece, and by treating a large number of sheets of paper in the same manner, artificial boards are produced. Linen pieces thus treated furnish a very elastic material of great cohesive power. By treating linen and paper together in this manner, a material is obtained of great firmness and strength, which is said to be well adapted for making roofing tiles, gas and water pipes, articles of clothing, and even for boats (*Dingl. polyt. J.* ccliv. 514).

Animal Cellulose.—Schäfer (*Ann. Ch. Pharm.* clx. 312), from his analyses of the mantles of the *Pyrosomida*, *Salpida*, and *Phallusia mamillaris*, finds that the cellulose, or tunica (v. 918) derived from them is identical with vegetable cellulose. The mantles, after being boiled in a Papin's digester to remove chondrigen, were treated with dilute hydrochloric acid to remove the inorganic constituents. These consisted of calcium sulphate, sodium sulphate, and traces of iron, calcium carbonate, and calcium phosphate. The mantles were then boiled for several days in a saturated solution of caustic potash, and subsequently washed with alcohol and water. The mantles so treated retained their original form, but had become transparent like glass, but not horny, as Berthelot found in *Cynthia papillata*. The substance thus obtained is quite free from nitrogen, and contains 44.09 p. c. carbon, 6.30 hydrogen, and 49.61 oxygen.

With iodine and sulphuric acid it gives a violet colour like vegetable cellulose. It is soluble in ammonio-cupric oxide, from which it is precipitated like cellulose by acids. The precipitate is soluble in dilute hydrochloric acid, and gives the cellulose reaction with iodine and zinc chloride. It is converted into sugar by prolonged heating with dilute sulphuric acid in closed tubes. Like vegetable cellulose, it is converted into pyroxylin by the action of fuming nitric acid. The mantles so converted into pyroxylin retain their form, but are very brittle. They are soluble in ether, which on evaporation leaves a film like the ordinary collodion film. These reactions leave little doubt of the complete identity of animal and vegetable cellulose.

CEMENTS. A good cement for broken glass and porcelain basins may be prepared by soaking half an ounce of isinglass in distilled water, then pouring off the water, and adding so much alcohol as just to cover the isinglass, the solution being promoted by heat. A quarter of an ounce of mastic is then dissolved in three quarters of an ounce of alcohol; the two solutions are mixed; a quarter of an ounce of powdered gum-ammoniac is added; and the mixture, after being well shaken, is evaporated in a water-bath to the consistence of strong glue. The cement thus prepared is poured into a glass in which it soon solidifies to a jelly, and is then ready for use. It is warmed just before using, and is applied with a brush to the perfectly clean, warm, fractured surface; it hardens in 24 hours (*Dingl. polyt. J.* ccliv. 344).

Hydraulic Lines and Cements.—Roman and Portland Cements are compounds of

alumina, lime, and silica in closer or looser combination according to the temperature at which they have been burnt. Besides the constituents above named, magnesia, potash, soda, and generally sulphuric and phosphoric acids are also present. Of these subsidiary bodies, sulphuric acid (as gypsum) is so hurtful to the quality of the cement, that if a sample contains any considerable quantity—even 3 p. c.—it should be rejected. The gypsum is burnt dead at the temperature employed in making the cement, and does not combine with water until after the rest of the mass has hardened, and then, as it slowly takes up water and expands, it causes the whole to crumble. Much magnesia seems also to injure the quality, but a moderate proportion of soda improves it (C. Bender, *Dingl. polyt. J.* cii. 254).

Wartha (*ibid.* ciii. 527) found that the hardening power of a natural hydraulic lime, made from a somewhat siliceous marl, was not impaired by mixing it with even 15 p. c. of nearly pure unslaked lime, but that when ferruginous siliceous lime was added, the mass, after binding, fell to powder when immersed in water. This effect appears to be due to the circumstance that the slaking of the impure dead-burnt lime does not take place till after the cement has set, and that the consequent swelling causes the mass to break up.

According to Knapp (*ibid.* ciii. 513) the hydraulic properties of a cement depend as much on its mechanical state as on its chemical composition. Schott has shown that the coarse, sandy parts of Portland cement have but slight power of hardening under water, but if they be rubbed to a fine powder, this powder exhibits all the properties of the original fine cement.

The so-called Scott's Cement.—It was observed some years ago by Captain H. Scott that quicklime heated to redness in the vapour of burning sulphur lost its power of slaking, but acquired the property of gradually hardening when stirred up in water. F. Schott (*Dingl. polyt. J.* ciii. 52) has examined the mode of formation of the cement thus produced, with the view of determining the nature of the compound formed, and the best mode of preparing it. His principal results are: that cold dry lime does not absorb cold dry sulphur dioxide, but that at a red heat complete absorption takes place without evolution of gas; that when sulphur dioxide is passed over red-hot lime contained in a tube, combination takes place, attended with evolution of light and heat, the product being a mixture of sulphate and sulphide of calcium, with excess of lime in uncertain proportion; that when calcium sulphite is heated to moderate redness, it is resolved into sulphate and sulphide, according to the equation $4\text{CaSO}_3 = 3\text{CaSO}_4 + \text{CaS}$, forming a mass devoid of hydraulic properties, but that when heated to whiteness it sinters, leaving a mass containing only about half the sulphur required by the above formula, and capable of hardening under water.

A mass having all the properties of Scott's cement may be prepared by strongly igniting a mixture of gypsum and lime, in the proportion of 2 mols. of the former to 3 mols. of the latter. The cement so formed is the better the higher the temperature at which it has been formed, and the less calcium sulphite it contains.

Cement-stone found near Jena.—This stone, which is largely used for the manufacture of cements, contains about 90 p. c. of matter, chiefly earthy carbonates, soluble in hydrochloric acid. The composition of the soluble portion is as follows:

CaCO_3	MgCO_3	CaSO_4	FeO	FeO	MnO	Na_2O	K_2O	SiO_2	H_2O
49.84	26.96	0.36	3.83	4.17	0.22	0.40	0.35	2.96	0.66 = 89.75.

These numbers show that the dolomitic constituents of the stone may be nearly represented by the formula $2\text{MgCO}_3 \cdot 3\text{CaCO}_3$.

The residue, insoluble in hydrochloric acid, after being freed from soluble silica by digestion in sodium carbonate was found to contain:—

Potassium Silicate	Sodium Silicate	Calcium Silicate	Magnesium Silicate	Ferric Silicate	Aluminium Silicate	Sand
0.26	0.47	2.01	0.16	0.95	3.04	3.26 = 10.45

The oxygen ratio in the metallic oxides and the silica, viz., $\text{RO} : \text{R}'\text{O}_2 : \text{SiO}_2 = 1 : 2.7 : 3.8$ leads to the formula $\text{RO} \cdot \text{SiO}_2 + \text{R}'\text{O}_2 \cdot \text{SiO}_2$, which is that of zeolite, natrolite and labradorite (E. Reichardt, *Dingl. polyt. J.* cc. 219).

CERITE METALS. The atomic weights of these metals have lately been discussed by Mendeleeff in his paper 'Ueber die periodische Gesetzmässigkeit der chemischen Elemente,' (*Ann. Ch. Pharm. Suppl.* viii. 186). For the atomic weights hitherto received, viz. $\text{Ce} = 92$, $\text{La} = 92$, $\text{Di} = 95$, he proposes to substitute $\text{Ce} = 138$, $\text{La} = 180$, $\text{Di} = 138$. His reasons for proposing this change are founded chiefly on the differences between the observed properties of these metals and those which, if their received atomic weight were correct—they might be expected to have according to Mendeleeff's system of classification of the elements (see ELEMENTS).

With regard to cerium in particular, Mendelejeff points out that there are but two known oxides of this metal, not three, as usually stated, the so-called ceric oxide ($\text{Ce}^{\text{IV}}\text{O}_2$) being purely hypothetical, as it has never been obtained in the separate state, and no salts corresponding with it in composition are known. The two known oxides CeO and CeO^{II} , according to the atomic weight $\text{Ce} = 92$, become $\text{Ce}^{\text{IV}}\text{O}_2$ and CeO^{II} or Ce_2O_3 , if the proposed atomic weight 138 is adopted. Mendelejeff has made a determination of the specific heat of cerium (semifused and dried in hydrogen), which he finds to be 0.050. This number multiplied by 138 gives, for the atomic heat the product 6.9, which is much nearer to the mean value of the atomic heats of the elements, than that obtained with the commonly received atomic weight of cerium, viz. $0.05 \times 92 = 4.6$.

On the other hand, Rammelsberg (*Deut. Chem. Ges. Ber.* vi. 81) objects to the proposed change: (1). Because if there are but two oxides of cerium, CeO and CeO^{II} (or $\text{Ce}^{\text{IV}}\text{O}_2$ and CeO^{II}) these oxides will exhibit the unusual oxygen-ratio 3 : 4. (2). If the higher oxide is to be regarded as an independent oxide CeO^{II} (or Ce_2O_3) and not as a compound of monoxide and sesquioxide, $\text{CeO} \cdot \text{Ce}_2\text{O}_3$, it ought to form analogous salts, e.g. $\text{Ce}^{\text{IV}}(\text{SO}_4)^4$ or $\text{CeO}^{\text{II}} \cdot 4\text{SO}_3$, or $\text{Ce}^{\text{IV}}\text{SO}_4 \cdot (\text{CeO}^{\text{II}})^3(\text{SO}_4)^3$, whereas in nearly all the known ceroso-ceric salts, the proportion of Ce^{IV} and $(\text{CeO}^{\text{II}})^3$ is different from this (v. 586); thus the ceroso-ceric sulphate which crystallises in brown-red hexagonal forms, has the composition $\text{Ce}^{\text{IV}}\text{SO}_4 + 18 \text{ aq.}$, or $\frac{3\text{CeO}^{\text{II}}}{\text{Ce}^{\text{IV}}(\text{SO}_4)_3} + 18 \text{ aq.}$

The reduction of the higher to the lower oxide of cerium is regarded by Mendelejeff as analogous to that of TiO^{IV} to $\text{Ti}^{\text{III}}\text{O}_2$; but ceroso-ceric oxide is reduced to cerous oxide by hydrochloric acid, with evolution of chlorine, which is not the case with titanic oxide. Cerous oxide decomposes solution of sal-ammoniac, an effect not produced by sesquioxides, $\text{M}^{\text{III}}\text{O}_3$. Lastly ceroso-ceric oxide crystallises in the regular system, like most oxides of the form $\text{MO} \cdot \text{M}^{\text{III}}\text{O}_3$, whereas, according to Mendelejeff's formula CeO^{II} , it should be isomorphous with TiO^{IV} and ZrO^{IV} .

For didymium and lanthanum Mendelejeff proposes the atomic weights $\text{Di} = 138$, $\text{La} = 180$, giving to the respective oxides the formulae $\text{Di}^{\text{IV}}\text{O}_2$ and LaO^{III} , whereas both are usually regarded as monoxides. In favour of the dissimilar formulae of these oxides, Mendelejeff adduces the fact, communicated to him by Marignac, that none of the corresponding salts of didymium and lanthanum are isomorphous; that didymium sulphate separates easily and nearly pure from a mixed solution of the two sulphates; and that the formulae commonly given to these sulphates are not analogous, that of the didymium salt being $3\text{DiSO}_4 \cdot 8\text{H}_2\text{O}$, and that of the lanthanum salt $\text{LaSO}_4 \cdot 3\text{H}_2\text{O}$. The unusual formula $3\text{DiSO}_4 \cdot 8\text{H}_2\text{O}$ will be changed according to Mendelejeff's atomic weight, into $\text{Di}^{\text{IV}}(\text{SO}_4)^4 \cdot 8\text{H}_2\text{O}$. That the dissimilarly constituted oxides CeO^{IV} , $\text{Di}^{\text{IV}}\text{O}_2$, LaO^{III} should constantly occur together in nature, need occasion no surprise, inasmuch as many similar cases are known, e.g. the simultaneous occurrences of $\text{Nb}^{\text{IV}}\text{O}_5$ and TiO_2 , of $\text{W}^{\text{VI}}\text{O}_3$ and $\text{Nb}^{\text{IV}}\text{O}_5$, and of $\text{V}^{\text{V}}\text{O}_5$ and CrO_3 .

On the other hand, Rammelsberg states, as the result of his own observations, that sulphate of didymium is isomorphous with the sulphates of yttrium and cadmium, the general formula of these sulphates being $3\text{R}^{\text{III}}\text{SO}_4 + 8 \text{ aq.}$; hence he infers that, according to Mendelejeff's view, cadmium oxide should also be a sesquioxide $\text{Cd}^{\text{III}}\text{O}_3$; and since greenockite, wurtzite, and cinnabar are also isomorphous, the oxides of zinc and mercury should also be $\text{Zn}^{\text{III}}\text{O}_3$ and $\text{Hg}^{\text{III}}\text{O}_3$. Rammelsberg regards the isomorphism of the three cerite metals as positively established, and hence concludes that the oxide of lanthanum must be analogous in composition to cerous oxide and didymium oxide.

According to Mendelejeff's view, however, lanthanum oxide and ceroso-ceric oxide should be isomorphous, since their formulae are LaO^{III} and CeO^{II} , whereas in reality, lanthanum oxide is trimetric, like PbO and CuO , while ceroso-ceric oxide is monometric. Again, lanthanum oxide dissolves easily in hydrochloric acid, whereas ceroso-ceric oxide dissolves slowly and with reduction. The chlorides of the cerite metals also, which, according to Mendelejeff, are $\text{Ce}^{\text{IV}}\text{Cl}_4$, $\text{Di}^{\text{IV}}\text{Cl}_4$ and LaCl_3 , are very much alike, are probably isomorphous when they crystallise with 4 aq., and are very different in character from the volatile chlorides RCl^{III} and RCl^{IV} which are decomposed by water, such as TiCl_4 and ZrCl_4 .

For all these reasons Rammelsberg is of opinion that the changes proposed by Mendelejeff in the atomic weights of the cerite metals cannot be admitted.

CERIUM. The following method of preparing pure cerium salts is given by C. Erk (*Zeitschr. f. Chem.* [2] vii. 100):—Finely powdered cerite is made into a thin paste with sulphuric acid, kept warm for several hours, and then gently heated; the white powder is then exhausted by repeated treatment with boiling dilute nitric acid; the filtered solution, after treatment with sulphydric acid, and filtration, is mixed with a little hydrochloric acid and oxalic acid; the oxalates are ignited in a platinum dish.

2nd Sup.

T

with constant stirring, and dissolved in rather strong nitric acid; the solution is evaporated to a syrupy consistence, and then mixed with a large quantity of boiling dilute sulphuric acid; and the precipitate of basic ceroso-ceric sulphate is washed with hot water as long as the washings give a precipitate with oxalic acid.

The addition of magnesia to the oxalates previous to ignition, as recommended by Bunsen and by Jögel, is unnecessary; it is also very difficult to separate the magnesia perfectly from the ignited product.

Popp's method (1st Suppl. 419), which consists in treating a solution containing cerium, lanthanum, and didymium with chlorine and sodium acetate, is efficient for the preparation of pure cerium salts, but not for the preparation of pure lanthanum and didymium compounds, on account of the easy reducibility of ceroso-ceric oxide by free acetic acid. The precipitate described by Popp as a peroxide of cerium, is according to Erk, a basic acetate.

Electrolysis of Cerium Salts.—A concentrated solution of cerous chloride subjected to the action of a Bunsen's battery of three elements gave free chlorine at the positive, and a deposit of ceroso-ceric hydrate at the negative pole. Fused cerous chloride gave, at the negative pole, small quantities of metallic cerium, together with reddish white laminae of cerium oxychloride (formed by the action of atmospheric moisture). At the positive pole (consisting of gas carbon) hydrogen chloride was evolved, a larger quantity of ceroso-ceric oxide was formed, and the resulting mass, when treated with water, gave off a very fetid gas. Strong solutions of cerous sulphate turned yellow at the positive pole, from formation of ceroso-ceric sulphate, while at the negative pole there was formed, besides a little metallic cerium, a waxy deposit of ceroso-ceric sulphate which afterwards became crystalline. The electrolysis of a neutral solution of cerous nitrate yielded, at the negative pole, a brownish yellow mass, and a quantity of ammonia sufficient to precipitate the whole of the cerium. An aqueous solution of cerous acetate yielded a basic acetate which dried up to brownish amorphous lumps. Neither of these reactions yielded an oxide of cerium higher than ceroso-ceric oxide $\text{Ce}^{\text{IV}}\text{O}^{\text{II}}$ (Erk, *loc. cit.*).

Cerous Platinochloride.—A salt having the composition $2\text{CeCl}_2 \cdot 3\text{PtCl}_4 + 8\text{H}_2\text{O}$ is described by Holzmänn (i. 333). Another containing $4\text{CeCl}_2 \cdot 3\text{PtCl}_4 + 36\text{H}_2\text{O}$ has lately been obtained by Marignac (*Ann. Ch. Phys.* [4] xxx. 65), from a solution containing excess of platine chloride. It is very soluble in water, and crystallises only from syrupy solutions, redissolving on the slightest rise of temperature. It forms dimetric crystals, P.O.P, having the angle P : P in the lateral edges = $121^\circ 40'$ to 122° and $\text{oP} : \text{P} = 106^\circ$ to $106^\circ 20'$. The crystals are orange-red, deliquesce in moist air, but effloresce in the air of a warm room during cold dry days. They give off half their water at 100° .

Marignac has also obtained platinochlorides of lanthanum and didymium, isomorphous with the cerium salt.

Oxides. When pulverised cerite is heated with strong sulphuric acid and then treated with water, an abundant evolution of hydrogen takes place; and this effect is renewed if the cerite, after the lapse of a considerable time (about a year), be again treated with the acid and water. This effect appears to be due to a power possessed by the lower oxides present in the mineral of decomposing water in presence of strong acids, whereby they are raised to a higher state of oxidation (Sonnenschein, *Deut. Chem. Ges. Ber.* iii. 632).

Ceroso-ceric oxide is a more powerful oxidising agent than most oxides represented by the formula $\text{M}^{\text{IV}}\text{O}^{\text{II}}$, and this power is attributed by Sonnenschein to the peculiar state of the oxygen contained in it. He observes that when ceroso-ceric oxide is treated with strong sulphuric acid, the odour of ozone is evolved, and the presence of ozone may be further rendered evident by its well-known reactions. The oxide forms with sulphuric acid, a brown-red solution which may be used in place of permanganate for the titration of iron, inasmuch as it is very permanent, and indicates the termination of the oxidation by a distinct change of the brown-red colour of the solution to a light salmon-colour. The same solution may be used for decomposing the excess of sulphuretted hydrogen produced in many operations of chemical analysis.

Ceroso-ceric oxide added to *strychnine* previously mixed with strong sulphuric acid, produces a fine blue colour which affords a very delicate test for the presence of *strychnine*. It does not produce the same colour with any other alkalioid, (see *ALKALIOIDS*, p. 43).

Nitrates. A solution of ceroso-ceric hydrate in nitric acid mixed with nitrate of magnesium or zinc, yields red rhombohedral crystals of a double salt, having, according to Holzmänn's analysis (*J. pr. Chem.* Lxxv. 330), the composition $2\text{Ce}^{\text{IV}}\text{N}^{\text{V}}\text{O}_6 \cdot (\text{Ce}^{\text{IV}})^{\text{II}}\text{N}^{\text{V}}\text{O}_6 + 15 \text{ aq.}$ Zschiesche, however, (*ibid.* cvii. 54) found that the

green nickel salt prepared in like manner, and crystallising in the same form, is not a ceroso-ceric but a cerous salt $\text{Ni}^{\text{N}^{\circ}\text{O}^{\circ}}\text{Ce}^{\text{N}^{\circ}\text{O}^{\circ}} + 8 \text{ aq.}$, and that analogous double salts containing cobalt and manganese may be prepared in a similar manner. He attributes Holzmänn's result to a defect in the method of analysis, which consisted in precipitating the cerium oxide directly from the solutions, washing it, and, then determining the quantity of ceric oxide present by treatment with hydrochloric acid. Now a precipitate of cerous oxide thus formed oxidises very quickly in contact with the air; but the oxidation may be completely prevented by mixing the solution before precipitation, with a large excess of sal-ammoniac, and treating the precipitate with hydrochloric acid without first drying it. Operating in this manner Zschiesche found that the double nitrates above mentioned contained only cerous, no ceric oxide. Rammelsberg has also analysed the ceroso-magnesium nitrate and finds its formula to be exactly analogous to that of the nickel salt, viz. $\text{MgN}^{\text{N}^{\circ}\text{O}^{\circ}}\text{Ce}^{\text{N}^{\circ}\text{O}^{\circ}} + 8 \text{ aq.}$ He finds that the red magnesium salt analysed by Holzmänn, and designated by Bunsen as magnesio-ceric nitrate, becomes pale yellow after one recrystallisation, and nearly colourless after two, and therefore considers that this salt owes its red colour merely to the ceric mother-liquor with which the crystals are drenched.

Basic Ceroso-ceric Acetate. The light yellow precipitate obtained in Popp's method of separating cerium from the allied metals is, according to Erk (*Zeitschr. f. Chem.* [2] vii. 115), a basic acetate having the composition $\text{C}^{\text{H}}\text{Ce}^{\text{O}}\text{O}^{\text{O}}$. It is easily soluble in water, but insoluble in dilute aqueous sodium acetate.

Cerous Oxalate dried at ordinary temperatures has the composition $\text{CeC}^{\text{O}}\text{O}^{\text{O}} + 4\text{H}^{\text{O}}$; after drying at 100° it contains $\text{CeC}^{\text{O}}\text{O}^{\text{O}} + \text{H}^{\text{O}}$. The last molecule of water cannot be expelled without decomposing the salt (Erk).

Sulphates. Marignac some years ago described a cerous sulphate, CeSO^{O} . 8H^{O} , crystallising in right rhombic octahedrons (*Recherches sur les formes cristallines de quelques composés chimiques*, Genève, 1855). Czudnowicz, on the other hand (*J. pr. Chem.* xxx. 19), obtained a trihydrated cerous sulphate in the form of hexagonal prisms; and this result was corroborated by Hermann (*ibid.* xcii. 126), who, moreover, obtained another cerous sulphate in octahedral crystals having the composition $3\text{CeSO}^{\text{O}}.8\text{H}^{\text{O}}$, analogous to that of didymium sulphate; the two salts being formed under the same circumstances, namely, by the evaporation of a solution of cerous sulphate at a gentle heat. Recent observations by Marignac (*Ann. Chim. Phys.* [4] xxx. 57) have shown that these statements are correct, and that the octahedral $\frac{8}{3}$ -hydrated salt is formed most readily by evaporation in a vacuum at ordinary temperatures—the hexagonal trihydrated crystals by evaporation in the air at 40° – 50° .

The crystals of the salt $3\text{CeSO}^{\text{O}}.8\text{H}^{\text{O}}$ have the faces $\text{P} \cdot 2\text{P}$, predominant, $\infty \text{P} \infty$, $4\text{P} \infty$, and others subordinate. The principal angles are as follow:

In the Brachydiagonal principal section	In the Macrodiaagonal principal section	In the Basal principal section
$\text{P} : \text{P} = 114^{\circ}12'$	$111^{\circ}10'$	$103^{\circ}14'$
$2\text{P} : 2\text{P} = 99^{\circ}48'$	$95^{\circ}48'$	$136^{\circ}17'$

Notwithstanding the analogy of composition between this salt and the sulphate of didymium, the two salts are not isomorphous, the crystals of the didymium salt being monoclinic.

The crystals of the hexagonal salt, $\text{CeSO}^{\text{O}}.3\text{H}^{\text{O}}$, are mostly combinations of the hexagonal prism ∞P with the pyramid P , sometimes also with $\frac{1}{2}\text{P}$, and two secondary pyramids (see CRYSTALLOGRAPHY, ii. 138). Angle $\infty \text{P} : \infty \text{P} = 120^{\circ}$ to $120^{\circ}15'$; $\infty \text{P} : \text{P} = 130^{\circ}10'$; $\infty \text{P} : \frac{1}{2}\text{P} = 112^{\circ}55'$. This salt is isomorphous with the corresponding sulphate of lanthanum.

Cerose-ceric Sulphates.—The red hexagonal crystals which separate by slow evaporation from a solution of cerose-ceric oxide in sulphuric acid, consist, according to Rammelsberg (*v.* 587), of $3\text{CeSO}^{\text{O}}.\text{Ce}^{\text{O}}(\text{SO}^{\text{O}})^3 + 18 \text{ aq.}$ Zschiesche, on the other hand, (*J. pr. Chem.* cvii. 65; *Zeitschr. f. Chem.* [2] vii. 40) assigns to them the composition, $6\text{CeO}.6\text{SO}^{\text{O}} + \text{Ce}^{\text{O}}\text{O}^{\text{O}}.3\text{SO}^{\text{O}} + 27 \text{ aq.}$, or perhaps $5(\text{CeO}.8\text{SO}^{\text{O}}) + 2(\text{CeO}^{\text{O}}.2\text{SO}^{\text{O}}) + 27 \text{ aq.}$ Rammelsberg (*Dout. Chem. Ges. Ber.* vi. 85.), from a fresh analysis of the salt in well-defined crystals, deduces the formula $3\text{CeSO}^{\text{O}}.\text{Ce}^{\text{O}}(\text{SO}^{\text{O}})^3 + 21 \text{ aq.}$, which, agrees with his earlier formula, excepting in the amount of water.

From the mother-liquors of the hexagonal salt, or from a solution of cerose-ceric hydrate in dilute sulphuric acid, there is deposited a yellow salt, not in measurable crystals, which, according to Rammelsberg, has the composition $\text{Ce}^{\text{O}}\text{S}^{\text{O}}\text{O}^{\text{O}} + 8 \text{ aq.}$ or $\text{CeSO}^{\text{O}}.\text{Ce}^{\text{O}}(\text{SO}^{\text{O}})^3 + 8 \text{ aq.}$; according to Erk it contains 14 aq.

The yellow basic salt formed from either of the preceding by the action of water, appears to lose acid by long keeping; hence the formula assigned to it (*v.* 587) viz. $2\text{Ce}^{\text{O}}\text{O}^{\text{O}}.3\text{SO}^{\text{O}} + 8 \text{ aq.}$ must be regarded as uncertain. According to Erk, this salt is

decomposed by washing with hot water, and loses all its sulphuric acid by repeated boiling with water. When washed with cold water, pressed between filter-paper, and dried over oil of vitriol, it has the composition $\text{Ce}^2\text{HSO}_4 + 2\text{aq.}$ or $2\text{CeSO}_4 \cdot \text{Ce}^2\text{O}^3 \cdot 11\text{H}_2\text{O} + 4\text{aq.}$

Compounds of the Cerium Sulphates with Luteo-cobaltic and Rosco-cobaltic Sulphate. When a hot, strongly acid solution of ceroso-cerie sulphate* is mixed with a hot saturated acid solution of luteo-cobaltic sulphate, a light yellow crystalline precipitate is formed, which the microscope shows to be made up of hexagonal prisms. After washing with a small quantity of cold water, it has the composition $12\text{NH}_4 \cdot \text{Co}^2(\text{SO}_4)^2 \cdot \text{Ce}^2(\text{SO}_4)^2 \cdot 11\text{H}_2\text{O}$. It may be heated to 150° without decomposition.

The corresponding *cerous salt* $12\text{NH}_4 \cdot \text{Co}^2(\text{SO}_4)^2 \cdot 3\text{CeSO}_4 \cdot 11\text{H}_2\text{O}$ is obtained by adding a hot concentrated solution of luteo-cobaltic sulphate to a hot nearly neutral solution of cerous sulphate as long as the supernatant liquid remains colourless. A yellow precipitate is then formed, having a somewhat paler colour than the ceric salt just described, but resembling it in form, so that the two salts appear to be isomorphous.

Rosco-cobaltic double salts of analogous composition have likewise been obtained, but they are very easily decomposed by water. The compound $10\text{NH}_4 \cdot \text{Co}^2(\text{SO}_4)^2 \cdot \text{Ce}^2(\text{SO}_4)^2 \cdot 5\text{H}_2\text{O}$ is produced as an orange-brown crystalline precipitate, by adding a solution of ceroso-cerie sulphate to an excess of a hot, strongly acid solution of rosco-cobaltic sulphate, or by adding the latter to an excess of the cerium salt. The crystals belong to the regular system. The corresponding *cerous salt* is obtained as a homogeneous precipitate, only when a solution of cerous sulphate is added to a large excess of rosco-cobaltic sulphate. The crystals, which resemble those of the ceric salt, have the composition $10\text{NH}_4 \cdot \text{Co}^2(\text{SO}_4)^2 \cdot 3\text{CeSO}_4 \cdot 5\text{H}_2\text{O}$. An attempt to prepare a corresponding lanthanum salt was unsuccessful. The amount of cerium in these salts appears to vary within certain limits, and the rosco-cerie salt appears to be always mixed with a certain quantity of cerous salt.

It was not found possible to prepare ceroso-cerie oxide free from didymium by oxidising a solution of cerous salt with lead dioxide and sulphuric acid, and then mixing it with luteo-cobaltic sulphate, the double salt thereby produced always retaining a certain quantity of didymium (C. H. Wing, *Sill. Amer. J.* [2] xl. 356).

CERULEOLACTIN. A hydrated aluminium phosphate, $3\text{Al}^2\text{O}^3 \cdot 2\text{P}^2\text{O}^5 \cdot 10\text{H}_2\text{O}$. Intely found in botryoidal and reniform masses in the Rindöberg mine at Katzeuclenberg in Nassau (see PHOSPHATES).

CERUSSITE, PbCO_3 . This mineral is known to accompany the galena of Kirilbaba in Bukowina.

Crystals of remarkable beauty have recently been met with, measuring 13 mm. long and 7 mm. broad, and of a yellowish or greyish-white colour. Both as individuals and in groups they are but slightly attached to the quartz or decomposed mica-slate, and consequently exhibit almost perfect development. A prismatic development along the principal axis, and occasionally simultaneously along the brachydiagonal, is generally observed in them. In addition to the three pinacoids, of which the basal is but slightly developed, there are found the often greatly developed prism ∞P , in a less degree the brachyprism, ∞P_3 , the brachydomes $\frac{1}{2}\text{P}_\infty$, P_∞ , 2P_∞ , 3P_∞ , 4P_∞ , the pyramid P , and, what is new for cerussite, the brachypyramid P_4 . The orientation of these forms, often apparently very distorted through dissimilar development of faces, is facilitated by an almost constant surface character of individual forms. The macropinacoid always presents a fine vertical striation, sometimes by oscillatory combination with ∞P . The brachypinacoid, ∞P_∞ has strongly marked horizontal striation, or decreases gradually by the occasional introduction of the faces of the brachydomes; of the latter, P_∞ has strong vertical striation. The ratio of the macrodiagonal, brachydiagonal and principal axis is 1.6306 : 1 : 1.1852. The Kirilbaba crystals often bear considerable resemblance to hexagonal combinations, and some resemble the arragonite of Bilin (v. Zepharovich, *Jahrbuch f. Mineralogie*, 1871, 286).

CERYLIC ETHERS (Hesse, *Dent. Chem. Ges. Ber.* iii. 637). The white mealy coating which forms on the capsules of the opium poppy (*Papaver somniferum*) after the petals have fallen off, and increases in quantity as the fruit ripens, consists of a waxy substance called *Opium-wax* or *crosin* [? identical with the cerosin of the sugar-cane, i. 836]. In consequence of the method adopted for obtaining opium from the poppy-heads, part of this wax becomes mixed with the drug, and is found in the residue or marc which remains when the opium is exhausted with water. When this marc, after being treated with a little potash-solution to remove resinous colouring matters, is boiled with alcohol, the alcoholic liquor deposits on cooling a considerable quantity of nearly white crystals, which may be freed from adhering base

pounds by dilute hydrochloric acid, and from a peculiar sticky substance by recrystallisation from boiling alcohol.

The wax thus obtained is nearly white, but is still a mixture which cannot be resolved into its constituents by alcohol. The best reagent for the purpose is chloroform, which at the boiling heat dissolves the true wax, and leaves a substance which crystallises in colourless prisms, melts at a temperature above 200° , and is probably related to lactacerein and hyoscerin.

On exposing the chloroform solution to a temperature of $+10^{\circ}$, it deposits colourless scales; and if the mother-liquor be then cooled down to -10° , another body is obtained crystallising in small prisms. The compound crystallising at $+10^{\circ}$ may be purified by recrystallisation from chloroform. It then forms white satiny scales composed of flattened prisms, melts at 82.5° , resolidifies at 80° , and gives by analysis 82.13 p. c. carbon, and 13.73 hydrogen, agreeing with the formula of ceryllic cerotate $(C^{18}H^{34}O^2 = C^{17}H^{32}.C^{17}H^{32}O^2)$ (i. 837). This ether dissolves easily in boiling alcohol, and separates almost completely in small prisms on cooling. Ether and acetone dissolve a considerable quantity at boiling heat, and deposit the greater part of it on cooling. It is not acted upon by dilute solution of potassium permanganate or by cold strong sulphuric acid, which however blackens it when heated. It is not acted upon by potash-solution, but by fusion with potassium hydrate it is decomposed, yielding a waxy acid; heated on platinum foil, it first melts and then volatilises, giving off a waxy odour and a smoke which is not easily inflamed, but when once set on fire, burns with a bright and very smoky flame.

The second compound, which separates at -10° from the mother-liquor of the preceding, may be sufficiently purified by treating the crystalline mass with a quantity of chloroform not sufficient to dissolve it all, and removing the undissolved portion, which is contaminated with ceryllic cerotate. The chloroform solution thus obtained deposits small dull translucent nodules, which, when recrystallised from boiling alcohol, yield a white powder composed of small prisms melting at 79° , solidifying in the crystalline form at 76° , and having the composition of ceryllic palmitate $(C^{18}H^{34}O^2 = C^{17}H^{32}.C^{16}H^{31}O^2)$. It dissolves in chloroform, alcohol, ether, and acetone somewhat more readily than the preceding, is not attacked by potash-solution, but is easily decomposed by melting potash, yielding a neutral body which melts at about 100° , probably ceryllic alcohol, and a crystallisable fatty acid.

CETYL ALCOHOL, $C^{18}H^{38}O$. This alcohol is known to be easily converted into sebic acid by the action of nitric acid. On the other hand, when a mixture of sebic acid and caustic baryta is submitted to dry distillation, there is formed, besides a hydrocarbon $C^{18}H^{36}$ boiling at 124° , and other products, a solid body, which, by repeated crystallisation from alcohol, may be obtained in white crystals having the properties and composition of cetyl alcohol; it melts at 40° and resolidifies at the same temperature (Scherlenner, *Deut. Chem. Ges. Ber.* iii. 616).

CHALCEDONY. Some remarkable concretions of chalcedony from Brazil are described by H. Rosenbusch (*Jahrbuch f. Mineralogie*, 1871, 175). They are found in a bed of marl in the valley of the Jahu, a tributary of the Tiété, on the table land of S. Paulo, forming long cylindrical tubes, some 50 mm. long and from 5 to 8 mm. in diameter. They are for the most part well rounded and hollow; the interior is coated with red ochre which contains much organic matter, a tube when heated emitting a strong empyreumatic odour. Some of the flattened tubes are clearly formed by the union of several smaller ones. In a microscopic section of a tube perpendicular to its axis, a fibrous structure is observed, the fibres being uniformly radii; that cut parallel to the axis is finely granular. The tube is coated on the outside with a crust of quartz crystals, which in their turn, are covered with chalcedony, and on which finally, and lying in contact with the marl, is another layer of quartz. These crystals exhibit the one rhombohedron only, the other being altogether absent or but slightly apparent. Other quartz concretions from this region are much contorted, many having dendritic forms. These remarkable structures, which strikingly resemble the industrial limestone of Auvergne, are in all probability of organic origin.

CHAMOMILE OIL, BLUE. This volatile oil, obtained from the flowers of the wild chamomile (*Matricaria Chamomilla*) by distillation with water (iii. 858; *Gmelin's Handbook*, xiv. 365) has lately been examined by Kachler (*Deut. Chem. Ges. Ber.* iv. 36).

The crude oil is a mixture. On rectifying it, after distillation in a current of steam, it began to boil at 105° , and between this and 188° a small quantity of a faintly blue oil, smelling strongly of chamomile, passed over; between 188° and 255° a second fraction of a somewhat darker colour was obtained. The magnificent blue vapour which characterises this oil was first formed above 255° , the temperature rising slowly

to 295°, and 87 grams distilling over. The portion distilling above 295° was still blue, but more syrupy. The temperature then rose above that at which a mercury thermometer could be employed, the vapour became violet, and a thickish, but still blue oil, was obtained. Finally, there remained in the retort 41 grams of a brown tar.

All these fractions, which had an acid reaction, were washed with potash-solution; the wash-water was acidified with sulphuric acid and exhausted with ether; and the strong, unpleasant-smelling residue remaining after distilling off the ether, was dissolved in water, saturated with ammonia, and converted into a silver salt, the analysis of which indicated that the acid is rutic or capric acid $C^{10}H^{20}O_2$ (anal. 43.1 p.c. C., 6.5 H., 38.4 Ag.; calc. 44.2 C., 6.8 H., 38.7 Ag.).

The first two fractions, after repeated rectification, yielded a liquid boiling at 150°–168°, which had a composition indicated by the formula, $C^{10}H^{16}O$ (anal. 79.1 p.c. C., 10.8 H.; calc. 79.0 C., 10.5 H.)

The analysis of the portions of higher boiling point (165°–185°) indicated increasing amounts of carbon and hydrogen, the mean of several determinations being 82.93 p.c. C., and 11.10 p.c. H.; probably due to the presence of a hydrocarbon $C^{10}H^{16}$, isomeric with oil of turpentine. Bizio's analyses (*Wien. Acad. Ber.* xliii. [2] 292) also lead to the same conclusion.

The blue fraction, after washing and drying over calcium chloride, was repeatedly rectified, and the various portions analysed. The portions of lower boiling point are, as is plainly shown by their colours, the least pure. That obtained between 270°–300° has the purest colour, a magnificent azure-blue, similar to that of an ammoniacal copper-solution. From numerous analyses of this, and from the results obtained by Bizio and Borntrüger (*Ann. Ch. Pharm.* xlix. 243), it is evident that this body is an isomeric or polymeric of camphor.

C ¹⁰ H ¹⁶ O		Bornträger.				Bizio.	Kachler.				
						300°	275°	281°	(287°–288°)		289°
C 79.0	70.85	79.81	79.86	78.41	79.8	79.0	78.92	78.5	78.4	79.5	
H 10.6	10.60	10.69	10.89	10.69	10.4	10.3	10.37	10.7	10.7	10.5	

Accurate determinations of the vapour-density could not be obtained, as the oil is partly decomposed when heated for some time above 310°–320°; nevertheless, the experiments prove that the molecular formula is certainly double, and probably twice the empirical camphor formula, $C^{10}H^{16}O$.

A comparison of this portion of the chamomile oil, which appears to be pure, with those of the corresponding fraction of the oil obtained by distillation of galbanum by Mössner (ii. 758), shows them to be very similar in properties, though they appear to differ considerably in composition:

Blue Chamomile Oil, 281°–289°.		Blue Galbanum Oil, 289°–290° (Mössner).	
C = 79.25 per cent.		83.74 per cent.	
H = 10.40 per cent.		11.43 per cent.	

Kachler, finds, however, that the galbanum oil is a very variable mixture according to the temperature at which the resin is distilled. It contains varying quantities of a colourless hydrocarbon, which has the composition of turpentine oil, and may be driven off by heating for two or three days at 230°–250°. This hydrocarbon, when purified by distillation, is not identical with the colourless, limpid, turpentine-like galbanum oil obtained by distillation of galbanum in a current of steam. It is less limpid, has a perfectly different, unpleasant odour, and boils at 240°–260°, whereas the latter boils at 160°–165°. The high percentage of carbon in Mössner's blue oil is probably due to an admixture of this hydrocarbon. Kachler found that the blue galbanum oil, after purification from this body &c., gave 79.07 and 80.8 p.c. C., and 10.42 and 10.4 H.; numbers agreeing well with the camphor formula.

On treating chamomile oil with potassium and with phosphoric anhydride in the same way as Mössner treated galbanum oil, the behaviour of the two oils was found to be identical, and the products obtained were of the same composition.

Products of the treatment with potassium:—

From Galbanum oil.				From Chamomile oil.	
$n^{20}C^{10}H^{16}$		Mössner (255°).		Kachler (255°).	Kachler (250°–255°).
C	88.0	88.7	88.8	88.0	88.1
H	11.4	11.3	11.1	11.4	11.8

The vapour-density, determined by Dumas' method, was 14.8, that calculated for $3C^{10}H^{16}$ being 14.1.

Products of the action of phosphoric anhydride:—

		From Galbanum oil.	From Chamomile oil.
C	$\text{PCl}_5 \cdot \text{H}^+ \text{O}$	Kachler 89.2	Kachler 88.8
H		10.4	10.8

Bearing in mind the extreme difficulty of preparing such bodies in the pure state, the analytical results obtained with the two oils could not perhaps be regarded as perfectly conclusive in favour of their identity, were it not for some characteristic reactions which seem to remove all doubt. On adding an ethereal bromine solution to a dilute ethereal solution of the product from the treatment of the blue chamomile oil with potassium, the liquid becomes, after a short time, azure blue. This colour is not persistent; on the evaporation of the ether (which should be saturated with water,) it turns green, and finally brown. The product from galbanum oil, and the products of the action of phosphoric anhydride on the two oils, all give exactly the same reaction.

On agitation with nitric acid, sp. gr. 1.25, a similar reaction is observed. The brownish colour at first produced soon passes into a deep violet; afterwards oxidation takes place, and the colour disappears.

CHEMICAL ACTION. *Coefficient of Chemical Activity or Elective Attraction.* Mills (*Phil. Mag.* [4] xl. 134; xlv. 343), in studying the action of phosphorus oxychloride upon certain nitrates, has found that the decomposition proceeds with a certain degree of uniformity, the analysis of the residual products showing indeed that, in any series of operations with the same nitrate, the ratio between the weights of chlorine retained and phosphoric oxide produced is sensibly constant. This ratio, multiplied into 4.06 or $\frac{\text{Cl}}{\text{P}_2\text{O}_5}$ is designated by the symbol α .

The experiments were thus conducted. A weighed quantity of pure anhydrous nitrate was placed in a suitably arranged reaction-tube, a proportion of phosphorus oxychloride (free from hydrochloric acid and non-fuming) was added, and heat gradually applied until the action reached a maximum, a current of *absolutely* dry air passing slowly through the apparatus during the whole operation. When no more coloured gases were expelled, it was judged that the reaction was completed; the excess of oxychloride was then distilled away, and the residue after weighing was dissolved in water and analysed.

The nitrates of silver, lead, thallium, potassium, sodium, lithium, cesium, and rubidium were submitted to experiment. Barium nitrate was not attacked by phosphorus oxychloride. The accompanying table affords an example of the results:—

	I.	II.	III.
Silver nitrate employed	2.1746	1.0519	2.7633
Residue obtained	2.1800	1.0589	2.7345
Temperature	121°	120°	120°
Composition of the residue, viz.,			
Silver nitrate	40.77	25.96	57.87
Silver chloride	49.77	61.91	36.44
Phosphoric oxide	9.47	12.93	6.60
	100.01	100.80	100.91
Hence the values of α are re- spectively	5.21	4.74	5.47

The residual nitrate is calculated, not by difference, but from the original nitrate on the basis of the chloride found. In the case of the potassium salt, the amount of nitrate obtained by calculation did not even remotely approximate to the undetermined difference, and a determination of the unattacked nitrate by Harcourt's process (iv. 89) was also unsuccessful.* The analysis of the lithium residues was attended with

* In Harcourt's process, if the potassium nitrate be mixed with a small proportion of potassium

several inconveniences, inasmuch as the mass in the tube became vesicular, and finally interrupted the passage of air; from this circumstance, the oxychloride never wholly distilled away, and had, consequently, to be determined by another operation. In the case of thallium nitrate, the dichloride, and not the sparingly soluble thallous chloride, was the result of the reaction.

Mean values of α —

Potassium nitrate 2·001	Sodium nitrate 1·70	Thallium nitrate 4·38	Silver nitrate 5·48
Lead nitrate 5·17	Lithium nitrate 1·61	Cæsium nitrate 2·21	Rubidium nitrate 2·38

The numbers to which α corresponds are ratios and not absolute quantities; they represent the potential energy or dynamical use which can be made of a nitrate; they are obtained under a law of chemical action, and are in themselves independent of any adventitious circumstances of manipulation. When one nitrate surpasses another in the power of fixing chlorine per unit of phosphoric oxide, that is an index of superior chemical activity, or to name the ultimate cause, attraction; and since this attractive effect can be estimated for several nitrates in a series, α becomes the coefficient of elective attraction of the nitrates.

If α be divided by the molecular weights, Σ , of the several nitrates calculated to an uniform weight of oxynitryl (NO^3), the following numbers, Q , are obtained:—

	α .	Σ .	Q .
{ Thallious nitrate	8·76	265·3	30·29
{ Silver "	5·48	160·94	31·01
{ Lead "	5·17	165·56	32·02
{ Rubidium "	2·38	147·40	61·93
{ Cæsium "	2·21	195·01	88·24
{ Potassium "	1·99	101·14	50·82
{ Sodium "	1·70	85·05	50·03
{ Lithium "	1·61	60·00	42·86

These numbers show that the elective coefficient is directly proportional to the symbolic (molecular) value, and that, with one exception, α and Σ increase and diminish in regular order; the quotients Q , therefore, represent the weights of nitrates which correspond with the unit of elective attraction. If these numbers be considered as an incomplete arithmetical series, of which the most probable value of the first term is 6·258, some interesting results are observable. The mean product of symbolic value into the specific heat is 6·246, and the identity of this number with the foregoing term is unmistakable. If s = specific heat, $\Sigma s = n \cdot 6·25$, n being integral. But $Q = n \cdot 6·25$; or since the results of experiment show that $m > n$, let $m = x n$; then by combining these two equations, we obtain $\alpha = \frac{1}{x}$ as the expression of the elective attraction in terms of the specific heat.

Again, comparing any two coefficients (α and α') we have $\alpha : \alpha' :: \frac{1}{xs} : \frac{1}{x's'}$, but in several instances $x = x'$, as is obvious from the foregoing table. Then $\frac{\alpha}{\alpha'} = \frac{s'}{s}$.

The following instances may be adduced in verification of the latter case:—

$$\begin{aligned} \frac{\alpha (\text{potassium nitrate})}{\alpha (\text{sodium nitrate})} &= 1·17 \text{ by the method of ratios.} \\ &= \frac{·2782}{·2388} = 1·17 \text{ by specific heat.} \\ \frac{\alpha (\text{thallious nitrate})}{\alpha (\text{silver nitrate})} &= 1·50 \text{ by the method of ratios.} \\ &= \frac{·1433}{·0942} = 1·53 \text{ by specific heat.} \end{aligned}$$

phosphate, the whole of the nitrate is not decomposed in the ordinary manner, and the apparent yield requires to be multiplied by the number 1·0689. When the phosphate is absent, a normal number is obtained.

That the intensity of elective attraction is proportional to molecular value is a result quite in accordance with ordinary chemical experience.

When silver nitrate is added to a dilute aqueous solution of potassium iodide bromide, and chloride (these salts having been mixed in any proportion), silver iodide, bromide, and chloride are successively precipitated, that is, in the order of their sym-bolic values. Silver chloride may be wholly converted into bromide by digestion with aqueous potassium bromide; and silver bromide is completely transformable into iodide by aqueous potassium iodide. In the formation of salts, baryta has the preference over strontia, and strontia over lime. In the fractional separation of the volatile members of the fatty series $C^nH^{2n}O^2$, by Liebig's process, the law is strictly observed, excepting in the case where $n = 2$, which is an intelligible anomaly. Houtz's method of separating the non-volatile members of the same series by means of magnesia exhibits the same order. In a mixture of the hydrocarbons C^nH^{2n-6} , benzene is the last to be chlorinated or nitrated. Warrington has shown the superiority of ferric over aluminic oxide as an absorber of alkalis in soils. In cases of jaundice, taurocholic acid is destroyed in the system before glycocholic acid.

Chemical Equilibrium of Carbon, Hydrogen and Oxygen (Berthelot, *Bull. Soc. Chim.* [2] xiii. 99). Carbon dioxide, through which a series of induction sparks is passed, is quickly decomposed, the decomposition increasing up to a certain point, then diminishing, then again increasing, then diminishing, and so on, without approaching any fixed limit. Neither is any constant proportion observed in the extreme limits between which the decomposition varies. Buif and Hofmann (*Chem. Soc. J.* xii. 293) observed that, when the decomposition of the carbon dioxide had gone on to a certain amount, the resulting mixture of carbon monoxide and oxygen was exploded by the spark, and the dioxide was reproduced. Berthelot did not observe this explosion, but thinks it might take place with weaker sparks than those which he employed. He finds that a mixture of 2 vol. carbon monoxide and 1 vol. oxygen no longer explodes when the admixed carbon dioxide amounts to between 60 and 65 p. c. of the total volume, the limit varying, however, according to the intensity of the sparks. Berthelot also confirms the observation of Dalton that a mixture of carbon monoxide and oxygen no longer explodes when it contains less than $\frac{1}{4}$ th or more than $\frac{1}{4}$ ths of its volume of carbon monoxide. The limits depend to a certain extent on the intensity of the spark, and in any given mixture the combustion is sometimes complete, sometimes more or less incomplete. The decomposition of carbon dioxide is completely prevented by the presence of a large quantity of oxygen or carbon monoxide. Mixtures of 16.6 CO² with 83.4 CO, or of 13.0 CO² with 87.0 CO, were found to contain exactly the same quantities of carbon dioxide after the spark had been passed through them for an hour.

The decomposition of aqueous vapour exhibits the same general features as that of carbon dioxide, not approximating to any fixed limit. The presence of an excess of the water-vapour interferes with the union of hydrogen and oxygen. Under the prolonged influence of the spark, a small quantity of hydrogen or of oxygen in presence of a large excess of the other gas is completely converted into water.

With regard to the equilibrium of hydrogen, oxygen and carbon, Berthelot has already investigated the reaction between hydrogen and carbon monoxide (1st *Suppl.* 30). The products of this reaction are carbon dioxide and acetylene.

In presence of a considerable quantity of water-vapour or carbon dioxide, however, no acetylene is formed, whereby the relations are very much simplified. To prevent condensation of water, the reactions were carried on in tubes which were heated to 100° in a current of steam. Two mixtures were experimented on, consisting of

H = 20.0	CO ² = 20.0	CO = 40.8 vol.
and H = 20.0	CO ² = 20.0	CO = 21.5 "

These mixtures are equivalent in composition to the two explosive mixtures,

H = 20.0	O = 10.0	CO = 60.8
and H = 20.0	O = 10.0	CO = 41.5.

After electric sparks had been passed through these gaseous mixtures for half-an-hour, exactly half the carbon dioxide in each was decomposed, with formation of a volume of water-vapour equal to that of the undecomposed gas. The equilibrium resulting from the influence of a series of electric sparks is therefore the same as that which, in Bunsen's experiments on the combustion of carbon monoxide and hydrogen, (1st *Suppl.* 483), is produced by the sudden explosion of similarly constituted mixtures.

Division of a body between two Solvents, Berthelot and Jungfleisch (*Compt. rend.* lxxix. 338) have experimented on this subject, by dissolving a substance in one

of the two liquids, then adding a measured volume of the other solvent, and shaking the whole strongly, the temperature being kept constant by means of a water-bath. The quantity of substance dissolved in the liquid was determined from time to time till the results became constant—a state which was sometimes not attained for an hour or two—and the quantity of the substance dissolved in each of the two solvents was then ascertained.

A body brought in contact with two liquids, in each of which it is soluble, always divides itself between them in a simple ratio, however great may be its solubility in one of them, and the excess of the volume of this same solvent. The quantities dissolved simultaneously by the two liquids stand to one another in a constant ratio, called the coefficient of division. This coefficient is independent of the relative volumes of the two liquids, but varies with their concentration and the temperature, as shown by the following experiments:—

INFLUENCE OF TEMPERATURE.

*Weight of Succinic acid
in 10 c. c. of the—*

	Aqueous Solution	Ethereal Solution	Coefficient of Division
{ At 15° . . .	0.376	0.060	6.2
{ „ 0 . . .	0.376	0.078	4.9
{ „ 15 . . .	0.106	0.019	5.5
{ „ 0 . . .	0.098	0.019	5.0

These numbers show that the coefficient of division changes with the temperature, but at a very slow rate. Decrease of temperature increases the action of the ether, that is to say, of the more volatile liquid; but it is not yet proved that this law is general.

INFLUENCE OF CONCENTRATION.

The coefficient of division varies with the final concentration of the solvents; it is not, however, proportional to the weight of substance dissolved, but increases at a slower rate.

The numbers *w* in the following tables denote the weight in grams of substance dissolved in 10 c. c. of one or the other solvent after agitation.

Succinic acid, Water, and Ether, at 15°.

In Water (<i>w</i>)	In Ether	Coefficient of Division <i>C</i>
0.486	0.073	6.6
0.420	0.067	6.3
0.365	0.061	6.0
0.236	0.041	5.7
0.121	0.022	5.4
0.070	0.013	5.2
0.024	„	5.2

$$C = 5.1 + 3 w.$$

Benzoic acid, Water, and Ether, at 10°.

*Weight of Benzoic acid
in 10 c.c. of the—*

Aq. Solution	Ether. Solution	Coefficient of Division
0.00304	0.277 (<i>w</i>)	1 : 91
0.00258	0.227	1 : 88
0.00150	0.119	1 : 80
0.00110	0.078	1 : 71

In this case the action of the ether greatly exceeds that of the water, contrary to what happens in the case of succinic acid. The results may be represented by the formula:

$$\frac{1}{C} = 63 + 100 w.$$

Oxalic acid, Water, and Ether, at about 11°.

Aq. Solution (w)	Ether. Solution	Coefficient of Division C
0.473	0.052	0.0
0.436	0.046	9.5
0.304	0.031	9.8
0.203	0.0205	9.9

The results may be represented by the formula :

$$C = 10.5 - 3.3 w;$$

in which w refers to the aqueous solution ; as also in all the following series :—

Malic acid, Water, and Ether, at about 18°.

Weight of Malic acid in 10 c. c. of the Aqueous Solution	Coefficient of Division C
4.1	26
2.2	36
1.0	40
0.35	47

$$C = 49 - 5.6 w.$$

Tartaric acid, Water, and Ether, at about 20°.

$w = 5.26$	2.60	1.00	0.4
$C = 91$	96	120	130

Acetic acid, Water, and Ether, at about 18°.

$w = 2.0$	1.0	0.3	0.1
$C = 1.2$	1.4	1.8	2.3

The results obtained with malic, tartaric, and acetic acid show that, in very soluble bodies, the coefficient changes with the concentration more rapidly than in less soluble bodies. The cause of this difference is that concentrated solutions of tartaric or acetic acid dissolve ether in other proportions than dilute solutions, so that the actual solvents are not comparable. Sulphuric and hydrochloric acid are dissolved in considerable quantity by ether, only when they are concentrated; if their aqueous solutions are dilute, the quantities of them taken up by ether can no longer be estimated with accuracy.

Ammonia, Ether, and Water, at about 17°.

$w = 0.71$	0.52	0.27
$C = 83$	100	135

Bromine, Water, and Carbon Bisulphide.

w in 10 c. c. water	w in 10 c. c. CS ²	C
0.176	10.2	1 : 58
0.030	2.46	1 : 82
0.020	1.55	1 : 78
0.0011	0.09	1 : 80

Iodine, Water, and Carbon Bisulphide, at about 18°.

w in 10 c. c. water	w in 10 c. c. CS ²	C
0.0041	1.74	1 : 420
0.0032	1.29	1 : 400
0.0016	0.66	1 : 410
0.0010	0.41	1 : 410
0.00017	0.076	1 : 440

The coefficient of division of iodine between water and carbon bisulphide may be regarded as independent of the concentration.

General Laws and Theory of the Preceding Phenomena (Berthelot, *Ann. Chim. Phys.* [4] xxvi. 408).—The fact that the coefficient of division is independent of the relative volumes of the two solvents when the latter form two distinct layers, is easily explained as follows:—Suppose the dissolved substance to be uniformly distributed in each of the superposed liquids; then, in order that equilibrium may subsist, it is necessary and sufficient that there be equilibrium at the surface of contact of these liquids, as it is there only that the actions take place which cause the dissolved body to pass from one liquid to the other. Consequently the equilibrium cannot be disturbed by addition of a further quantity of either liquid saturated to the same degree by the dissolved body.

The same reasoning is applicable to a multitude of phenomena, in which one and the same body is distributed between different portions of the same system, such as the division of a gas between a liquid and an empty space above; the formation of a saturated vapour in presence of excess of liquid; the solution of a solid body (in excess) in a liquid; and the limited decomposition (dissociation) of a solid or liquid which is giving off gases. All these divisions obey similar laws, because they are determined solely by actions taking place at the surface of separation of two distinct portions of a heterogeneous mass.

2. The coefficient of division appears to approximate to a certain limit as the liquids become more dilute. This coefficient is in fact represented by a formula of the form $C = M + Nw$, which approaches nearer and nearer to its first term as w becomes smaller. This limit may be substituted for the coefficient in all that relates to dilute liquids.

Let A be the total weight of the body dissolved before any division takes place; B the weight which remains and the first solvent at the end of the experiment; k the weight dissolved in the first instance by a given fraction of the second solvent. If now this second solvent be made to act successively in equal fractions, then after n reactions, the quantity of the soluble substance remaining dissolved in the first liquid will be represented by the relation $\frac{A}{B} = (1 + k)^n$, that is to say, it will decrease in

geometric progression. If, on the contrary, the same volume of liquid be used at once, the quantity remaining will be $\frac{A}{B} = 1 + nk$. It is therefore advantageous to employ

the second solvent in successive fractions, and the advantage becomes greater as the coefficient k is larger. The principles which regulate the exhaustion of a dissolved substance by a second solvent are the same as those which apply to the evaporation of a gas dissolved in a liquid (see *Ann. Ch. Phys.* [4] xx. 422).

3. The preceding laws afford the means of determining whether a body dissolved in a liquid is a definite compound or a mixture, namely, by agitating the solution with several successive portions of the second solvent, and determining the coefficient of division at each operation. If the liquid is sufficiently dilute, these successive values of the coefficient will be exactly or nearly equal in the case of a definite compound; but in the case of a mixture of several compounds, these coefficients will vary the more rapidly in proportion as the division-coefficients of the several dissolved compounds differ more from one another, the bodies most soluble in the second solvent, either for example, being eliminated more quickly than the others.

4. The division-coefficient tends towards a certain limit, not only as the liquids become more dilute, but likewise as they become more concentrated, whenever the dissolved body is soluble to a finite extent in each of the liquids. This limit corresponds with the saturation of the two liquids by the dissolved body, and differs more or less from the limit which holds good for the same liquids in the dilute state. At first sight it might appear that this limit of saturated liquids would be expressed by the ratio of the solubilities in the two liquids condensed separately at the same temperature; but it is not so in reality: something, indeed, appears to take place analogous to the diminution of the vapour-tension of mixed liquids, which is usually less than the sum of the separate tensions. Take, for example, the case of iodine in presence of water and carbon bisulphide. 10 c.c. of carbon bisulphide saturated with iodine at 18° contain 1.85 gram of iodine; and 10 c.c. of water at the same temperature can take up 0.014 gram iodine. The ratio of these two solubilities is 1 : 132. On the other hand, when carbon bisulphide nearly saturated with iodine is shaken up with water at 18°, 10 c.c. of the carbon bisulphide retain 1.74 iodine, and 10 c.c. of the water take up 0.0042 iodine. Now the ratio of these numbers is 1 : 410, that is to say, the coefficient of division is only about one-third as great as the ratio of the solubilities. In like manner, for succinic acid in presence of water and ether, the ratio of the solubilities from saturated solution is 10⁴, whereas the coefficient of division for the same degree of concentration is only 6.8.

The same holds good when the soluble body dissolves to a finite extent only in one of the liquids, but is capable of mixing in all proportions with the other. Take, for example, the case of bromine in water and carbon bisulphide: here, as already determined (p. 283), the coefficient of division is about 1 : 80; but the ratio of the solubilities is infinite.

5. With regard to the relations between the coefficient of division and the chemical composition of the substance dissolved, it is found that ether removes from water with comparatively greater facility—

a. The more highly carburetted of two homologous acids, *e.g.*, succinic more easily than oxalic acid; butyric more easily than acetic acid. β . A monobasic in preference to the corresponding bibasic acid; *e.g.* acetic rather than oxalic, butyric rather than succinic acid. γ . A monobasic acid rather than a bibasic acid of nearly the same centesimal composition; *e.g.* acetic rather than succinic acid. δ . Of two acids containing the same proportion of carbon and hydrogen, the less oxygenated is the more easily removed; *e.g.* succinic acid $C^4H^6O^4$ rather than malic $C^4H^6O^5$, malic rather than tartaric $C^4H^4O^7$.

6. Two bodies placed simultaneously in contact with two solvents are distributed between them just as if each of the bodies acted alone. This law, which has been verified by Berthelot in the action of water and ether on various mixtures of acetic and tartaric, of acetic and oxalic, and of oxalic and tartaric acid, is analogous to the law of solubility of mixed gases.

State of Salts in Solution (Berthelot a. St. Martin, *Ann. Chim. Phys.* [4] xxvi. 433). The method of experimenting above described is applicable to the determination of the state of acid salts in solution, and to the question of the division of a base between two acids in solution.

I. To determine the state of an acid salt in solution, a measured volume of the solution, of known strength, is agitated with a known volume of ether. Three cases may occur: a. The water completely decomposes the acid salt into neutral salt and free acid. In this case the solution will yield to the ether a quantity of acid equal to that which the ether, under similar circumstances, would take from a solution of the free acid of the same strength. β . The water partially decomposes the acid salt, so that the solution contains a mixture of acid salt, neutral salt, and free acid; in this case the quantity of free acid removed by the ether will afford the means of calculating by means of the division coefficient, the quantity of acid which existed in the solution in the free state before the agitation. γ . The water exerts no action on the acid salt. In this case the ether, both before and after agitation, remains perfectly neutral to litmus.

As the coefficient of division between water and ether varies with the temperature and with the concentration of the aqueous liquid, it is necessary to make a comparative experiment with the acid of the salt which is the subject of experiment. For this purpose, a solution of the free acid is prepared of the same acidimetric strength as that of the acid salt; and the coefficient of division between this solution and the ether is determined, using volumes of these liquids exactly equal to those which were employed in experimenting on the acid salt, the two experiments being made simultaneously, so that the conditions of temperature may be the same.

When the acid salt is completely resolved into neutral salt and free acid, the two experiments will give the same result; in the contrary case, the acid salt will yield a smaller proportion of free acid; and by a series of trials, the particular solution of free acid may be found which yields to ether the same proportion of the acid as the acid salt. In all cases, if the liquid is dilute, the proportion of free acid in the solution of the acid salt may be calculated from the quantity found for the solution of free acid. Supposing that the quantities of free acid yielded to the ether by the two solutions are proportional to the quantities which remain dissolved in them, the sum of the two quantities dissolved by the water and the ether after agitation will give the quantity of pre-existing acid. This calculation supposes that the coefficient of division is constant, which is sensibly true for dilute liquids (p. 283).

The principal results obtained by this mode of experimenting are the following:—

1. Acid salts of monobasic acids, such as the biacetate and bibenzoate of potassium, cannot exist in dilute aqueous solution, but are immediately broken up into neutral salt and free acid. From a solution of sodium biacetate, for example, ether dissolves out a portion of the free acid, but not the sodium acetate or biacetate. Moreover, the coefficient of division is exactly the same as that of a solution of acetic acid of the same degree of acidity.

2. Acid salts of polybasic acids, on the contrary, can exist in solution, but generally in a state of partial decomposition. Such is the case with the bioxalates, bitartrates and especially the bisuccinates of potassium and ammonium, which last salts are more

soluble in water than those of the other two classes, and contain an acid more soluble in ether. Potassium quadroxalate splits up on solution into the bioxalate and free oxalic acid. All these acid salts are as insoluble in ether as the corresponding neutral salts.

3. *The quantity of salt decomposed increases slowly and continuously with the degree of dilution.*

4. *The quantity decomposed likewise changes continuously with the proportion between neutral salt and excess of acid present, in such a manner that the stability of the acid salt is increased by the presence of an excess, either of neutral salt or of free acid, the increase of stability being quicker however in the latter case than in the former.*

Division of a Base between two Acids.—Experiments on this division were made by adding to the aqueous solution of the neutral salt of an acid which is dissolved out by ether from its aqueous solution in considerable quantity, another acid whose coefficient of division is very different from that of the former acid. The whole was then agitated with ether, and the final condition of the two liquids determined. At the same time, two other liquids of the same acid strength, each of them however, containing only one of the two acids, were treated in a similar manner.

By a series of experiments thus made on solutions of sodium acetate with dilute solutions of hydrochloric, sulphuric, oxalic, and tartaric acids, it was found that each of these acids is able completely to displace the acid of the acetate from its bases. Reciprocal experiments, in which acetic acid was added to the solutions of sodium chloride, sulphate, oxalate, and tartrate, confirmed this result.

It was proved also that ammonia has no power to displace the alkali-metals from their acetates and oxalates.

By adding oxalic acid solution to a sufficiently dilute solution of common salt, it was found that about $\frac{1}{10}$ th of the oxalic acid was converted into sodium bioxalate, about 5 p. c. of the sodium being removed from its combination with the chlorine.

The results obtained by the preceding methods are corroborated by the thermic phenomena exhibited in the solution of salts in water and in the mutual action of acids and metallic salts. On this subject numerous experiments have been made by Berthelot. In one series (*Compt. rend.* lxxv, 207 and 263), the reactions of salts of potassium, sodium and ammonium with hydrochloric and nitric acids were examined. The strength of the solutions was such that two litres contained an equivalent of the salt in grams. Similar solutions of the two acids were made. With the solution of each salt was mixed an equal volume of the acid proper to it, and the change of temperature was observed. In these cases the heat absorbed or disengaged was barely perceptible, and scarcely greater than that allowed for experimental errors.

Thus for the salts of potassium:

Similar experiments were tried with the sulphates of the alkali-metals and oxalic acid, in a solution, whose strength was half an equivalent in grams to two litres of water.

On mixing the solution of the other salts with the acid solution, similar quantities of heat were absorbed. Such figures indicate a decided reaction between the neutral and the acid salt.

To examine the nature of this reaction, different quantities of acid solution were successively added to solutions of potassium sulphate, and the heat absorbed was observed. Thus there were in solution successively $\text{K}^2\text{SO}^4 + \text{H}^2\text{SO}^4$, $\text{K}^2\text{SO}^4 + 2\text{H}^2\text{SO}^4$, &c. $\text{K}^2\text{SO}^4 + 10\text{H}^2\text{SO}^4$; and it was found that the quantity of heat absorbed became greater as the quantity of acid added was greater, but that it had a limiting value, about 2,000 units of heat, a quantity which may be looked upon, as that which represents a complete transformation of the neutral into the acid sulphate. Similar results were obtained with oxalate of sodium.

Again experiments were made by adding to solutions containing one equivalent of sulphuric acid, one, two, or more equivalents of neutral potassium sulphate. The result was similar to that just described, reactions being obtained which approached more and more closely to that which would correspond with complete conversion of the sulphuric acid into the acid sulphate of potassium. Oxalic acid gave a similar result with neutral oxalate of sodium. The limiting value for the quantity of heat absorbed in these last experiments—a value which may be supposed to belong to a complete

* The unit of heat is the quantity of heat required to raise 1 gram of water 1° C.

conversion of an equivalent of sulphuric acid into acid sulphate of potassium by the action of a large quantity of neutral sulphate, or of an equivalent of oxalic acid into acid oxalate of sodium by means of neutral oxalate—was the same as that found for the converse reaction, being 2,000 units of heat for the sulphate of potassium, and 600 units for the oxalate of sodium; and it is interesting and important to remark that the heat given out during the conversion by means of potash, of sulphuric acid into potassium sulphate, viz., 15,700 units, when reduced by this number 2,000, gives 13,700 units, the same quantity that is given out during the conversion of a monobasic acid, such as nitric or hydrochloric acid by the same means. A similar comparison may be made for the case of sodium oxalate.

Lastly, experiments were tried as to the effect of the water of solution, and it was found that, on mixing an equivalent of sulphuric acid with an equivalent of neutral potassium sulphate, each in the first instance dissolved in one litre of water, then each in two, afterwards each in five litres, and so on, the quantity of heat absorbed became less and less. This represents a reaction less and less complete as the solution is more and more dilute. In a solution in which one equivalent of the acid salt is contained in 20 litres of water, little more than the half will remain as an acid salt, the remainder being split up into free acid and neutral sulphate.

These facts concur in showing that there is a species of equilibrium, by means of which, in the case of the salt of a bibasic acid, the four bodies, the water, the acid salt, the free acid, and the neutral salt, all coexist in the same solution. The proportion in which they coexist depends upon the proportions of water, acid, and neutral salt present.

The formation of an acid sulphate by solution is accompanied by an absorption of heat, which however is only apparent, the actual formation of the acid salt being attended with a development of heat, and the fall of temperature observed being due to secondary phenomena connected with the solution of the salt in water, which, taken together, overpower the effect due to the formation of the salt.

In the case of monobasic acids, the experiments were made as follow:

Solution of sodium acetate—one equivalent in grams dissolved in two litres of water—was mixed with aqueous nitric acid, 1 eq. in 2 litres, and the quantity of heat given out during the mixing was determined. Next, solution of sodium nitrate, 1 eq. in 2 litres, was mixed with acetic acid solution of the same strength, and the heat given out was observed. The quantity of heat found as the representative of the chemical combination which takes place was, for the first operation, +450 units, and for the second, -60; the total, found by subtracting the second from the first, that is, by adding 60, is 510 units. Comparing this with the difference between the heats developed during the neutralisation of weak nitric acid and of weak acetic acid with soda, the number is found to be exactly the same, and in favour of the nitric acid combination. Hence it is concluded that when nitric acid and acetic acid in equivalent quantities are present in the same solution and in presence of one equivalent of soda, the nitric acid takes the whole of the soda to itself, and the acetic acid remains completely uncombined.

Hydrochloric acid, in presence of acetic acid and soda, likewise completely satisfies itself by forming sodium chloride, as proved by the heat evolved. The phenomena observed when a bibasic acid and a monobasic acid are together presented to a single base in solution are various, and such is the case when two bibasic acids are simultaneously presented to the same base. Carbonic acid is completely displaced from its combination by nitric, acetic, sulphuric, and tartaric acid, no bicarbonate being formed. Sulphuric acid completely displaces acetic acid from its combination with the alkalis, and during the reaction much heat is given out. Tartaric acid almost completely displaces acetic acid, but during the reaction heat is absorbed. The result is confirmed by the method of two solvents, above described, which shows complete conversion of acetates into tartrates.

The reactions of the oxalates and sulphates in presence of nitric and hydrochloric acids are more complex than those mentioned above. Here it is found that acid salts are formed in quantity depending on the amounts of the various bodies present. The quantity of water especially has an important influence on the result. As already pointed out, the six bodies in the solution form a kind of equilibrium among themselves. For example, the result of the finished reaction, and consequently the amount of heat given out, depends on the equilibrium due to the quantities formed of sodium sulphate, sodium bisulphate, free sulphuric acid, sodium nitrate, free nitric acid, and water.

The following experiments relate to the formation of metallic salts by the union of acids with the oxides of zinc, copper, lead, &c., and particularly of ferric oxide, (Berthelot, *Compt. rend.* lxxiii. 1472; lxxiv. 48 and 119).

In the case of many of the salts of these metals, the concentration of the solution

exerts a far greater influence on the quantity of heat disengaged during a reaction than it does in the case of salts of the alkalis. Thus equivalent quantities of—

	Heat-units.
Zinc acetate (1 eq. in grams in 10 litres) and caustic potash (1 eq. in 2 litres) being mixed, gave	+ 4400
Zinc acetate (1 eq. in 2 litres) and caustic potash (1 eq. in 10 litres).	+ 540

This effect is almost entirely due to the difference in concentration of the zinc acetate: for if a solution of caustic potash, one equivalent in two litres, be diluted with water so as to become ten litres, the thermal effect is scarcely appreciable, neither is the effect of the dilution of an alkaline acetate more perceptible. On the other hand, solution of zinc acetate, 1 equivalent in 2 litres,

diluted to 4 litres, gives 500 heat-units.

" 10 " 101 "

The heat developed during the solution of zinc oxide in acetic acid in presence of different quantities of water, increases as the solution is diluted; and the same is the case with many other salts. In some cases, however, as in those of the acetates of potassium and sodium, and in that of zinc sulphate, the addition of water has little or no effect after a certain point is reached.

Experiments were also made to ascertain, by observation of the heat developed or mixing solutions of various salts, when double decomposition takes place. Thus zinc acetate was mixed with sodium sulphate, and zinc sulphate with sodium acetate, and it was found that, in the former case, the heat given out is nothing more than that due to the dilution of the zinc acetate, while in the latter the occurrence of double decomposition must be supposed, in order to account for its development or absorption. It is thus shown that, on mixing two solutions of salts, the final result is that the stronger base unites with the stronger acid, and the weaker base with the weaker acid; in fact that salts are formed in the order of their stability, double decomposition occurring when necessary for this final result. This was shown to hold for the various salts of several metals, but the most striking results were obtained in the case of the ferric salts.

Ferric sulphate, nitrate, and acetate were examined, each salt first by itself in solutions of varied concentration, then in mixture with solutions of other salts, with the view of determining, by means of the heat given out during dilution and mixture, the state of the union existing between the acid and base. The instability, or at least the feebleness, of the union was first pointed out by Péan de St. Gilles in the case of the acetate. Solutions of the salts: first, recently dissolved; secondly, recently dissolved, but boiled for some minutes and then cooled; and, thirdly, after the solution had been kept for three months,—were mixed with equivalent solutions of caustic potash, and the following results were obtained:—In the case of the sulphate, the heat developed in all three cases is nearly the same; but in the case of the nitrate, while the solution of the salt recently dissolved in the cold is sensibly unchanged by boiling, the same solution kept for three months gives a result which proves that slow disunion between the base and the acid has been going on. The acetate is also found to be slightly decomposed when the solution is kept for a long time, but when it is boiled for a few minutes, the acid and base are found to be almost completely disunited.

When a solution of ferric acetate is boiled and then mixed with solution of potassium sulphate, a secondary disengagement of heat takes place, indicating a molecular coagulation or condensation, which appears to correspond with the assumption of the insoluble state in which the oxide is found after this kind of precipitation.

The general results of the investigation are that, in solutions of ferric salts, the oxide and the acid are united in an incomplete and feeble manner, and the union is affected by the water of the solution, and greatly by temperature: this is most apparent in the case of salts formed with the weaker acids. The reaction of the water in breaking up the salt is not instantaneous, but progressive, as is the case with the decomposition of ethers by water; and finally the effects are not always reversible by reversing the conditions: for the oxide of iron once separated from its acid assumes a molecular condition which prevents it from returning to its old state in combination.

In the action of an acid on its corresponding ferric salt, heat is liberated, in the case of the nitrate and sulphate, when the acid solution is added, which indicates an increased union between the oxide and the acid, due to the presence of free acid. A solution of an alkaline salt of the same acid does not produce much

effect on the solution of the ferric nitrate or sulphate, but when solution of sodium acetate is mixed with solution of ferric acetate, complete though gradual decomposition takes place.

The presence of two ferric salts in a solution diminishes the decomposing power of water on each of them.

When a solution containing an equivalent of nitric acid is mixed with a solution containing an equivalent of ferric sulphate or ferric acetate, the sulphuric acid or the acetic acid is displaced by the nitric acid. Sulphuric acid completely displaces acetic acid from ferric acetate.

Finally, the double decompositions which take place on adding solutions containing various salts in equivalent quantities to solutions of ferric salts confirm the rule, that the stronger acid joins itself to the stronger base.

Ammonia Salts.—By observations on the heat developed in the combination of ammonia with strong and weak acids in presence of various proportions of water, Berthelot finds that, in the case of strong acids, the results are not sensibly affected either by different degrees of dilution or by the presence of excess of ammonia or of the acid, but that with weak acids, as phosnic, boric and carbonic, the proportion of acid, base, and water exercises a very decided influence on the quantity of heat developed; thus, in the formation of ammonium borate in presence of quantities of water varying from 220 to 1320 eq. the heat evolved varies from 2250 to 3640 units; and in the formation of the carbonates of ammonium, the quantities of heat evolved vary with the proportions of carbonic anhydride, ammonia and water, in the manner shown in the following table:—

CO ² +	NH ³ in presence of 110H ² O disengages	9730
+ 1½ NH ³	" "	146H ² O " 10940
+ 2 NH ³	" "	220H ² O " 12340
+ 3 NH ³	" "	330H ² O " 13240
+ 4 NH ³	" "	440H ² O " 13620
+ 5 NH ³	" "	550H ² O " 13920
+ 6 NH ³	" "	660H ² O " 14040
+ 7 NH ³	" "	770H ² O " 14070

These results show that the proportion of water present exercises a much more marked influence on boric acid than on carbonic acid, but that the decomposing influence of water seems to produce, at first, greater effects on the compounds of the latter, which however rapidly becomes very small, whilst with boric acid the progression is more regular (*Compt. rend.* lxxiii. 864).

The opinion generally entertained that no thermal effects are produced by mixing neutral salts is not justified by the behaviour of salts with weak acids. Whilst the carbonates of potassium and sodium and the bicarbonate of ammonium are not only not decomposed by water, but do not evolve any heat when mixed with neutral salts of the alkalis, the neutral carbonates of the fixed alkalis absorb heat on being brought together with the neutral ammonium carbonate, and liberate heat with the bicarbonate of ammonium. Neutral ammonium carbonate mixed with potassium or sodium carbonate liberates heat.

Ammonium bicarbonate is decomposed by the carbonates of potassium and sodium, heat being absorbed, whilst it evolves heat when mixed with neutral ammonium carbonate.

Ammonia alone does not produce any reaction with potassium carbonate.

These facts can only be explained on the supposition that neutral ammonium carbonate does not exist as such in its aqueous solution, but that part of it splits up into bicarbonate and free ammonia. If, then, potassium bicarbonate be present, it is neutralised by the ammonia. The action of the ammonium bicarbonate upon the neutral potassium salt must be regarded as a double decomposition, inasmuch as potassium bicarbonate is formed, together with neutral ammonium carbonate, which again splits up in the manner already described. Whatever the original state of things may have been, the final equilibrium arrived at is always the same, giving rise simultaneously to five compounds, viz., the neutral carbonate of potassium (or sodium) and ammonium, the bicarbonates of the same bases, and free ammonia.

Bicarbonate of ammonium does not show any thermic reactions when brought into contact with the neutral salts (chloride, nitrate, sulphate, &c.) or with the bicarbonates, of potassium and sodium; moreover the difference of the heats of combination of the bicarbonates of potassium and ammonium is the same as the difference of the heats of combination of the potassium and ammonium salts with strong acids: hence it appears that ammonium bicarbonate in presence of water is quite as stable as the bicarbonate of potassium and sodium.

From this it may be inferred that it is not the gaseous tension of ammonia and carbonic acid exhibited in the solid ammonium carbonates which causes these salts in their aqueous solution to change their states of equilibrium.

In general, it appears that any system formed by a mixture of ammonia, carbonic acid, and water, always tends to the same state of equilibrium, whatever its original conditions may have been. When the original state of combination is less advanced than that required for the existence of equilibrium, heat will be evolved, whereas it is absorbed when the original state of combination is more advanced than that corresponding to the state of equilibrium.

It is this state of incomplete combination, that is to say, the manner in which the base of a salt divides itself between acid and water, which characterises the weak acids, and may in future enable us to define more precisely than before the vague terms *weak and strong acids and bases*.

The neutral salts formed by *strong acids* are stable, inasmuch as the addition of water or an excess of base does not give rise to any decomposition or other reaction indicated by the thermometer. *Weak acids*, on the other hand, form with most of the strong bases, and especially with ammonia, salts capable of being decomposed by water (Berthelot, *Compt. rend.* lxxiii. 951, 1003).

The thermal phenomena produced when two salts are mixed in solution indicate generally that the strong acids combine by preference with the strong bases, leaving the weak acids to combine with the weak bases, so that the salt most stable in the presence of water, and as a necessary consequence the one least stable, are formed.

1st. *Both salts formed with Strong Acids.*—When solutions of two neutral and stable salts are mixed, a feeble thermal effect is produced, which is not the sum of the effects produced by pure water on the two solutions separately, taken at the same temperature.

2nd. *One salt formed with a Strong, and one with a Weak Acid.*—Experiments on the action of the neutral carbonates, bicarbonates, phenates, borates, cyanides and sulphhydrates of the alkali-metals on ammonia salts have shown that the potash or soda always combines with the stronger acid, leaving the ammonia to combine with the weaker. If the ammonium salt formed is stable in presence of water, the thermal effects produced by the mixing are but slight; if, on the other hand, the ammonium salt produced is decomposed by water, as the carbonate for example, an appreciable absorption of heat is the result.

These facts, together with others observed in the reaction of salts both containing weak acids, show that double decomposition takes place between salts in solution, by which the compound most stable under the conditions of the experiments is always formed chiefly, if not exclusively.

The various conditions of equilibrium thus developed play an important part in cases where some of the salts are precipitated as well as in those in which they all remain dissolved (Berthelot, *Comp. rend.* lxxii. 1050).

Precipitation. In the formation of precipitates there is for the most part a development of heat, just as in the solidification of a melted substance; but in the former case the operation is much more complicated, as various other actions have to be considered, such as crystallisation, change of aggregation, &c.

1. *Formation of a Solid Compound.*—The heat disengaged in the formation of a precipitate is due in great part to the separation of a solid body, as is shown by an examination of those salts which produce precipitates only when the solutions are concentrated, such as lead chlorido, potassium picrate, and calcium tartrate. *Lead Chloride.*—On adding a dilute solution of sodium chloride to one of lead nitrate, so that no precipitate is formed, an absorption of heat takes place, about equal to that produced by the dilution of the lead solution; but when a precipitate is formed, there is a disengagement of + 2000 heat-units for each equivalent of lead chloride actually precipitated. *Potassium Picrate.*—If dilute solutions of potash and picric acid be mixed, the heat disengaged corresponds to that of neutralisation, but when a precipitate is obtained, + 10,000 heat-units are disengaged for each equivalent of salt precipitated. *Calcium Tartrate.*—Solutions of sodium tartrate and calcium chloride remain limpid when first mixed, heat being at the same time disengaged (+ 1040). After the lapse of some minutes, however, a crystalline precipitate of calcium tartrate is formed, accompanied by a further disengagement of heat (+ 2060). From each of these examples it may be seen that it is not the chemical reaction which causes the chief disengagement of heat; but it must not be imagined that all precipitation is attended with evolution of heat, as the effects of dehydration, &c., sometimes render it even negative.

2. *Dehydration of the Compounds Precipitated.*—Lime. Andrews has observed that the precipitation of lime from dilute solutions by potash gives rise to an absorption of

heat, which may be explained by the fact that calcium hydrate dissolves in water with disengagement of heat, so that the precipitation of lime should be accompanied by a dehydration, that is a decomposition, the heat absorbed by which more than compensates for that which is disengaged during the solidification of the calcium hydrate. *Calcium carbonate* also precipitated in an amorphous form gives rise to an absorption of heat, which Bertholot believes to be due to the partial dehydration of the compound at the moment of its precipitation. *Magnesium carbonate*, *ferrous carbonate*, and *manganese carbonate* give rise to an absorption of heat, representing a dehydration of the insoluble compound. *Calcium sulphate* and *strontium sulphate*.—The mixed solutions of sodium sulphate and calcium or strontium chloride remain clear, a slight absorption of heat taking place; on causing precipitation, however, by the introduction of some crystals of the sulphate, there is a slight disengagement of heat. *Barium sulphate*, when precipitated, on the contrary, evolves considerable heat (+ 2500 to + 2900). These results indicate the existence of a thermic action of a contrary sign to that of solidification, and varying in the different salts.

3. *Separation of the Acid and Base in Salts*.—Not only can the saline hydrates which exist in solution be transformed into precipitated hydrates of a different type by double decomposition, but even a partial or total separation between the acid and base may be effected, in which case, as in that of dehydration, heat is absorbed. In general this decomposition is not complete, the normal compound being separated into two others, a basic hydrated salt, which is precipitated, and an acid salt which remains dissolved. *Zinc Carbonate*.—The composition of this precipitate varies according to the temperature and the proportions of water, base and carbonic acid which are present, and its formation is attended with absorption of heat. In the normal reaction, when equivalent quantities are used, the total absorption of heat does not take place at once, a secondary reaction setting in by which a further but comparatively small amount is absorbed. These phenomena correspond with the formation of a basic hydrocarbonate mixed with double salts of variable composition. If an alkaline bicarbonate be substituted for the carbonate, neutral zinc carbonate is precipitated, the heat absorbed in this case being much less than with the alkaline carbonates. This reaction also takes place by two stages, and after a time a third action commences, accompanied by an absorption of heat, and a very feeble evolution of gas. This is due to the formation of zinc bicarbonate, which subsequently undergoes decomposition, neutral zinc carbonate (mixed with a double salt) being precipitated, and carbonic acid remaining in solution. The absorption of heat is more feeble than with the neutral alkaline carbonates, as it represents only the decomposition of the zinc bicarbonate into neutral carbonate and carbonic acid. *Copper carbonate*, precipitated by an alkaline carbonate, produces in strong solutions (1 equiv. = 2 lit.) an absorption of heat, which, like the precipitation, is immediate; after a short time effervescence sets in with further cooling, indicating that normal cupric carbonate has but an ephemeral existence. *Ferric carbonates*.—On treating crystalline ferric nitrate with potash, 7870 heat-units were disengaged, from which it may be calculated that ferric nitrate (1 equiv. = 2 lit.) poured into potassium carbonate (1 equiv. = 2 lit.) would absorb -100. From the results obtained with ferric sulphate and iron-alum, it may be inferred that no definite ferric carbonate is formed, but divers complex systems containing a basic salt, an acid salt, and free acid. *Alumina*.—From the results of treating aluminium sulphate with potassium carbonate, it would appear that a molecular condensation of the alumina takes place. *Chromium*.—With chrome-alum and an alkaline carbonate there is, at first, an absorption of heat, and afterwards a feeble effervescence, accompanied by a disengagement of heat, indicating that there is a special molecular change in the chromium oxide comparable with the formation of a polymeric body.

4. *Changes in the State of Aggregation*.—This is the case with those precipitates which are amorphous in the first instance, but gradually aggregate and finally become crystalline; these successive changes, which may be observed under a microscope, give rise to an evolution of heat. *Strontium carbonate* is precipitated in an amorphous state, accompanied by absorption of heat (-400), but the precipitate after a time becomes crystalline, causing an evolution of heat + 400 to + 560. With *barium carbonate* the difference between the two actions is less marked. *Lead carbonate* at first disengages + 400, but the thermometer mounts rapidly, and ultimately the amount of heat disengaged is 2620. In *silver carbonate* the thermic results correspond with amorphous states which succeed one another too rapidly to be distinguished. From results obtained with dilute solutions, however, it is calculated that the heat evolved in the combination of carbonic acid and hydrated silver oxide exceeds that of the formation of silver nitrate. The precipitation of the *oxalates*, which are for the most part crystalline, disengages much heat, the calcium salt evolving as much as barium sulphate.

Many effects marked by thermic phenomena are produced during the double decomposition of salts; at the moment when the solutions are mixed, a certain definite equilibrium is attained, depending upon the proportions of water, of the primitive salts, and of those newly formed; but when these latter are insoluble, they undergo further changes both chemical and physical, such as dehydration, crystallisation, &c. The heat disengaged, therefore, is not the measure of the forces set in action, except in those cases where each individual change causes an evolution of heat, or the contrary.

Decomposition of Crystalline Salts in Solution.—*Crystalline Dissociation* (Favre a. Valson, *Compt. rend.* lxxiii. 1144; lxxiv. 1016, 1065; lxxv. 798, 925, 1000, 1066, 1071. *Gazzetta chimica italiana*, ii. 100, 563, 569. *Chem. Centr.* 1872, 26, 457, 475, 572, 651, 730; 1873, 42. *Chem. Soc. J.* [2] x. 22, 600, 1068; xi. 32, 129). When a crystalline salt is dissolved in water, a variety of phenomena take place. In the case of a crystal of sodium sulphate ($\text{NaSO}_4 + 10\text{HO}$)* for instance, it may be conceived, in the first place, that there is a disaggregation of the molecules which compose the crystalline edifice, and that, moreover, there is an effect analogous to fusion. The latter is probably of a complex nature, being accompanied (1) by the disunion of the chemical molecules, and (2) by the separation of the water associated with the salt to form the crystal, or by the addition of more water to it. The quantitative chemical methods hitherto applied to the solution of this problem do not enable us to distinguish between the separate amounts of work of which the final result is made up. It is better, therefore, to resort to thermochemical methods; but, even then, serious difficulties present themselves: for, although the combination of molecules gives heat, and their separation produces cold, still the final result represents only the difference between these two, and in the present state of science this difficulty cannot be directly resolved.†

The sulphates have many advantages for this investigation, as they differ considerably in their crystalline form; and while some are anhydrous and others contain more or less water of crystallisation, many of them, being isomorphous, are capable of crystallising together. These salts have been examined in the crystalline state, either anhydrous or containing more or less water of crystallisation, and in the state of salts partially dehydrated by heat or by treatment with alcohol. Table I. contains the results obtained with salts of various degrees of hydration; Table II. those given by isomorphous salts crystallised together:—

TABLE I.

Substance	Heat-units	Substance	Heat-units
$\text{FeSO}_4 \cdot 7\text{HO}$	— 2182	$\text{MgSO}_4 \cdot \text{HO}$	5493

$\text{ZnSO}_4 \cdot 4 \cdot 55\text{HO}$	+ 1198		
$\text{ZnSO}_4 \cdot 6 \cdot 17\text{HO}$	— 397		

* O = 8; S = 16.

† This problem resembles that of simultaneous equations of several unknown quantities in algebra requiring, in order to solve it, as many independent equations as there are unknown quantities.

TABLE II.

Substance	Heat-units	The crystals contain
Copper sulphate and zinc sulphate crystallised together		
ZnSO ⁴ .5HO : : : .	— 1166	23.28 p. c. ZnSO ⁴ .5HO
CuSO ⁴ .7HO : : : .	— 2060	44.30 p. c. CuSO ⁴ .7HO
Copper sulphate and magnesium sulphate crystallised together		
MgSO ⁴ .5HO : : : .	— 1194	10.94 p. c. MgSO ⁴ .5HO
CuSO ⁴ .7HO : : : .	— 2130	47.37 p. c. CuSO ⁴ .7HO

It will be observed that the anhydrous sulphates give very different numbers, although they are mostly positive, and that this difference disappears as the number of equivalents of water in the crystal increases. Hence it appears that the greater part of the heat evolved during the solution of an anhydrous salt, or of a salt in a state of hydration inferior to its normal state, is due to the formation of the crystal which contains the normal proportion of water. Moreover, the heat due to the combination of the first molecule of water, greatly exceeds that due to the succeeding molecules: thus between anhydrous magnesium sulphate and the same with one equivalent of water, there is a difference of 4659 heat-units for the addition of one equivalent of water, whilst between magnesium sulphate with five and that with seven equivalents, there is only a difference of 666 for two equivalents of water.

Another question now arises as to what is the state of a salt partly dehydrated by alcohol? It will be found, by interpolation of the numbers in Table I., that the number of heat-units corresponding to zinc sulphate dehydrated by alcohol and containing five equivalents of water, is 1000, whilst zinc sulphate with five of water, obtained by crystallisation with copper sulphate, gives — 1166, being a difference of 2166 heat-units.

Again, with regard to double salts, it is found by experiment that the amount of heat set free by the solution of one of two salts remains sensibly the same, even if the water already contains the other salt in solution, so that if two salts are dissolved in water, the total amount of heat is the same as the sum of the two determined separately. If, however, they exist crystallised together as a double salt, they give a very different result:—

TABLE III.

Substance	Heat-units	A. Sum	Substance	D. Heat-units	Difference between A and B
KSO ⁴ . . .	— 3170	— 4386	Double salt, with 7HO	— 7180	2794
CuSO ⁴ .5HO . .	— 1216				
(NH ⁴)SO ⁴ . . .	— 975	— 2191	Double salt, with 7HO	— 5622	2431
CuSO ⁴ .5HO . .	— 1216				
KCl . . .	— 4574	— 2251	Double salt, with 2HO	— 3491	1241
CuCl.2HO . .	+ 2323				

It will be seen from this table that the amount of cold produced by double salts in dissolving is much greater than the sum of the amounts produced by the two salts dissolved separately. This effect appears to be due to the fact that a certain amount of work is done in the formation of a double salt, giving rise to a disengagement of heat, and that when the double salt is dissolved, there is an inverse work of decomposition, characterised by cold; according to this supposition, the numbers in the column of differences represent the work of combination or decomposition. Experiment also seems to establish a relation between the heat disengaged and the contraction which takes place when a salt is dissolved. If the density d , of an anhydrous salt is known, the volume V , occupied by an equivalent p , can be deduced from it. When this equivalent is dissolved, say in a litre of water, it is easy to determine the increase of volume v . The difference $V - v$ represents then the contraction of the salt on being

dissolved, whilst $\frac{V-v}{V}$ will represent the *coefficient of contraction* with respect to the original volume V .

The values of d in the following table are those given by Filhol; the values of v are deduced by methods which will be described further on (p. 298):

TABLE IV.

Anhydrous salts	p	d	$V = \frac{p}{d}$	v	$V-v$	$\frac{V-v}{V}$	c
KSO ⁴ . . .	87 gr.	2.6	33	21	12	0.36	— 3170
NaSO ⁴ . . .	71	2.6	27	10	17	0.63	354
CuSO ⁴ . . .	80	3.5	22	4	18	0.81	8149
ZnSO ⁴ . . .	80.75	3.4	23	4	19	0.83	9289
MgSO ⁴ . . .	60.50	2.6	23	3	20	0.87	10152

In this table c is the number of heat-units, and it will be seen that they increase in the same ratio as the contraction $V-v$, or the coefficient of contraction $\frac{V-v}{V}$; from this it would appear that the heat disengaged increases with the contraction effected in the substance, and is, at least partly, the immediate consequence of it.

From the general principle that the different forces necessary to produce a given effect are equivalent to one another, it follows that the contractions produced in a liquid: (1) by lowering the temperature, (2) by external compression, (3) by the solution of a salt, may be considered as three effects of the same order, and consequently equivalent to the forces which produce them. From the known coefficient of the expansion of water (0.0001320 according to Kopp) it follows that a litre of water, when cooled 1°, contracts to 9,998,680 c. c. and that a contraction of 1 c. c. per litre corresponds with a fall of temperature equal to 7.576°, i.e. to 75.76 units of heat. This number is therefore the measure of the work required to compress a litre of water by 1 c. c. at 15°. On the other hand, Regnault has shown that the coefficient of compression of water = 0.00004685, for one atmosphere: consequently the compression of a litre of water by 1 c. c. requires a force of 20.34 atmospheres. From this it may be inferred that a litre of water subjected to a compression of 21.34 atmospheres would disengage 7576 units of heat.

If then we suppose a salt to be dissolved in a litre of water in quantity sufficient to produce a contraction of 1 c. c. it follows that the sum of the forces which come into play, whatever may be their mode of distribution, is equivalent to 7576 units of heat, or to a pressure of 21.34 atmospheres.

For sodium sulphate the following numbers have been obtained:

Anhydrous salt (Equivalent),	$P = 71$ grams
" " (Density)	$D = 2.681$
" " (Volume)	$V = \frac{P}{D} = 26.5$ c. c.
Hydrated salt with 10H ₂ O (Equivalent)	$P = 161$ grams
" " (Density)	$D = 1.463$
" " (Volume)	$V = \frac{P}{D} = 110.0$ c. c.

The volume of the anhydrous salt, 26.5 c. c. added to the volume of 10H₂O = 90, gives 116.5 c. c., whereas the actual volume of the crystallised salt is only 110 c. c. Consequently:

1. Sodium sulphate and water, in uniting to form the crystallised hydrate, suffer a contraction of 6.5 for 116.5, i.e. $\frac{1}{18}$ th of the total volume.

2. When 1 eq. (71 grams) of anhydrous sodium sulphate is dissolved in a litre of water, a liquid is obtained whose density = 1.0606, and volume therefore = 1099.8 c. c.; and as the volume of the anhydrous salt itself is 26.5, the total volume of the two has suffered by solution a contraction of 20.5 - 9.8 = 16.7 c. c.

3. When 1 eq. (161 grams) of crystallised sodium sulphate is dissolved in a litre of water, the density of the solution is 1.0559 and its volume 1099.5 c. c.; and as the crystallised salt itself has a volume = 110 c. c. the total volume has suffered a contraction of 1110.0 - 1099.5 = 10.5 c. c.

To determine the force required to compress the water, as strongly as it is contracted

by the act of dissolving the salt, the above-mentioned numbers, 7576 heat-units and 21.34 atmospheres, must be multiplied by the number of cubic centimeters in each case. The results are given in the following table :

TABLE V.

1 eq. salt dissolved in 1 litre of water	Contraction of volume	Contraction measured in Heat-units	Contraction measured in Atmospheres	Heat-units observed in the Calorimeter
Anhydrous salt . . .	16.7 c. c.	126519	356	+ 354
Hydrate	10.5	79518	224	- 9300
Crystallisation . . .	6.5	49244	139	+ 9654

The calculated numbers in the third column differ greatly from those in the last, which are obtained by direct observation. Now the water, in dissolving the salt, gives up to it almost all the heat developed by its own contraction. If then T and T' denote the numbers of heat-units equivalent to the internal work expended in the combination of the anhydrous and hydrated salts respectively with water, we have for the anhydrous salt, $T + 354 = 126519$ heat-units, therefore $T = 126165$; and for the hydrate, $T' - 9300 = 79518$ units, therefore $T' = 88818$. Hence $T - T' = 37317$ heat-units, which number expresses the quantity of heat given up by the water ($10\text{H}_2\text{O}$) to the salt SO^*Na to form the crystallised salt $\text{SO}^*\text{Na} + 10\text{H}_2\text{O}$, and agrees approximately with the experimental number 39590 given at the end of the following table.

The value and distribution of the work are therefore as follows:—

TABLE VI.

		Heat-units
Units of heat evolved by the water for contraction of . . .	$\left\{ \begin{array}{l} 16.7 \text{ c.c. in } \text{SO}^*\text{Na} + \text{Aq} \\ 10.5 \text{ c.c. in } \text{SO}^*\text{Na}.10\text{H}_2\text{O} + \text{Aq} \\ 6.5 \text{ c.c. in } \text{SO}^*\text{Na} + 10\text{H}_2\text{O} \end{array} \right.$	$\left\{ \begin{array}{l} 126,519 \\ 79,548 \\ 49,244 \end{array} \right.$
Algebraic sum of the Heat-units given by the Calorimeter . . .	$\left\{ \begin{array}{l} \text{SO}^*\text{Na} + \text{Aq} \\ \text{SO}^*\text{Na}.10\text{H}_2\text{O} + \text{Aq} \\ \text{SO}^*\text{Na} + 10\text{H}_2\text{O} \end{array} \right.$	$\left\{ \begin{array}{l} + 354 \\ - 9,300 \\ + 9,654 \end{array} \right.$
Heat-units as measure of the in- ternal work of combination between salt and water . . .	$\left\{ \begin{array}{l} \text{SO}^*\text{Na} + \text{Aq} \\ \text{SO}^*\text{Na}.10\text{H}_2\text{O} + \text{Aq} \\ \text{SO}^*\text{Na} + 10\text{H}_2\text{O} \end{array} \right.$	$\left\{ \begin{array}{l} 126,165 \\ 88,848 \\ 39,590 \end{array} \right.$

The Alums.—The salts of this group are particularly well adapted for the enquiries under consideration, on account of their great resemblance to one another in form and composition.

The following tables exhibit the quantities of heat developed or absorbed in the solution of these salts in water under various conditions:—

TABLE VII.

Thermic action in the solution of 1 eq. of an alum in a large quantity (about 1000 eq.) of water.

Alums	Equivalents	Heat-units at 8°-11°	Heat-units at 19°-20°
Potassium alum	474.5	- 9803	- 9883
Ammonium alum	453.5	- 9580	- 9631
Potassio-chromic alum	500.5	- 9651	- 9409
Ammonio-chromic alum	479.5	- 9628	- 9889
Potassio-ferric alum	503.0	- 16016	-
Ammonio-ferric alum	482.0	- 16571	- 18060

These numbers show that the action of water on the first four alums at the temperatures of experiment is nearly the same. The last two, on the other hand, undergo a greater amount of separation. The experiments with ammonio-ferric alum show that at the higher temperature (19°-21°) a still greater separation of the constituent salts takes place.

The quantities of heat absorbed were found not to vary sensibly when the salts were dissolved in comparatively small quantities of water, so small indeed as to become saturated with them.

The following table shows the quantities of heat evolved when the alums dried at 85° were dissolved in water at 20° . Most of them when dried at 85° retain 10 mols. of water, but the ammonio-ferric salt melts below 85° and loses 42.72 p. c., or 23 mols. water, and afterwards dissolves so slowly and imperfectly as to be unfit for thermic determinations. To obtain the total heat of hydration of the alums which still retain 10 mols. water, the numbers in the fourth column must be increased by those which represent the thermic effect produced on dissolving the 24-hydrated salts in water, that is to say the numbers in Table VII. but with opposite sign.

TABLE VIII.

Alums dried at 85°	Molecules of water still present	Equivalents		Heat of Hydration
Potassio-aluminic alum . .	10.00	348.50	12.416	22.047
Ammonio-aluminic alum . .	10.83	335.00	12.093	21.724
Potassio-chromic alum . .	11.67	389.50	3.825	
Ammonio-chromic alum . .	10.75	360.25	4.851	

The evolution of heat—more than 12,000 units—which accompanies the solution of the 10-hydrated aluminic alums may be regarded as the difference between the total heat which would be evolved in the conversion of the 10-hydrated into the 24-hydrated salts, and the quantity absorbed in the solution of the latter in water.

There is, however, another way in which the phenomenon may be viewed. The contraction which generally takes place in the solution of salts is accompanied by a considerable evolution of heat, arising from the great resistance which water offers to compression; in fact, those salts which evolve most heat in dissolving, likewise give rise to the greatest amount of contraction; and the calorific effect actually observed is the difference between the absorption of heat resulting from the disintegrating action of the water which brings about the destruction of the crystalline edifice, and the disengagement of heat proceeding from the contraction of the total volume which takes place when the salt is dissolved. Moreover, the 24 mols. of water which exist in the alums in the solid state, would, if uncombined, require 17,000 heat-units to pass into liquid state; but the chromium and aluminium alums in dissolving absorb only about 9,500 units. It would seem, therefore, that the latent heat of water is considerably diminished when it is associated with the saline constituents of crystallised alums.

The behaviour of the violet chrome-alums is peculiar. When a solution of one of these salts is kept boiling for a considerable time, it becomes green and uncrystallisable, and the solution of the salt thus modified gives, when treated with barium chloride in the cold, only a slight precipitate; the filtered liquid also gradually becomes turbid, showing that the precipitation is taking place gradually; at length, however, all the sulphuric acid is thrown down. If to a solution of violet chrome-alum modified as above, the quantity of barium chloride required to throw down all the sulphuric acid be added in four equal portions, the first two portions will be precipitated directly and completely, whereas the third and fourth portions will give rise to a slow precipitation. Hence Favre et Valson infer that the formula of green chromic sulphate is $\text{SO}_4[\text{Cr}(\text{SO}_4)_2]$, the group $\text{Cr}(\text{SO}_4)_2$ being regarded as a metallic radicle, *sulphochromyl*.

These results are corroborated by the thermic phenomena exhibited in the successive precipitations of the sulphuric acid by barium chloride. Table IX. gives the quantities of heat evolved in the precipitation of modified solutions of the chrome-alums by barium chloride in halves and in fourths:—

TABLE IX.

Chrome-alums	Excess of Barium Chloride (A.)	1. half	2. half	1. fourth	2. fourth	3. fourth
Potassio-chromic alum . .	8251 heat-units	8142 h.u.	204 h.u.	4104 h.u.	4102 h.u.	146 h.u.
Ammonio-chromic alum . .	7641 "					

Here it is seen that the first two of the four precipitations give rise to equal developments of heat, whereas the calorific effect of the third is much smaller. The difference between the quantities of heat evolved in the precipitation of the two chromo-alums by excess of barium chloride (column A), seems to show that these two salts are not modified by water in exactly the same manner.

The numbers in the last three columns show that the precipitable sulphuric acid proceeds from both the sulphates contained in the double salt. But since, as the following numbers show, the decomposition of potassium sulphate by barium chloride gives about 3,800 heat-units, the precipitation of the sulphuric acid of sulpho-chromyl sulphate, if this salt were alone present, would give about 4,900 units, that is to say, as much as the decomposition of barium chloride by free sulphuric acid:

TABLE X.

TABLE A.				Heat-units
Potassium sulphate precipitated by barium chloride gives	.	.	.	3,357
Ammonium sulphate	"	"	"	3,279
Free sulphuric acid	"	"	"	5,053

An equivalent of aluminium sulphate precipitated by 3 eq. of barium chloride develops 11,877 units of heat, and if the 3 eq. be added separately, the successive quantities of heat evolved are nearly equal to one-third of this amount.

The following table gives the quantities of heat evolved on precipitating the several alums and their constituent salts with barium chloride, both directly after preparation, and after standing for a considerable time:—

TABLE XI.

Alums	Precipitation immediately after preparation	Precipitation after 14 days	Immediate precipitation of the Constituent Salts	Precipitation of Constituent Salts after 14 days
Potassio-aluminic alum . .	15,026	14,944	14,893	14,902
Ammonio-aluminic alum . .	14,888	14,650	14,812	14,787
Potassio-chromic alum . .	14,767	13,623		
Ammonio-chromic alum . .	14,636	13,900		
Potassio-ferric alum . .	18,161	18,092		
Ammonio-ferric alum . .	18,288	18,399		

These numbers show: (1.) That no alteration is produced by keeping, in the solutions, of any of the alums, excepting the chrome-alums, which appear to be modified by keeping in the same manner as by boiling. (2.) That the heat evolved in the precipitation of the two aluminic alums is nearly the same as that which is developed by the precipitation of their constituent salts. Hence it follows that these alums can neither be produced from their constituent salts within an aqueous solution, nor can they subsist in aqueous solution after they have been formed by crystallisation.

If from the nearly 15,000 heat-units evolved in the precipitation of the first four alums by barium chloride, we deduct the 3,300 units developed by the precipitation of potassium or ammonium sulphate, there remain 11,700 units due to the precipitation of the aluminium sulphate contained in the alums. This number agrees nearly with that found by direct observation. Divided by 3, it gives 3,900 for the quantity of heat due to the precipitation of 1 mol. sulphuric acid from the aluminium sulphate. But the precipitation of barium chloride by free sulphuric acid gives about 5,000 heat-units, that is to say considerably more. With the iron-alums it is otherwise: for on subtracting from the 18,300 heat-units of the last table likewise the number 3,900, there remain 15,000 units, the third of which, viz. 5,000, is the same as the amount of heat developed in precipitation by free sulphuric acid. This seems to show that in the iron-alums the disuniting action of the water goes further than with the other alums, not only separating the constituent sulphates one from the other, but likewise resolving the ferric sulphate itself into acid and base.

The following table gives the quantities of heat developed in the successive precipitation of the sulphuric acid of various alums;—

TABLE XII.

Alums	1. half	2. half	1. fourth	2. fourth	3. fourth	4. fourth
Potassio-aluminic .	7,601	7,815				
Potassio-chromic .	7,514	7,388	3,680	3,702	3,665	3,699
Ammonio-ferric .			4,570	4,600	4,793	4,712

When a sufficiently dilute solution of a ferric alum is heated, its original brown colour becomes gradually lighter, and at length like that of cobalt solutions; if the liquid be then heated for some time to the boiling point, a more or less considerable quantity of ferric oxide is precipitated, containing small quantities of sulphuric acid. This is shown by the following numbers:—

TABLE XIII.

	Ammonio-ferric alum			Potassio-ferric alum
	1.	2.	3.	
Fe^2O^3 { precipitated .	64.3	66.3	59.1	76.1
{ not precipitated .	16.1	13.2	21.0	4.7
SO^2 { precipitated .	5.4	5.8	41.1	60.3
{ not precipitated .	186.0	185.6	151.5	130.9

The effect appears to be due to the disuniting action of the heat superadded to that of the water, a view confirmed by the thermic results obtained on precipitating the ferric alums by ammonia (*Compt. rend.* lxxiv. 1016, 1065; *Chem. Centr.* 1872, 457, 475).

Favre & Valson have also studied the solution of the alums in water with reference to the alterations of physical state, more especially the contraction in volume—the *coercive effect*, as they designate it—thereby produced (*Compt. rend.* lxxv. 798, 925, 1000, 1066; *Chem. Centr.* 1872, 572, 730; 1873, 42).

The results were obtained by two methods: first, by a comparison of the densities of the solid salts and the solutions; secondly, by observing the increase of volume caused by the solution of a known weight of the salt in a determinate quantity of water contained in a reservoir surmounted by a narrow calibrated tube. Table XIV. contains the direct results of observations; Table XV. the results deduced therefrom. To render these numbers comparable, the formulae of the salts examined are all reduced to 1 eq. of sulphuric acid. Column *P* contains the equivalent (molecular) weights of the salts. The numbers in columns *d*, *h*, *dh*, refer to *normal solutions*, that is to say, solutions containing 1 eq. of the salt in a litre of water. Column *d* shows the densities of the salts; column *h* the heights in millimeters to which the respective solutions rise in capillary tubes of $\frac{1}{4}$ mm. diameter. These and the following observations were made at a temperature of 20°. Column *dh* gives the products of the densities and capillary heights. The numbers in column *v* express the increase of volume which the water acquires by solutions of 1 eq. of the salt. These values are easily calculated from the densities of the solutions. For, supposing that a weight *x* of the salt is dissolved in a litre of water, so that the total weight of the solution is $1 + x$, further that $1 + y$ is the density of the solution, and $1 + v$ the volume, we have $1 + v = \frac{1 + x}{1 + y}$, therefore $v = \frac{x - y}{1 + y}$.

Column *D* contains the densities of the salts in the anhydrous state; column *V* their volume = $\frac{P}{D}$. Before solution, the total volume is $1 + V$, after solution it is

$1 + v$; consequently, $V - v$ is the contraction, and the quotient $\frac{V - v}{V}$ is the coefficient of contraction, that is to say, the contraction of the solution referred to the unit of volume. These numbers are given in the last two columns of the second table.

TABLE XIV.

Names of the salts		Temperature	Density
		°	
Potassium sulphate		21.8	2.653
Ammonium sulphate		22.3	1.786
Aluminium sulphate, dehydrated		22.5	2.672

Potassio-chromic alum, green		22.0	1.0602
Ammonio-chromic alum, green		22.0	1.0517

The density of an anhydrous potassio-aluminic alum shows that it is a chemical compound, not a mere mixture of its constituents: for the sum of the weights of the constituent salts divided by the sum of their volumes gives the number 2.665, whereas the actual density of the alum is only 2.617. With ammonio-aluminic alum, on the contrary, the observed density, 2.333, is very nearly the same as the mean density of the constituent salts, namely, 2.337. Nevertheless it is most probable that this salt is also a chemical compound, inasmuch as it does not give off ammonium sulphate till raised to a temperature much higher than that at which ammonium sulphate volatilises when heated by itself. The same is the case with the other ammonia alums.

The relations of volume and density of the crystallised alums are given in Table XVI.

As the values of V differ but slightly, it may be assumed that the molecular volumes of all the crystallised alums are equal.

The values $V_1 - v_1$ measure the contraction which the water undergoes by dissolving the hydrated salts. If from these we subtract the corresponding values $V - v$ in Table XV, which measure the contraction consequent on the solution of the anhydrous salts, the differences will give the portion of the contraction which is a consequence of the formation of crystals. For potassio-aluminic alum, for example, $V - v = 19.86$ and $V_1 - v_1 = 9.17$; and the difference of these numbers, 10.69, is greater than $V - v$ itself, showing that the contraction produced by the crystallisation is greater than that which is a consequence of the solution of the hydrated salt. Direct experiments with sodium sulphate have shown that for this salt the reverse takes place (p. 294).

The conversion of the violet solutions of the chrome-alums into green is accompanied by a diminution of the density of the liquid. Normal solutions of the two violet chrome-alums were heated in sealed tubes to the boiling temperature, and their densities

TABLE XV.

Anhydrous salts	Formula	Equivalent weight $\frac{P}{P}$	Normal solutions			Equivalent volume $\frac{P}{V} = \frac{P}{D}$	v	$V - v$	$\frac{V - v}{V}$

Ammonio-chromic alum . . .	$\text{SO}_4 \left(\frac{3\text{Cr}_3\text{Am}}{4} \right)$	65.87	1.0567	58.2	61.3	26.65	8.68	17.97	0.675

TABLE XVI.

Formula	P	D	$V' = \frac{P}{D}$		r_1	$V_1 - r_1$	$\frac{V_1 - r_1}{V_1}$
$\text{SO}^4 \left(\frac{3\text{Al}\frac{3}{2}\text{K}}{4} \right) + 6\text{HO}$	118.62	1.745	67.98	1.0565	58.81	9.17	0.135
$\text{SO}^4 \left(\frac{3\text{Al}\frac{3}{2}\text{Am}}{4} \right) + 6\text{HO}$	113.33	1.634	69.36	1.0497	60.62	8.74	0.126
$\text{SO}^4 \left(\frac{3\text{Fe}\frac{3}{2}\text{K}}{4} \right) + 6\text{HO}$	125.78	1.827	68.84	1.0560	65.18	3.66	0.053
$\text{SO}^4 \left(\frac{3\text{Fe}\frac{3}{2}\text{Am}}{4} \right) + 6\text{HO}$	120.50	1.712	70.38	1.0508	66.35	4.03	0.057
$\text{SO}^4 \left(\frac{3\text{Cr}\frac{3}{2}\text{K}}{4} \right) + 6\text{HO}$	125.12	1.816	68.90	1.0604	61.04	7.86	0.114
$\text{SO}^4 \left(\frac{3\text{Cr}\frac{3}{2}\text{Am}}{4} \right) + 6\text{HO}$	119.87	1.697	70.64	1.0538	62.70	7.94	0.112
$\text{SO}^4\text{Al}\frac{3}{2} + 6\text{HO}$	111.17	1.767	62.90	1.0539	51.34	8.56	0.136

afterwards determined at 22°. These densities were found to be 1.0572 and 1.0402, numbers differing from those in Table XVI. viz., 1.0636 and 1.0567, which were determined before the solutions had been heated. The diminution of density in the solutions of the two chrome-alums is nearly the same.

The numbers in Table XV. under the head of normal solutions, afford the means of extending to the alums the relations of density and capillary height formerly established by Valson for other salts (pp. 244-246). The following are the moduli of density and capillarity of the several metals contained in the alums, deduced from the numbers in Table XV. a solution of ammonium sulphate being taken as the standard:—

TABLE XVII.

	Moduli of density	Moduli of capillarity
Ammonium (Am)	0.0000	0.0
Potassium (K)	0.0284	1.5
Aluminium (Al $\frac{3}{2}$)	0.0190	1.7
Iron (Fe $\frac{3}{2}$)	0.0209	1.9
Chromium (Cr $\frac{3}{2}$)	0.0252	2.0

The moduli of density are the numbers which must be added to the density of a normal solution of ammonium sulphate 1.0378 to obtain the densities of the other normal solutions. The moduli of capillarity are the numbers which must be subtracted from the capillary height of ammonium sulphate, 59.7, in a tube 5 millimeters in diameter, to obtain the capillary heights of the other normal saline solutions (p. 246). The following table exhibits the agreement between the observed and calculated results:—

TABLE XVIII.

Normal solutions of alums	Density		Capillary calc.	Height obs.
	Calc.	Obs.		
Potassio-aluminic alum	1.0591	1.0595	58.0	58.0
Ammonio-aluminic alum	1.0520	1.0521	58.4	58.4
Potassio-ferric alum	1.0606	1.0600	57.9	57.8
Ammonio-ferric alum	1.0535	1.0535	58.3	58.3
Potassio-chromic alum	1.0638	1.0636	57.8	57.9
Ammonio-chromic alum	1.0567	1.0567	58.2	58.2

The product of the height of each normal solution into its density gives the numbers in column dh of Table XV. which are nearly the same for all the alums.

These results confirm the conclusion deduced from the thermic phenomena before considered, namely, that double salts, and especially the alums, cannot exist in presence of water, but are resolved into their constituent salts; both for the density and for the capillary height the same numbers are obtained, whether by direct determination with solutions of the alums, or by calculations from the numbers belonging to the constituent salts (*Compt. rend.* lxxv. 798 and 925; *Chem. Centr.* 1872, 572, 730).

A comparison of the thermic effects and the alterations of volume accompanying the solution of the alums leads to the following conclusions:—

The numbers in column v of Table XV. show that different salts in dissolving undergo very different changes of volume; for whereas ammonium sulphate increases by about 27 c. c. for 1 eq., potassium sulphate increases by only 20 c. c., and aluminium sulphate by only 0.35 c. c. The solution of the sulphates of potassium and ammonium is attended with a fall of temperature, whereas aluminium sulphate exhibits a considerable rise. The slowness with which this salt dissolves when in the anhydrous state renders it unfit for calorimetric experiments, but when dehydrated at 200° and then brought back to the composition $Al_2(SO_4)_3 \cdot 6H_2O$ it gives 23919 heat-units in dissolving. If it could be employed in the anhydrous state, it would doubtless give a higher number.

These examples, together with those formerly cited, show that there is a certain connection between the thermic phenomena and the contraction of volume attending the solution of salts. The hydrated alums, in dissolving, exhibit a contraction smaller than that which might be expected from a comparison of the values obtained for v_1 and V_1 ; but at the same time the act of solution is accompanied by an absorption of heat, amounting to about 10,000 units in the case of chrome-alum with 24 eq. water, and to 18,000 units in that of the ferric alums with the same amount of water. Nearly the same absorption of heat is likewise observed in the solution of the aluminic alums; at the same time the values of v_1 and V_1 show that the corresponding contractions are nearly the same; the latter observation applies also to the iron-alums. On the other hand, the contractions which take place in the solution of the anhydrous alums are greater than those which accompany the solution of the hydrated alums.

The partially dehydrated alums exhibit in dissolving, not an absorption but a development of heat; thus potassio-aluminic alum with 10H₂O gives + 12,416 heat-units instead of - 9,803 (the absorption observed with the 24-hydrated salt), making altogether a difference of 22,219 heat-units. This difference would be much greater if it were possible to operate with perfectly anhydrous alums.

In examining the relations between the phenomenon of contraction and the external thermic effects accompanying the solution of salts, it must be borne in mind that solution is a complex effect resulting from several different forms of work, of which only the final result can be directly observed.

This has already been explained in the case of sodium sulphate. Table XIX. will facilitate the application of similar considerations to the alums.

In this table V_1 , v_1 , V and v , have the same values as before. The column $V_2 = V + 6H_2O$ contains the volumes of the anhydrous salts plus that of their water of crystallisation in the uncombined state; hence, as V_1 is the volume of the crystallised salt, the differences $V_2 - V_1$ measure the contractions which take place on assumption of the water of crystallisation. Lastly, the differences $V - v$ denote the contractions which accompany the solution of the hydrated salt, and $V_1 - v$, those which ensue on the solution of the crystallised salt. The sum of the values $V_2 - V_1$ and $V_1 - v$ is necessarily $V_2 - v$: for the ultimate state of a solution must be the same whether it is made from the hydrated or from the anhydrous salt, and consequently the contraction produced by the anhydrous salt must be equal to that produced by the hydrated salt together with that resulting from the addition of the action of crystallisation.

When the values of v are calculated for the first two alums, starting from the corresponding values for aluminium sesquisulphate and for the sulphates of potassium and ammonium, we obtain the numbers 5.19 and 7.00, agreeing approximately with 4.83 and 6.88. A similar calculation for the same alums with respect to the values $V - v$ gives the numbers 19.4 and 18.37, agreeing approximately with 19.86 and 18.65. For the other alums, however, this calculation cannot be carried out, because the densities of the anhydrous ferric and chromic sulphates are unknown. Nevertheless, the above-mentioned coincidences seem to show that moduli of contraction exist analogous to those previously established for the thermal phenomena densities and capillary actions.

Table XX. exhibits the quantities of heat, which, according to principles previously developed, correspond with the work of the solution. $V - v$ denotes the

internal work which measures the contractive force exerted by the salt in the water. $V_2 - V_1$ measures the work employed in the formation of the crystal, and $V_1 - v_1$ the work which is rendered available on the solution of the crystallised salt. The numbers in this table were obtained by multiplying the corresponding numbers of the preceding table by 75.76, which number answers to the quantity of heat abstracted from a litre of water when its volume is diminished by 1 c. c.

TABLE XX.

Formulae of the Salts		$V - v$	$V_1 - v_1$	$V_2 - V_1$
		Heat-units	Heat-units	Heat-units
SO ⁴ K		99,170	—	—
SO ⁴ Am		78,700	—	—

	Potassio-chromic	145,005	59,547	85,685
	Ammonio-chromic	136,141	60,153	75,836

The interpretation of these numbers leads to the same or similar consequences as those which have already been developed in the case of sodium sulphate (p. 294).

The numbers in the last table are very high, and out of all proportion to those obtained with the calorimeter, which are for the most part very low and not unfrequently negative. They cannot be explained either by the fusion of the crystallisation-water or by that of the salts themselves. The mechanical work corresponding with these large quantities of heat seems indeed to indicate considerable modifications of internal structure. The solvent action of the water may perhaps consist in separating the elements of the salt and bringing them, if not into the free state, at least into a state of partial independence, very different from that in which they existed in the original salt. The existence of such a state is, moreover, indicated, as already explained, by the phenomena of density, capillarity, and contraction. Starting from these different points of view, we always arrive at the same conclusion, namely that in sufficiently dilute saline solutions, each of the metallic and chlorous radicles produces effects which are independent of those produced by all the rest.

Finally, Favre and Valson sum up their results in the following theorem: 'Solution brings the elements of the dissolved bodies into a state of mutual independence, and the internal mechanical work required for the production of this effect is measured by the alterations of volume which take place in the act of solution, and consequently by that quantity of heat which comes into play as soon as the same effects of contraction (coercion) are produced in the solvent by equivalent quantities of work' (*Compt. rend.* lxxv. 1000).

Nascent State. According to H. Sainte-Claire Deville (*Compt. rend.* lxx. 20, 550) the assumption of a so-called nascent state in bodies ascribes to them a system of arbitrarily chosen properties, which contributes nothing to the explanation of chemical reactions. By the examination of a number of phenomena in which this peculiar state of bodies is supposed to come into play, such as the action of zinc on solutions of nitric acid, of sulphuric and nitric acid, and of hydrochloric and nitric acid, the ultimate result of which is the formation of sulphate, nitrate or chloride of zinc and of ammonia, Deville found that hydrogen is never evolved in contact with the zinc at any temperature or any degree of concentration of the nitric acid, and that the quantity of ammonia formed is altogether independent of the concentration of the acid. When zinc is treated with excess of nitric acid, the resulting solution contains nitrous acid, a little nitrogen dioxide, often a large quantity of nitrogen monoxide, very little nitrogen, and finally ammonia. These results are explained by Deville as follows:—The evolution of nitrogen takes place as represented by the equation,

and, assuming that the acid was contained in the liquid in the form of the hydrate $\text{N}^{\text{a}}\text{O}^{\text{a}}.2\text{H}^{\text{a}}\text{O}$, and that it loses 5 at oxygen, there will remain ammonium nitrate $\text{NH}^{\text{a}}.\text{NO}^{\text{a}} = \frac{1}{2}(\text{N}^{\text{a}}\text{H}^{\text{a}}\text{O.N}^{\text{a}}\text{O}^{\text{a}})$. Moreover, experiment shows that only a portion of the liberated nitrogen remains united with the elements of water, the rest emerging

as gas. This, according to Deville, explains the formation of nitrous acid, nitrogen, and part of the ammonia.

The evolution of nitrogen monoxide takes place according to the equation,

and assuming, as before, that the hydrate $\text{N}^2\text{O}^3 \cdot 2\text{H}^2\text{O}$, or $2\text{NO}^2\text{H} \cdot \text{H}^2\text{O}$, is present in the liquid and gives up 4 at. oxygen to the zinc, there will remain ammonium nitrate $\text{NH}^4\text{NO}^3 = \frac{1}{2}(\text{N}^2\text{H}^4\text{O} \cdot \text{N}^2\text{O}^3)$. Only a part of the nitrogen monoxide, however, remains combined with the elements of water, the rest escaping as gas or remaining dissolved.

Devilh has also found—by a large number of experiments in which the proportional quantities of ammonia, nitrogen monoxide, nitrogen and nitrous acid, formed in a liquid of known temperature, concentration, and tension of the dissolved gases, were determined—that the quantity of ammonia formed and the quantity of zinc required to produce it from nitric acid, do not vary much with the concentration of the acid. As the concentration becomes greater, the quantity of nitrogen evolved decreases and that of nitrogen monoxide increases.

When zinc acts upon a mixture of sulphuric and nitric acids, the quantity of hydrogen evolved diminishes as the proportion of nitric acid increases, and after a certain time, no more hydrogen is evolved. Hence it is inferred that the two acids act upon the zinc just as if each of them were present alone. When the nitric acid is in excess, the bars of zinc become surrounded with a layer of saline solution containing a large proportion of zinc nitrate. Around this layer the sulphuric acid rapidly decomposes the zinc nitrate, reproducing free nitric acid, which again dissolves zinc; and thus the action goes on, the sulphuric acid never coming into direct contact with the zinc. This accounts for the complete disappearance of the hydrogen.

A mixture of hydrochloric and nitric acids likewise acts upon zinc as if the acids were separate, and not as if they had previously formed aqua regia, which would decompose the ammonia. Moreover, sulphuric acid dissolves zinc less quickly than hydrochloric acid, and in such proportion that 0.29 eq. of nitric acid is sufficient to arrest completely the action of 1 eq. sulphuric acid, whereas to stop the action of 1 eq. hydrochloric acid, 0.67 eq. nitric acid is required. Lastly, sulphuric acid very easily displaces the nitric acid of zinc nitrate, whereas the conversion of this salt into chloride, requires a very large excess of hydrochloric acid and prolonged boiling. Hence, when a layer of dissolved zinc nitrate has formed around the zinc, hydrochloric acid can more easily penetrate this layer without decomposing the zinc nitrate, and thus reach the zinc and give off hydrogen.

All these reactions may, therefore, be referred to simple mechanical effects analogous to the polarisation of the electrodes or the elements of a battery, in which the chemical action is arrested by a layer of gas which prevents the liquid from coming in contact with the metals.

Influence of certain Liquids in retarding or arresting the action of Acids on Metals.—(Marangoni a. Stefanelli, *Il nuovo Cimento*, [2] iv. 373). The evolution of hydrogen from dilute sulphuric acid by the action of zinc is quickly arrested on adding a small quantity of an essential oil, such as oil of myrtle, thyme, lavender, turpentine, or cherry-laurel, and agitating briskly with a glass rod, but recommences, though less strongly, on addition of a certain quantity of alcohol. Fixed oils likewise arrest the action completely, but less quickly than essential oils; ether, naphtha, benzene, and nitrobenzene have but little effect, the evolution of hydrogen being merely retarded by them while the agitation continues, and recommencing soon after the liquid is left at rest. The action of dilute nitric acid on copper is retarded by essential oils while they are agitated with the liquid, but quickly recommences on repose; fixed oils produce but little retardation; ether, naphtha, benzene, and nitrobenzene scarcely any. Similar remarks apply to the effect of these various liquids on the action of hydrochloric acid upon zinc. That of dilute nitric acid on zinc is not sensibly retarded by either of them.

The retarding action in all these cases is due to the formation, on the surface of the zinc, of a film of liquid which protects the metal from contact with the acid. The agitation of the mixture facilitates the formation of this film, partly by bringing the particles of the oily liquid in contact with the metal, partly by removing the bubbles of hydrogen which adhere to its surface.

A comparison of the observations made by Marangoni a. Stefanelli with those of Duclaux (*Ann. Chem. Phys.* [4] xxi. 373) on the surface-tension of liquids, leads to the conclusion that the permanence of the protecting film is greater in proportion as the density of the oily liquid approaches more nearly to that of the acidulated water, and diminishes in proportion as this liquid has a greater superficial capillary tension (which is proportional to the product of its density into the height to which it rises in
2nd Sup.

capillary tube of given diameter). The fixed oils produce but little retarding effect, because, though they differ but little from the acidulated water in density, they have a considerable superficial tension; ether, naphtha, and benzene, on the other hand, though their superficial tension is small, cannot form permanent films on the metal under the acidulated water, on account of their small specific gravity; but the volatile oils above mentioned have but little superficial tension, and a density (0.869—0.886) not differing greatly from that of the acidulated water: hence they have the greatest tendency to form permanent films on the surface of the zinc.

The authors also found that the effect of a film of essential oil on the zinc plates of a voltaic pile is similar to that of amalgamation, preventing local action to a certain extent. It diminishes the quantity and intensity of the current at the commencement of the action, but renders it for a certain time more constant. After two or three hours, however, it stops the action altogether.

CHINESE GREEN. See LOKAO.

CHINESE OIL-BEAN. These beans, belonging to the genus *Phaseolus*, are used in China for the production of sweet oil by pressure, while the pressed residue is made into a kind of cheese. The composition of a yellowish and a black variety, analysed by Stöckhardt (*Chem. Ackers*. 1872, 122), is given in the following table, together with that of the cake analysed by Voelcker:—

	Yellowish oil-bean	Black oil-bean	Oil-bean cake
Water	6.60	7.14	12.82
Albuminoids	38.51	38.04	45.93
Oil	20.53	16.88	5.32
Non-nitrogenous extractive matter	21.61	27.79	24.52
Crude fibre	5.13	5.53	5.71
Ash	4.50	4.62	5.70
	100.00	100.00	100.00

The Chinese oil-beans resemble lupine-seeds in containing no starch and a much larger proportion of fat and nitrogen than beans, peas, vetches, or lentils.

CHINOLINE, C^9H^7N . Lulavien's experiments with this base, shortly noticed in the *First Supplement* (p. 430), have since been published in detail (*Ann. Ch. Pharm.* clv. 311). The chinoline was prepared by Williams's process (1st *Suppl.* 869) by distilling cinchonine with potassium hydrate, and collecting apart the portion which passed over between 215° and 245° .

Potassium and sodium do not act upon chinoline at ordinary temperatures, but on applying heat, an unstable red body is formed without evolution of hydrogen, and, on removing the excess of potassium and treating the mass with water, a brown amorphous insoluble substance remains. Chinoline is not decomposed by ordinary nitric acid at the boiling heat, or by the fuming acid at ordinary temperatures, but on heating it with the latter, copious red fumes are evolved, and on addition of water, an amorphous yellow body separates out. Chinoline is not oxidised by heating with a mixture of potassium chromate and sulphuric acid, but the liquid, on cooling, deposits characteristic gold-yellow needles of acid chromate of chinoline. Melting potash produces, with chinoline, a greenish-blue, and on prolonged heating, a dark violet, unstable coloration, which disappears, with formation of a brown amorphous substance, when the fused mass deliquesces or is dissolved in water.

This colour is likewise produced when any derivative of chinoline is fused with an alkali or alkaline earth; sometimes even on fusing cinchonine with potash.

Chinoline-sulphonic acid, $C^9H^7N.SO^2H$, is formed when chinoline is heated with ordinary concentrated sulphuric acid, but is best prepared by heating chinoline for several days on the water-bath with fuming sulphuric acid till a drop of the solution, after dilution with water, no longer gives a turbidity with soda-ley; part of the chinoline, however, remains unattacked, even after heating for forty hours. The product is a brown opaque thickish liquid, from which the pure acid may be obtained by pouring it into a large quantity of water, saturating with baryta, precipitating the excess of baryta with the exact quantity of sulphuric acid required, and concentrating the yellow filtrate till it begins to crystallise. The acid forms large, hard, well-defined crystals, which are colourless, shining, strongly refractive, permanent in the air, and

anhydrous. It dissolves sparingly in cold, more easily in hot water or in strong hydrochloric acid; in hot alcohol more freely than in cold, but is insoluble in ether. Its solutions, like those of other chinoline derivatives, exhibit a tendency to supersaturation. The aqueous solution reddens litmus and slowly, and decomposes barium carbonate. The acid bears a rather high temperature without decomposition, but decomposes when melted on platinum-foil, giving off acid vapours and an odour of chinoline. It is not perceptibly attacked by boiling nitric acid. When fused with potash it gives off chinoline, and on treating the fused mass with water, a brown, amorphous insoluble body separates, which is dissolved by acids, and reprecipitated by alkalis. The original mass, treated with acids, gives off a small quantity of sulphur dioxide. Chinoline-sulphonic acid or its barium salt, cautiously heated with barium hydrate, gives the blue-green coloration above mentioned.

Barium chinoline-sulphonate, $\text{Ba}(\text{C}^6\text{H}_4\text{SO}_3)^2$, is prepared from the brown liquid formed by heating chinoline with fuming sulphuric acid, by pouring this liquid into a large quantity of water, supersaturating with baryta, removing the excess of barium with carbonic acid, filtering, evaporating to dryness, redissolving in boiling water, and evaporating to a small bulk. It may be heated without decomposition to 250° , dissolves but sparingly even in hot water, and always separates in the amorphous state on evaporation.

The *lead salt* is obtained as a white granular precipitate on mixing the aqueous solution of the acid with neutral lead acetate and ammonia, or with the basic acetate. The acid, neutralised with ammonia, does not precipitate *silver nitrate*, but the liquid, on standing, gradually deposits a white precipitate consisting of thin silky needles.

Bromochinolines.—When 1 mol. chinoline-sulphonic acid is heated in sealed tubes in the water-bath for about twenty-five hours with 6 atoms of bromine and a little water, the acid is resolved into sulphuric acid and bromochinolines, which separate into a solid yellow-brown substance. One part of this mass is dense and granular, the other part very loose, light, and of lighter colour. Both compounds are insoluble in water, very slightly soluble in cold, more easily in hot alcohol; they are easily separated by mechanical selection. When the denser product—which is the larger portion—was freed by water from adhering bromine, and dissolved in an insufficient quantity of hot alcohol, crystalline nodules separated containing no sulphur, a large quantity of bromine, and (after drying at 100°) quantities of carbon and hydrogen indicating a composition intermediate between tri- and tetrabromochinoline. They melt at 147° – 150° , are insoluble in water and in soda-ley, which latter does not attack them at the boiling heat, dissolve in strong hydrochloric acid, and are reprecipitated by water.

Liquid bromine acts at ordinary temperatures on chinoline or its aqueous solution, but the products are uncrystallisable. Better results are obtained with bromine-vapour. When a watch-glass containing 3 grams of chinoline, and a beaker containing 6 grams of bromine are placed within a bell-jar over sulphuric acid, the bromine disappears in two days, and the chinoline is converted partly into a dark red syrupy mass, partly into brown crystals. This product, probably an additive compound, forms with water a thick insoluble oil, the water turning yellow and acquiring the odour of bromine. A great part of the bromine may be removed by sulphurous acid, also with soda-ley, which does not separate chinoline from it. It is insoluble in hydrochloric acid. Alcohol dissolves it almost wholly, forming a red solution which, on standing, deposits white silky needles of tribromochinoline, $\text{C}^6\text{H}_3\text{Br}_3\text{N}$. This compound melts at 173° – 175° , solidifies, on cooling, in radiate groups of long needles, and volatilises completely, without decomposition, at a stronger heat, emitting a faint odour somewhat like that of chinoline. It is insoluble in water, very soluble in cold, easily in hot alcohol, also in strong hydrochloric or sulphuric acid, and is precipitated by water or soda as a loose crystalline mass. It is not acted upon by aqueous or alcoholic potash, silver oxide or strong sulphuric acid. When fused with potassium hydrate, it gives the blue-green colour exhibited by all derivatives of chinoline.

CHLORAL, $\text{C}^2\text{HCl}^3\text{O} = \text{COH}^2\text{OHO}$. Lieben showed in 1867 (*Compt. rend.* xlv. 1346) that the action of chlorine on alcohol at ordinary temperatures gives rise to the formation of mono-, di-, and tri-chloroacetal; and Paternò having since found that chloral can be formed by the decomposition of trichloroacetal (1st Suppl. 432), Lieben regards this series of reactions as the source of the formation of chloral by the ordinary process of passing chlorine into alcohol. The final product of the action of chlorine on *absolute* alcohol is chloral alcoholate, $\text{C}^2\text{H}^2\text{Cl}^3\text{O}^2 = \text{CHCl}^3\text{O}.\text{C}^2\text{H}^2\text{O}$, (Lieben, *Deut. Chem. Ges. Ber.* iii. 907).

Another view of the formation of chloral from alcohol is given by Wurtz & Vogt (*Compt. rend.* lxxiv. 777). The action of chlorine upon alcohol first gives rise to the formation of aldehyde and hydrochloric acid; $\text{C}^2\text{H}^2\text{O} + \text{Cl}^2 = \text{C}^2\text{H}^2\text{O} + 2\text{HCl}$

(1474); the hydrochloric acid acting upon the aldehyde and alcohol produces water and monochlor-ethyl oxide,

which latter by the further action of the chlorine is converted into tetrachlor-ethyl oxide, $\text{CCl}_3\text{CH} \left\{ \begin{smallmatrix} \text{OC}^2\text{H}_5 \\ \text{Cl} \end{smallmatrix} \right.$; and this compound is converted into chloral by the action of the water either present in the alcohol or formed in the manner just mentioned:

This tetrachlorinated ether—first obtained by Malaguti by the action of chlorine on ethyl oxide (ii. 540), and likewise formed according to Henry (p. 314) by the action of phosphorus pentachloride on chloral alcoholate is in fact converted into chloral by heating with water. Heated with alcohol instead of water, it yields hydrochloric acid and trichloroacetal, $\text{CCl}_3\text{CH}(\text{OC}^2\text{H}_5)_2$, which may be converted into chloral by the action of sulphuric acid. The tetrachlorinated ether distilled with sulphuric acid, also gives ethyl chloride and chloral:

Chloral is also formed when chlorine is passed into a cooled mixture of aldehyde and aqueous hydrochloric acid, or of aldehyde and water (Wurtz a. Vogt).

Reactions and Combinations. 1. Chloral is easily reduced to aldehyde by the action of nascent hydrogen evolved from an acid solution. If a solution of chloral hydrate be heated to 50° with zinc in a retort connected with a condenser cooled by ice, and very dilute acid gradually poured in, aldehyde will soon be obtained in quantity sufficient to admit of rectification, and identification by conversion into the ammonia compound. Polymeric modifications are formed at the same time, especially paraldehyde, which floats as an oily layer on the surface of the distillate (Persoune, *Compt. rend.* lxi. 227).

2. With phosphorus pentachloride chloral yields pentachlorethane, C^2HCl_5 (1st Suppl. 432), and with the chlorobromide, PCl_3Br_2 , it forms in like manner trichloro-dibromethane, $\text{C}^2\text{HCl}_3\text{Br}_2$. On adding water to the product of the reaction, an oil separates, which, when dried and submitted to fractional distillation under diminished pressure, yields the compound $\text{C}^2\text{HCl}_3\text{Br}_2$ as a colourless, transparent, highly refracting liquid, of sp. gr. 2.317 at 0° having a pleasant odour, insoluble in water, but readily soluble in alcohol and ether. It boils at about 200° with partial decomposition, but distils unchanged at 93° – 95° at a pressure of 14 millimeters. Its refractive index for D at 25.7° is 1.52991. When treated with alcoholic potash, it is rapidly decomposed, with formation of potassium chloride, and an oily substance distilling at 143° – 160° , but apparently not homogeneous (Paternò, *Gazzetta chimica italiana*, i. 500).

3. With sulphuric acid.—Chloral mixed with fuming sulphuric acid solidifies, after a short time, to a white crystalline mass, which contains neither insoluble chloral nor chloralide, but has the composition $\text{C}^2\text{H}^2\text{Cl}_3\text{S}^2\text{O}^{11}$, which is that of an anhydride of neutral chloral sulphate formed by combination of 4 mol. chloral and 2 mol. sulphuric acid, with elimination of 1 mol. water:

This compound is not altered by cold water, but is readily decomposed by warm water, potassium hydrate, or alcohol, in the latter instance with formation of chloral alcoholate. From ether, in which it is very soluble, it crystallises in needles.

On passing the vapour of sulphuric anhydride into chloral, the whole solidifies to a mass of needles differing from the compound just described. It crystallises from alcohol apparently unchanged, is insoluble in cold water, but is decomposed by warm water and by a solution of potassium hydrate. When gently heated it melts, and separates into two layers, whilst at a higher temperature it evolves hydrochloric acid, and leaves an oil which does not solidify and is not acted upon by water (Grabowski, *Deut. Chem. Ges. Ber.* vi. 225).

4. A concentrated solution of chloral hydrate mixed in the cold with neutral potassium sulphite yields chloroform, potassium formate and a compound of chloral with acid potassium sulphite. But at a temperature approaching the boiling point the chlorine of the chloral is acted upon, and by adding the solution of the latter very gradually to the hot solution of the sulphite, to avoid loss of chloral by production of chloroform, then cooling and evaporating, there are obtained a diff. white salt, $\text{CH}(\text{SO}^2\text{K})\text{COH.HKSO}_3 + \text{H}_2\text{O}$, and a very soluble salt—

besides a little potassium formene-disulphonate (methionate), $\text{CH}^2(\text{SO}^*\text{K})^2$, potassium formate, chloride, sulphate, and hyposulphate.

The salt, $\text{CH}(\text{SO}^*\text{K})^2.\text{COH}.\text{HKSO}^3 + \text{H}_2\text{O}$, crystallises in indistinct rhombic plates, but when it is dissolved in hot water, crystals containing more water always separate in the form of soft, brilliant white needles entangled together, and so minute that the whole appears amorphous. A cold supersaturated solution is, however, easily prepared, and on dropping a crystal of the original form into it, crystals of the same kind go on forming for a short time, though they are soon overgrown by the more hydrated crystals. This salt is the compound of acid potassium sulphite with potassium aldehyde-disulphonate, this latter constituent having the composition of chloral in which two atoms of chlorine are replaced by SO^*K and the third by hydrogen. Boiled with potassium carbonate, it yields—besides the neutral sulphite—formene-disulphonate and formate, the behaviour of the aldehyde-disulphonate $\text{CH}(\text{SO}^*\text{K})^2.\text{COH}$ towards alkalis being in fact similar to that of chloral—

Lead peroxide gives the same salts together with lead sulphate.

On treating the cold solution of the double salt with bromine until it remains permanently coloured, the sulphite is oxidised, and potassium aldehyde-disulphonate, $\text{CH}(\text{SO}^*\text{K})^2.\text{COH} + \text{H}_2\text{O}$, is set free. A similar destruction of the double salt is effected by boiling it for half an hour with hydrochloric acid. By boiling the aldehyde-disulphonate with acid sulphite, the double salt can easily be reproduced. Potassium aldehyde-disulphonate can be heated to 130° without undergoing change, and loses its water of crystallisation but slowly at 170° – 175° ; above this it decomposes, swelling up into an exceedingly bulky twisted mass like 'Pharaoh's serpents.' The barium salt, $\text{CH}(\text{SO}^*\text{K})^2.\text{Ba}.\text{COH} + 2\text{H}_2\text{O}$, forms slender needles, sparingly soluble in water, which can be recrystallised from hot acetic acid.

A solution of potassium aldehyde-disulphonate warmed with excess of bromine yields a much more soluble brominated salt, $\text{CBr}(\text{SO}^*\text{K})^2.\text{COH}$, which crystallises out in needles on evaporating and cooling the solution. It is decomposed by heat, leaving a residue of potassium bromide and sulphate mixed with a little carbon. Neither silver nitrate, barium chloride, nor baryta-water precipitates its solutions. When it is boiled for a few seconds with potassium sulphite, the original double salt, $\text{CH}(\text{SO}^*\text{K})^2.\text{COH} + \text{HKSO}^3 + \text{H}_2\text{O}$, separates out again on cooling. Boiled for half an hour with potassium carbonate and neutralised with acetic acid, the tolerably concentrated solution, after heating with alcohol and cooling, gives a deposit of microscopic plates or needles of another brominated salt. This salt, when boiled for a few seconds with potassium sulphite, yields on cooling, crystals of $\text{CH}^2(\text{SO}^*\text{K})^2$; it must therefore be $\text{CHBr}(\text{SO}^*\text{K})^2$, obtained, together with potassium formate, from $\text{CBr}(\text{SO}^*\text{K})^2.\text{COH}$, just as $\text{CH}^2(\text{SO}^*\text{K})^2$ is obtained from $\text{CH}(\text{SO}^*\text{K})^2.\text{COH}$.

The second salt obtained by the action of potassium sulphite upon chloral, which is readily soluble in water, and has the complex formula above given, crystallises in large shining triclinic prisms, and can be obtained quite pure by repeated crystallisations from warm water. When heated, it swells up considerably, blackens, and leaves a residue of potassium sulphate and chloride and some carbon. Its water of crystallisation could not be directly determined, in consequence of decomposition taking place. It gives precipitates with silver and lead nitrates, soluble in nitric acid. Baryta-water precipitates barium sulphite from its solutions, the salts $\text{CCl}(\text{SO}^*\text{K})^2.\text{COH}$ and $\text{CHCl}(\text{SO}^*\text{K}).\text{COH}$ being doubtless left in solution; but these salts have not been obtained in the pure state, only a syrupy liquid being formed on evaporation. This, however, on treatment with acid potassium sulphite, reproduces the crystalline double salt. Either component of this double salt would, by further action of potassium sulphite, produce the salt, $\text{CH}(\text{SO}^*\text{K})^2.\text{COH} + \text{HKSO}^3$, by replacement of Cl, in the one case by H and in the other by SO^*H ; so that the tendency to produce the salt $\text{H}(\text{SO}^*\text{K})^2.\text{COH}$ appears to be fulfilled in two distinct ways so far as regards the stages of the process.

It is remarkable that the two components of the double salt are produced in the proportion to form it, no excess of either being found in the mother-liquor. The resemblance therefore that the two only compounds intermediate between chloral and potassium aldehyde-disulphonate which can result from the replacement of two atoms chlorine, can unite to form a double salt, actually occasions both of them to be produced in a perfectly definite proportion.

During the digestion of chloral hydrate with potassium sulphite, a strong penetrating smell is given off, quite distinct from that of either chloroform or chloral, some of

the chloral being apparently converted into mono- and dichloraldehyde. A very large quantity of it appears to be changed into these or other volatile bodies (Rathke, *Ann. Ch. Pharm.* clxi. 149).

5. Chloral digested with *hydrochloric* and *hydrocyanic acid* in aqueous solution, unites with the latter, forming chloral hydrocyanide, $C^2HCl^2O.CHN$, or, $CCl^2-CH(OH)(CN)$, which crystallises in prisms united in white cauliflower-like groups. It has a pungent bitter taste, dissolves easily in water, alcohol and ether, and when digested with moderately strong hydrochloric acid, yields sal-ammoniac and trichlorolactic acid, $CCl^2-CH\begin{matrix} OH \\ COOH \end{matrix}$ (Bischoff u. Pinnor, *Deut. Chem. Ges. Ber.* v. 113).

According to Hagemann (*ibid.* 151) chloral hydrocyanide is precipitated from watery solutions in oily drops by strong sulphuric acid, or fuming hydrochloric acid. It melts at $58^{\circ}-59^{\circ}$, solidifies at $57.5^{\circ}-58^{\circ}$, begins to boil at 120° , with partial decomposition, the greater part passing over at $140^{\circ}-145^{\circ}$.

Chloral hydrate, hydrocyanic acid, and fuming hydrochloric acid, heated for 4-5 hours in sealed tubes to $120^{\circ}-130^{\circ}$, gave, after the ammonium chloride had been removed, alcohol, a zinc salt of trichlorolactic acid (Hagemann).

6. When 1 mol. chloral hydrate is added to 1 mol. *potassium cyanide* under absolute alcohol, a powerful reaction sets in, accompanied by an abundant evolution of hydrocyanic acid. On adding water to the product, a heavy oil separates, from which, by repeated fractional distillation, ethyl dichloracetate, boiling between 154° and 157° , may be obtained; also, in the higher portion, a solid crystalline substance melting at 62° , and apparently identical with the chloral-hydrocyanide above described. When the dilute alcoholic solution mentioned above, from which the oil had been separated, is evaporated to dryness at 100° , and exhausted with absolute alcohol, it yields potassium dichloracetate, crystallising from the alcohol in large plates. When potassium cyanide and chloral hydrate react on one another in presence of water, hydrocyanic acid is evolved, and free dichloroacetic acid obtained, only a small amount of potassium dichloracetate being produced, and that being probably due to the presence of potassium hydrate or carbonate in the potassium cyanide employed. The reactions which take place may therefore be represented as follows:

When a solution of chloral hydrate in benzene is added to potassium cyanide, the reaction is somewhat different, hydrocyanic acid being evolved, and scarcely anything but chloral hydrocyanide being formed. On the other hand, if solid chloral hydrate be added to potassium cyanide under benzene, but little chloral hydrocyanide is produced, the benzene on spontaneous evaporation leaving microscopic prismatic crystals, melting at 123° , and having the composition $C^2H^2Cl^2O^2N$. This compound splits up on distillation into chloral and chloralide, melting at $112^{\circ}-114^{\circ}$ (Wallach, *Deut. Chem. Ges. Ber.* vi. 114).

7. Vapour of *cyanic acid* is readily absorbed by chloral, which sometimes solidifies at the moment of saturation; at other times, gas is evolved at a certain stage of the process, and the mixture solidifies immediately, or after some time, to a vitreous mass like fused borax. The product, however, in all instances, yields the same result when boiled with moderately concentrated hydrochloric acid, leaving a white granular powder, insoluble in water and in hydrochloric acid. This, however, is readily soluble in hot alcohol, and even more so in ether, from which it crystallises in microscopic prisms having the composition $C^2H^2Cl^2NO^2$, and melting at $167^{\circ}-170^{\circ}$, with partial decomposition. Boiled with potassium hydrate, it yields chloroform, formic acid, carbonic acid, and ammonia, so that its constitution may be expressed by the formula:

united by cyanic acid. On heating it to 200° , it splits up, chloral distilling over, and cyanamide being formed. It dissolves readily in alcoholic ammonia, and after removal of the excess of the latter, silver nitrate gives a precipitate of silver cyanate. The hydrochloric acid solution of the crude substance, after separation of the compound above described, yielded on evaporation, besides ammonium chloride, two distinct crystalline compounds, the quantity of which, however, was too small to admit of accurate examination (G. Bischoff, *Deut. Chem. Ges. Ber.* v. 86).

8. When dry *ammonia gas* is slowly passed into a small quantity (not more than 2 or 3 grams) of anhydrous chloral cooled to a very low temperature, great heat is

evolved and chloral-ammonia, $C^2HCl^3.NH^3$, analogous to aldehyde-ammonia, is formed, as a white, fusible, volatile body having the odour of aldehyde-ammonia. This compound is decomposed by strong sulphuric acid into chloral and ammonium sulphate, and by water into chloroform and ammonium formate:

If more than 2 or 3 grams of substance is used for the preparation of chloral-ammonia, there is always obtained, as secondary product, a syrupy mass, resolvable by distillation into chloroform, and a residue which yields hydrocyanic acid when distilled with phosphoric anhydride, and therefore appears to be formamide:

(Personne, *Compt. rend.* lxxi. 22).

9. Chloral unites also with *Amines and Amides*.—With *aniline* it forms trichlor-ethylidene-diphenylamine $C^{11}H^{13}Cl^3N^2$, a crystallised body analogous to Schiff's ethylidene-diphenylamine:

This compound melts at 100° – 101° , but soon begins to decompose when kept at this temperature. It is insoluble in water and decomposes when boiled with water or alcohol, evolving a penetrating odour like that of phenylisocyanide. Treated with acids it undergoes decomposition, yielding salts of aniline. It does not, therefore, appear to possess basic properties. Hydrochloric acid gas passed into its solution in benzene gives rise to the formation of a large quantity of aniline hydrochloride, and an oily body which has not as yet been obtained in a state fit for analysis.

Toluidine acts upon chloral in the same manner as aniline, giving rise to trichlor-ethylidene-ditoluylamine, $CCl^3CH \begin{Bmatrix} NHC^6H^4CH^3 \\ NHC^6H^4CH^3 \end{Bmatrix}$, a crystalline body which melts at 114° – 115° . When alcohol is added to the crude product of the reaction before cooling, large crystals of the compound $CCl^3CH \begin{Bmatrix} OC^2H^5 \\ NHC^6H^4CH^3 \end{Bmatrix}$ are obtained, melting at 76° – 77° (Wallach, *Deut. Chem. Ges. Ber.* v. 251).

Chloral also unites with *acetamide* and *benzamide*. Chloral-acetamide $C^2HCl^3.O.C^2H^3ON$ is a crystalline compound melting at 156° – 157° , yielding by distillation, first chloral, then acetamide, and leaving a black residue. With aqueous alkalis it gives chloroform, ammonia, and acetate and formate of the alkali-metal. Chloral-benzamide $C^2HCl^3.O.C^6H^5ON$ melts at 150° – 151° , and is decomposed by alkalis in a similar manner to the preceding compound (Wallach, *loc. cit.*; Jacobsen, *Ann. Ch. Pharm.* clvii. 243).

On adding chloral to a saturated solution of *urea*, combination takes place, the compound $C^2HCl^3.O.CO.H^2N^2$ being formed when the urea is in excess, and $2C^2HCl^3.O.CO.H^2N^2$ when the chloral is in excess. The latter body is also formed by heating dry urea with chloral to 100° (Jacobsen).

Chloral Hydrate, $C^2HCl^3.O.H^2O$.—This compound is formed by the direct combination of chloral and water. The crystalline substance formed by the action of chlorine on absolute alcohol has usually been regarded also as chloral hydrate; but Personne, Lieben, and others, have shown that the ultimate product of this reaction is not the hydrate but the alcoholate of chloral, $C^2HCl^3.O.C^2H^3O$ (p. 313).

According to Flückiger (*Zeitschr. f. Chem.* vi. 432) the best method of purifying chloral hydrate is to recrystallise it from pure carbon sulphide, which takes up about $\frac{1}{4}$ of its weight of chloral at 15° – 18° , and from $\frac{1}{2}$ to $\frac{1}{4}$ at the boiling heat. From the hot saturated solution the excess of chloral hydrate separates in beautiful prisms, which, on exposure to the air, quickly give off the solvent remaining attached to them. Chloral hydrate thus purified boils at 97.5° (thermometer wholly in the vapour).

According to Phipson (*Chem. News*, xxv. 257) pure chloral hydrate crystallises in oblique rhombic prisms, sometimes shortened in such a manner as to give them the appearance of acute rhombohedrons. The solution of the crystals in water is attended with considerable fall of temperature, whereas the formation of the solid hydrate by combination of chloral and water is attended with considerable evolution of heat. Half a pound of the hydrate mixed rapidly with half a pound of water, causes the thermometer to sink many degrees below 0° . Minute fragments of the crystals floating on the surface of pure distilled water move about rapidly with the peculiar gyratory motion exhibited under similar circumstances by camphor.

Constitution of Chloral Hydrate. To decide whether this body is a true diatomic alcohol (trichlorethylidene glycol) $CCl^3.CH(OH)^2$, or merely a compound of chloral with

water of crystallisation $\text{CCl}_3\cdot\text{CHO} + \text{H}_2\text{O}$, Meyer a. Dulk (*Deut. Chem. Ges. Ber.* iv. 963) have subjected it to the action of acetyl chloride, whereby they obtain tetrachlorinated ethyl acetate $\text{CCl}_3-\text{CH}(\text{Cl})\text{OC}_2\text{H}_5\text{O}$. Now chloral alcoholate treated in like manner yields the alcoholate of acetyl-chloral, according to the equation :

These results lead to the inference that chloral alcoholate is the ethylic ether of trichlorethylidene glycol; and therefore chloral hydrate as that glycol itself.

When perfectly anhydrous chloral and acetic anhydride are heated together to the temperature of 150° in molecular proportions, they unite, forming diacetyl chloral

hydrate $\text{CCl}_3-\text{CH}(\text{O.C}_2\text{H}_3\text{O})_2$, which boils constantly at $221^\circ-222^\circ$ (uncorrected),

has a sp. gr. of 1.422 at 11° , is not miscible with water, and is not attacked by cold potash-solution, though, on heating it, the odour of chloroform is perceptible; it is evidently trichlorinated diacetate of ethylidene glycol, the diacetate itself being similarly obtained by heating aldehyde and acetic anhydride to 180° as shown by Geuther (*Ann. Ch. Pharm.* cvi. 249).

When chloral hydrate is heated with five times its weight of syrupy glycerin, reaction begins at 100° and goes on to 230° , a distillate being obtained consisting of chloroform; formic acid, and undecomposed chloral hydrate, together with hydrochloric acid and allyl formate as secondary products (H. Byasson, *Compt. rend.* lxxv. 1628).

Valuation of Chloral Hydrate.—The quality of commercial chloral hydrate is usually tested by decomposing it with ammonia or a fixed alkali, and measuring or weighing the quantity of chloroform thereby set free. C. H. Wood (*Pharm. J. Trans.* [3] i. 703) recommends boiling the hydrate in aqueous solution with lime (which has no sensible action on chloroform) and distilling off the chloroform produced. To ascertain whether the hydrate contains any alcoholate, the aqueous portion of the distillate may be tested for alcohol with the iodoform test.

The decomposition with alkalis does not, however, afford perfectly accurate results, as some chloroform is taken up by the water, and some water dissolved by the chloroform. For this reason Versmann (*Pharm. J. Trans.* [3] i. 701, 966) prefers decomposing the chloral hydrate with sulphuric acid: 5 to 6 c.c. concentrated sulphuric acid are put into a graduated, well-stopped tube, and heated by placing the tube in water at 60° ; 10 grams chloral hydrate are then added, the whole well shaken, and the tube put back into the hot water. The decomposition is instantaneous, and the anhydrous chloral floating on the acid may be read off as soon as the liquid has cooled down. By about twelve hours standing metachloral is produced. In comparative experiments a somewhat higher result is always given by sulphuric acid than by ammonia. In working with 10 grams of chloral hydrate by the ammonia-test, there is, in fact, a constant loss of 0.2 c.c. of chloroform, owing to the solubility of the latter in water; if, however, the necessary correction be made for this loss, the result will agree with that obtained by the sulphuric acid test.

On the quality and valuation of commercial chloral hydrate, see also C. Müller (*Zeitschr. f. Chem.* [2] vii. 66; *Chem. Soc. J.* [2] ix. 444; *Chem. News*, xxiii. 113); Paul (*Pharm. J. Trans.* [3] i. 621; *Chem. Soc. J.* [2] ix. 134).

On the physiological action of chloral hydrate see Byasson (*Compt. rend.* lxxii. 742; *Chem. Soc. J.* [2] ix. 748). On its use as an antiseptic, *Dingl. polyt. J.* cxiv. 280.

Chloral Sulphydrates.—(1.) $\text{C}_2\text{HCl}_3\text{O.H}_2\text{S} = \text{CCl}_3-\text{CH}(\text{OH})\text{SH}$. Anhydrous chloral readily absorbs hydrogen sulphide, and after the action of the gas has been continued for about twenty-four hours, the whole solidifies to a white crystalline mass. This may be purified by distillation and subsequent crystallisation from ether or from absolute alcohol, whereby it is obtained in rhomboidal plates or quadrangular prisms, having the composition above given. Chloral sulphydrate has a disagreeable odour and characteristic taste, resembling that of chloral hydrate. It melts at 77° and boils at 123° . It is soluble in all proportions in anhydrous alcohol, ether, or chloroform, but is decomposed by water, with deposition of sulphur, the action being very complex. Alkaline solutions yield chloroform and an alkaline formate and sulphydrate. Nitric acid oxidises it, with formation of trichloroacetic acid. Sulphuric acid has no action on it in the cold, but when heated with it produces anhydrous chloral, whilst sulphuretted hydrogen and sulphurous anhydride are evolved and sulphur is deposited.

The physiological action of this compound is very similar to that of chloral hydrate. .2 to .3 gram administered to guinea-pigs, by subcutaneous injection of the ethereal solution, produced deep sleep and a slight acceleration of the movements of the heart (Byasson, *Compt. rend.* lxxiv. 1290).

(2) Hydrogen sulphide passed into an ethereal solution of anhydrous chloral, forms a number of compounds, only one of which has yet been isolated. This body has the composition

It is insoluble in water, soluble in ether and in alcohol. The alcoholic solution treated with lead acetate, yields lead sulphide and chloral hydrate (Hagemann, *Deut. Chem. Ges. Ber.* v. 154).

Chloral Alcoholate, $\text{C}^2\text{HCl}^3\text{O} \cdot \text{C}^2\text{H}^4\text{O} = \text{CCl}^3 - \text{CH} \begin{Bmatrix} \text{OH} \\ \text{OC}^2\text{H}^5 \end{Bmatrix}$. This compound is formed by direct combination of anhydrous chloral with absolute alcohol, and is also the final product of the action of chlorine on absolute alcohol. Roussin (*Compt. rend.* lxxix. 1144); *Jahresber.* 1860, 504) obtained by this latter process a crystalline product melting at 56° and boiling at 115° , which he supposed to be chloral hydrate. J. Thomsen (*Deut. Chem. Ges. Ber.* ii. 597) also regarded the product thus obtained as chloral hydrate. Personne, however (*Compt. rend.* lxxix. 1363), has shown that it is not the hydrate, but the alcoholate of chloral, inasmuch as it gives by analysis only 34.9 p. c. chlorine (the hydrate requiring 64.3 p.c.), and when distilled with potash, yields alcohol as well as chloroform.

Lieben also (*Deut. Chem. Ges. Ber.* iii. 907) finds that the ultimate product of the action of chlorine on absolute alcohol has exactly the composition of chloral alcoholate; it melts at 43° – 40° , and boils at 114° – 115° . Its vapour-density, determined by Dumas' process between 157° and 198° , was found in two experiments to be 3.68 and 3.49; now the formula $\text{C}^2\text{H}^2\text{Cl}^3\text{O}^2$ calculated for a condensation to 2 volumes requires 6.08; hence it appears that the alcoholate is resolved at high temperatures into its components.

According to Lieben, the alcoholate may perhaps be produced from previously formed trichloroacetal, according to the equation:

It is possible also that dichloroacetal, formed by the action of chlorine on the alcohol, may be converted, by an analogous reaction, into the mono-ethylin $\text{HO}(\text{C}^2\text{H}^2\text{Cl}^2)\text{OC}^2\text{H}^5$, which, by further action of chlorine, is converted into chloral alcoholate.

Lastly, the question as to the composition of the crystalline product of the action of chlorine on alcohol has been examined by Jungfleisch, Lebaigue a. Roucher (*J. Pharm.* [4] xi. 208), who were commissioned by the *Société de Pharmacie* in Paris, to undertake the enquiry. For this purpose they prepared by synthesis pure chloral hydrate (I.), and pure chloral alcoholate (II.), and compared these preparations with chloral hydrate prepared by Personne (P), with a sample of the hydrate prepared in Germany and sold under Liebreich's guarantee (L), and with a product prepared by Roussin (R). The results of the comparison show clearly that Roussin's product is the alcoholate, and not the hydrate.

	I.	P.	L.	II.	R.
Boiling point (corr.)	97	97	97.5	113.5	113.5
Sp. gr. at 66° of the liquid substance	1.5704	1.5771	1.5719	1.3439	1.3286.

According to C. A. Martius and P. Mendelssohn-Bartholdy (*Deut. Chem. Ges. Ber.* iii. 443) chloral hydrate boils at 95° , the alcoholate at 115° – 116° , and solidifies at 40° to a radio-crystalline mass. Its specific gravity at 40° in the fused state is 1.143. It dissolves easily in alcohol, ether, ethyl acetate, and light petroleum oils, and separates on cooling from the warm ethereal solution in long needles.

When chloral alcoholate is gently heated with phosphorus pentachloride (1 mol. of each), torrents of hydrochloric acid are evolved, the pentachloride disappears, and on adding water to the product to decompose phosphorus oxychloride, tetrachlorethyl oxide or chloroethyl-trichlorethylidene,

separates out as a heavy colourless oil, which boils without decomposition at 188° , is insoluble in water, has a pungent camphorous smell, and a sweetish bitter taste, and is decomposed by boiling potash, like chloral, yielding chloroform.

This compound is intermediate between trichloroacetal $\text{CCl}_3-\text{CH}(\text{OC}^2\text{H}^5)_2$ boiling at 230° , and trichloroethylidene dichloride $\text{CCl}_3-\text{CHCl}_2$ boiling at 158° . Its existence throws further light on the constitution of the hydrate and alcoholate of chloral. For if the latter were a molecular compound in which the chloral and alcohol existed as such, it ought to yield with phosphorus pentachloride the same products as are obtained from those bodies separately, viz. $\text{CCl}_3\cdot\text{CHCl}_2$ and $\text{C}^2\text{H}^5\text{Cl}$. But if chloral alcoholate is a real atomic compound, namely, the monothylic ether of trichloroethylidene glycol, $\text{CCl}_3-\text{CH}\begin{Bmatrix} \text{OC}^2\text{H}^5 \\ \text{OH} \end{Bmatrix}$, the action of phosphorus pentachloride on chloral alcoholate must give rise to the replacement of OH by Cl yielding, as actually observed, the body $\text{CCl}_3-\text{CH}\begin{Bmatrix} \text{OC}^2\text{H}^5 \\ \text{Cl} \end{Bmatrix}$. The alcoholate and hydrate must therefore be regarded as atomic compounds, the latter being the glycol of trichloroethylidene (p. 312).

The boiling points of the hydrate (95°) and of the alcoholate (115°) should, according to analogy, be higher than that of the compound $\text{CCl}_3-\text{CHCl}(\text{OC}^2\text{H}^5)$: but these temperatures, as shown by the vapour-density determinations, are not the real boiling points, but temperatures at which the compounds in question suffer decomposition. The decomposition of chloral hydrate into water and chloral is quite analogous to the decomposition of secondary alcohols, such as amylene hydrate into water and an olefine (L. Henry, *Deut. Chem. Ges. Ber.* iv. 101, 435; *Chem. Soc. J.* [2] ix. 255, 696).

The constitution of chloral alcoholate is further established, as already observed (p. 312), by its reaction with acetyl chloride, the product of which is acetyl-chloral alcoholate or the ethyl-acetic ether of trichloroethylidene glycol $\text{CCl}_3-\text{CH}\begin{Bmatrix} \text{OC}^2\text{H}^5 \\ \text{OC}^2\text{H}^3 \end{Bmatrix}$. This compound, purified by repeated fractional distillation, is a colourless transparent oil, having a peculiar odour, boiling constantly at 198° (uncorr.), and of sp. gr. 1.327 at 11° . It is not attacked by aqueous potash at the boiling heat.

Homologues of Chloral Alcoholate (Mendelssohn-Bartholdy a. Martius, *Deut. Chem. Ges. Ber.* iii. 443; Jacobsen, *Ann. Ch. Pharm.* clvii. 243). Chloral unites with the homologues of ethyl alcohol, forming crystalline compounds very similar to the ordinary alcoholate. They are decomposed by strong sulphuric acid with production of chloral.

The *methyl-compound*, $\text{CCl}_3-\text{CH}(\text{OH})(\text{OCH}^3)$, forms a crystalline somewhat hygroscopic mass, very much like the ethyl-compound, melting at 50° , boiling at 160° (Jacobsen), at 98° (Bartholdy a. Martius).

The *amyl-compound*, $\text{CCl}_3-\text{CH}(\text{OH})(\text{OC}^4\text{H}^{11})$, crystallises in long, very beautiful needles, nearly insoluble in water, easily soluble in alcohol and ether, melting at about 56° , boiling at 145° – 147° . It is not decomposed by heating with water, but sinks to the bottom as a heavy layer, which solidifies under the liquid only at very low temperatures (Jacobsen). According to Bartholdy a. Martius, it boils at 143° and has a specific gravity of 1.2340 at 25° . It solidifies at 25° to a crystalline mass, easily soluble in alcohol, ether, and light petroleum oil, from which last solvent it crystallises in tufts of long needles. By prolonged boiling with water, it is resolved into amyl alcohol and chloral (hydrate).

The *cetyl-compound*, $\text{CCl}_3-\text{CH}(\text{OH})(\text{OC}^{18}\text{H}^{37})$, is obtained in soft warty groups of microscopic needles, when cetyl alcohol is dissolved in a slight excess of warm chloral, and the solution is left to cool slowly (Jacobsen).

Chloral Mercaptide, $\text{CCl}_3-\text{CH}(\text{OH})(\text{SC}^2\text{H}^5)$, formed by the combination of chloral with ethyl sulphhydrate, dissolves easily in alcohol, ether, and carbon sulphide, and may be crystallised therefrom (Bartholdy a. Martius).

The alcohols of the aromatic series do not unite with chloral (Jacobsen).

CHLORATES.—*Barium Chlorate*, $\text{Ba}(\text{ClO}^3)_2$. Widemann prepares this salt by heating a mixture of 1 mol. crystallised aluminium sulphate, 1 mol. sulphuric acid, and 2 mols. potassium chlorate with a quantity of water, sufficient to give it a thin, pasty consistence. Crystallised potash-alum then separates on cooling, while chloric acid remains dissolved. A four-fold volume of water is then added, and the liquid, after filtration, is neutralised with baryta-water, whereupon barium sulphate separates out, together with a little more alum. The liquid is again filtered, the greater part of the alcohol removed, and the liquid, after a second filtration, is evaporated to the crystallising point (*Arch. Pharm.* [2] cxliv. 66).

Potassium Chlorate, KClO_3 . A method of preparing this salt on the large scale is described by W. Hunt (*Dingl. polyt. J.* ccc. 77). Diluted chlorine gas is passed into a brick tower, into which there also drops a solution of potassium chloride and milk of lime. The potassium chlorate thus formed is separated by crystallisation.

Decomposition by heat.—It is well known that the decomposition of potassium chlorate by heat is greatly facilitated by mixing it with various metallic oxides, as manganese dioxide, or cupric oxide in the state of powder; but the manner in which these substances act has not been very clearly made out. G. Hornsby (*Pharm. J. Trans.* xv. 352), maintained that oxygen, disengaged from potassium chlorate in presence of manganese dioxide, is always accompanied by chlorine, with production of a brilliant and intermittent light, which he attributed to electricity, engendered by the molecular change of the gaseous particles. On the other hand, Witt (*ibid.* 411) maintained that the oxygen obtained from such a mixture at a high temperature possesses much more combustible energy than the same gas prepared at a low temperature; and that the sparks observed by Hornsby were due to organic matters which, by chance, were in contact with the gas. Witt also recalls the two phases of the decomposition of potassium chlorate originally observed by Sécrullas, and confirmed by Millon:

and observes that the oxygen produced in the second stage of the reaction is much more active than that produced in the first stage, as, like ozone, it turns iodised test-paper blue. The same character is also met with in the oxygen prepared from potassium chlorate by the aid of manganese dioxide, although he further supposes that this oxide exerts a purely mechanical action, interposing itself between the particles of the chlorate, and thus facilitating its decomposition by heat, just as certain powders thrown into heated liquids facilitate their ebullition. The same kind of action is exerted by the oxides of copper, iron, and chromium, none of these bodies undergoing any change whatever. A similar view was subsequently put forward by Deville (*Leçons sur la Dissociation, professées à la Société chimique*, 1864, p. 353), who compares the decomposition of potassium chlorate by heat to the ebullition of water charged with a salt, the solution becoming concentrated as the vapour escapes. Here the vapour is oxygen and the potassium chloride produced becomes the salt which is concentrated. On adding a foreign body, oxide of copper, oxide of manganese, &c., to the chlorate in fusion, these auxiliaries of ebullition evidently favour the disengagement of oxygen, as they would favour in water the production of vapour. This view is, however, at variance with the fact that potassium chlorate loses its oxygen without entering into fusion.

E. O. Brown (*Pharm. J. Trans.* xv. 460) impugns this theory, and considers that the oxide of manganese acts by its proper nature, inasmuch as the same effect is not produced by the presence of other finely divided substances, powdered quartz for example. He attributes the supposed activity of the gas obtained under these circumstances to the presence of chlorine. Witt, however (*ibid.* 503), finds that the same or even greater activity is exhibited by oxygen evolved from substances not containing chlorine, namely, from a mixture of potassium dichromate and sulphuric acid.

Schönbein (*Jahresb.* 1855, 269; 1857, 62) suggested that potassium chlorate may be regarded as a compound of potassium chloride and ozone, and that this ozone is converted, by the combined active oxygen of the manganese dioxide, &c., into ordinary oxygen, which can then no longer remain united to the potassium chloride.

This view is controverted by Wiederhold (*Pogg. Ann.* cxvi. 171) on the ground that platinum black facilitates the decomposition of potassium chlorate, as well as bodies containing oxygen, and that the oxygen thus evolved turns iodised starch-paper blue, whence it cannot be ordinary oxygen. An intimate mixture of 2 pts. potassium chlorate with 1 pt. manganese dioxide begins to give off oxygen at 200° – 206° ; with cupric oxide, the evolution of gas begins at 230° – 235° , with platinum-black at 260° – 270° , with lead dioxide at 280° – 285° . Wiederhold attributes the action of these several substances to their power of absorbing heat; the relative volume of the catalytic substances appears also to be of some importance, inasmuch as those bodies which induce the decomposition at the lowest temperature are also the most bulky. When a mixture of manganese dioxide and potassium chlorate is heated for some time to 200° , the evolution of oxygen ceases, recommencing only at a higher temperature; then ceasing again, and so on by steps up to 260° ; but when the mixture of potassium chlorate with manganese dioxide or cupric oxide is quickly heated to 280° – 290° , a very tumultuous evolution of oxygen is set up, the temperature of the mixture rising at

once through 40° or 50° ; in the other mixtures the tumultuous evolution of gas does not take place till the heat is raised above 340° . During the heating of these mixtures, the temperature of the middle of the mass is always considerably below that of the external portions, uniformity of temperature being established after some time only; but when the mixture of potassium chlorate and manganese dioxide is heated to 250° , the temperature in the interior finally rises to 254° - 255° , so that an actual evolution of heat takes place. The same rise of temperature is observed in a mixture of potassium chlorate and cupric oxide at 290° . Since cupric oxide and manganese dioxide do not exhibit this rise of temperature when heated alone, Wiederhold attributes the excess of temperature to the evolution of heat accompanying the liberation of the oxygen. It is further to be observed, that when potassium chlorate is decomposed in contact with any of these substances, no perchlorate is formed.

When potassium chlorate is heated to fusion, then removed from the fire, and small quantities of pulverised manganese dioxide, cupric oxide, &c., are thrown into it, evolution of oxygen begins immediately, the temperature rising to incandescence (at least with cupric oxide, and with ferric oxide or manganese dioxide prepared in the wet way). The manganese dioxide does not lose any oxygen. When 0.1 gram of the catalytic substance was added to 3 grams of potassium chlorate, complete decomposition was produced by cupric oxide, and by ferric oxide and manganese dioxide prepared in the wet way; with lead dioxide, native manganese dioxide, and platinum black, on the other hand, it was only partial.

Further experiments on this subject have recently been made by Baudrimont (*J. Pharm.* [4] xiv. 81, 161) whose results agree in the main with those of Wiederhold. By heating in a mercury-bath a mixture of 4 pts. pure and finely pulverised potassium chlorate with 1 pt. of black copper oxide prepared in the wet way, he finds that in presence of copper oxide, potassium chlorate can give up its oxygen at 150° or 160° below its normal temperature of decomposition (about 400°), the disengagement of gas taking place easily and rapidly, and becoming tumultuous at about 300° , the temperature then rising suddenly to 390° without any sign of ignition. The whole of the oxygen of the chlorate is given off, together with a small quantity of chlorine, while the copper oxide is not altered in any way. Similar results were obtained with manganese dioxide. When the mixture of potassium chlorate and copper oxide was introduced into a platinum crucible previously heated nearly to dull redness, it fused, boiled quietly, then more quickly, with intumescence, and soon afterwards the decomposition was terminated by a general incandescence, leaving the crucible at a heat below redness.

The following experiments relate to the influence of various circumstances on the manner of the decomposition.

Influence of the Nature of the Body in contact.—The results are from experiments made upon 4 grams of potassium chlorate and 1 gram of the substance added. *Spongy Platinum.*—No action whatever up to 360° . When the two substances are fused together, the evolution of oxygen may be a little accelerated, but there is no incandescence. This result does not agree with Deville's theory. *Mercuric oxide.*—No action whatever up to 360° , the oxide being found intact after the operation. *Silver oxide.*—Gas is evolved at 220° , due however to the decomposition of the oxide. This soon ceases, and there is no further reaction even at 360° . Heated more strongly, the chlorate decomposes quietly, with formation of silver chloride and potassium oxide. This result is opposed to the statements of Schönbein and Witt, who say that the action of this oxide upon the chlorate is very energetic. *Potassium permanganate.*—Gas is slowly evolved at 360° , and the decomposition of the two salts proceeds simultaneously. The permanganate decomposes at about 250° into oxygen, potassium oxide and manganese sesquioxide; the last-named substance then reacts upon the chlorate, and gradually transforms it into potassium chloride and oxygen; the temperature not rising beyond 360° . *Black oxide of Copper.*—Result already given (*vid. sup.*). *Native Manganese dioxide.*—Sensible action, even before 200° , becoming continuous about 250° , and even violent about 310° - 320° , the thermometer rising beyond 380° . The loss in weight is 1.62 grams, the excess over the calculated loss, 1.66 grams, being due to the evolution of a little chlorine. *Ferric oxide.*—Action begins about 250° , but is not continuous until 320° - 325° . The evolution takes place readily, but there is no sudden rise of temperature, and the total decomposition of the salt requires a long time. *Black oxide of Cobalt, Brown oxide of Manganese, Dioxide of Lead.*—Action more feeble than with the substances previously named. A long time is necessary for the evolution of all the oxygen, and the temperature does not pass beyond 360° . The composition of these bodies undergoes no change during the reaction. All the preceding mixtures undergo true fusion when

the temperature rises to 360° . The weaker the action of the oxide, the less is the amount of chlorine evolved with the oxygen. *Alumina*.—Gas is evolved from 250° , but so much contaminated with chlorine, that the alumina appears to act as an acid. After the reaction the residue is alkaline, and the amount of potassium chloride present is 2.19 grams, instead of 2.44 grams, as required by theory.

Influence of the State of Division of the Substances.—Potassium chlorate is decomposed in presence of cupric oxide, with much greater facility when the salt is finely sifted than when it is only coarsely pulverised. 5 grams of a mixture of coarsely pulverised chlorate with one-tenth of its weight of cupric oxide, lost only 0.60 gram of oxygen at 360° whilst in a similar experiment with the salt finely sifted, the loss was 1.88 grams. But the influence of the state of the bodies is more plainly seen by comparing the effect of black copper oxide obtained in the moist way, with that obtained by ignition. The former decomposes the salt with great facility, and produces incandescence of the mixture when present to the extent of one two-hundredth part; while the latter acts only towards 310° – 320° , causing a very slow and feeble evolution of gas, and scarcely producing incandescence when present as a twentieth part. So also manganese dioxide and ferric oxide obtained in the moist way, act with much greater facility than native manganese dioxide and ferric oxide obtained by ignition.

Influence of the Proportion of the Active Substances as compared with the Amount of Potassium Chlorate.—By experiments with black copper oxide, manganese dioxide, and ferric oxide, in proportions varying from one half to one five-hundredth part of the mixture, it was found that, although the decomposition of the chlorate is accelerated by even so small a proportion of the active substance as one five-hundredth part, yet the greater the proportion of the latter, the more rapid is the decomposition, and the greater is the proportion of the chlorate decomposed; but there is no relation between these proportions and the equivalents of the substances employed. The mixtures in equal parts do not undergo any fusion at the temperature of boiling mercury, and only imperfectly when heated on a sand-bath. The phenomenon of incandescence is never produced when the maximum temperature is 360° , but is developed with great facility (the mixture in equal parts excepted), when a dull red heat is attained.

Influence of Temperature.—The decomposition of the mixtures generally commences at about 210° , or towards 300° when the active substance is present in very small proportion. Even at these low temperatures the mixture may be completely decomposed, but the evolution of oxygen is very slow, and the mixture does not enter into fusion. Oxygen so prepared is perfectly free from chlorine. When the temperature is raised to 310° – 320° , gas is evolved violently, there is an emission of heat without ignition, and the temperature passes all at once beyond 360° ; at the same time chlorine is liberated, and the mass undergoes complete liquefaction. At a still higher temperature the evolution of gas is still more rapid, and, in fact, the rapidity of the decomposition is in proportion to the temperature.

Chemical Actions which certain substances exercise upon Potassium Chlorate.—Potassium chlorate causes the inflammation of sulphur, wood-charcoal, graphite, sulphide of antimony, &c., below the temperature of boiling mercury, and during the reaction there is an enormous development of heat. Substances which react upon this salt generally abstract its oxygen, rarely its chlorine, and sometimes also seize its potash; when the last-named reaction occurs, there is always a large quantity of chlorine produced, due to the decomposition of the chloric acid liberated. When green oxide of chromium is heated in a mercury-bath with this salt, a considerable evolution of chlorine and oxygen occurs even below 200° , and the oxide is completely transformed into potassium chromate below 290° . Metastannic acid has no action upon the chlorate at 360° , but at a higher temperature chlorine and oxygen are evolved, and the residue is strongly alkaline. Tungstic acid begins to act upon the salt at 270° , and at 350° there is evolution of oxygen with much chlorine, and probably with formation of an alkaline tungstate. Silicic acid acts only beyond the melting point of the chlorate, with evolution of oxygen, chlorine, and excessively pungent white vapours, which may be chloride of silicon. Fused boric acid acts energetically, chlorine being liberated in great abundance.

CHLORHYDRINS. *Dichlorhydrin*, $C^2H^4Cl^2(OH)$.—According to Hübner a. C. Müller (*Zeitschr. f. Chem.* [2] vi. 344), dichlorhydrin prepared by Bortholot's process (i. 893) boils between 174° and 186° , and when subjected to fractional distillation does not exhibit any constant boiling point, though larger quantities pass over from 174° to 177° , and from 184° to 186° , than at the intermediate temperatures. Both the lower and the higher boiling portions exhibit the composition of dichlorhydrin, whence Hübner a. Müller infer that the dichlorhydrin boiling between 174° and 186° is a mixture of the two isomerides, $CH^2Cl-CHCl-CH^2OH$ and $CH^2Cl-CHOH-CH^2Cl$.

According to A. Watt, however (*Deut. Chem. Ges. Ber.* v. 257), the portion of the above-mentioned product which boils at 182° – 184° is not homogeneous, but resolvable into two portions of lower and higher boiling point respectively, the latter being very small in quantity. Hence Watt concludes that no second dichlorhydrin is produced, at least in any notable quantity. The same conclusion is arrived at by Markownikoff (*Deut. Chem. Ges. Ber.* vi. 1210), who finds that both the lower and the higher boiling portion yield by oxidation the same product, viz. a crystalline dichloracetone melting at 43° .

According to Claus (*Ann. Ch. Pharm.* clx. 42) dichlorhydrin is best prepared by the action of sulphur chloride on anhydrous glycerin:

Glycerin is concentrated till it boils at 105° ; 800 grams of it are then placed in a flask connected with a reversed condenser; and 2 kilograms of sulphur chloride are gradually added, the mixture being well shaken and heated in a salt-bath. After seven or eight hours, the condenser is removed, and the product heated for an hour longer to expel sulphur dioxide and hydrogen chloride. The cooled mass is exhausted with ether, the solution first distilled in a water-bath, and the residue distilled over the naked flame. 800 grams of glycerin thus treated yielded 700 grams of pure dichlorhydrin. The by-products consist of sulphuretted bodies of higher boiling point.

Dichlorhydrin has a specific gravity of 1.369 at 16° , and boils at 176° – 177° (Watt). By oxidation with *chromic acid* it yields chloroacetic acid and dichloracetone (Watt, Claus), and, by further action, hydrochloric acid and carbon dioxide, probably together with formic acid (Claus). By oxidation with *nitric acid* it gives oxalic acid and an oil having the smell of chloropicrin (Watt).

According to Markownikoff (*loc. cit.*) pure dichlorhydrin prepared by addition of hydrochloric acid to epichlorhydrin, is an oily liquid of sp. gr. 1.383 at 19° , boiling at 171° – 171.5° , soluble in 19 times its volume of water at 19° . By oxidation with chromic acid it is converted into a dichloracetone, $C^3H^4Cl^2O$, which crystallises in rhombic plates melting at 43° , and is therefore isomeric with the dichloracetone produced by the action of chlorine on acetone, which is a liquid boiling at 120° – 121° . The solid dichloracetone unites with sodium bisulphite, forming the compound $C^3H^4Cl^2O \cdot SO^2NaH + 3H^2O$, which crystallises in long four-sided prisms.

When dichlorhydrin in ethereal solution is added by drops to *sodium* immersed in anhydrous ether, a violent action takes place, the ether distilling over, and a white saline substance being left which, when separated from the remaining sodium by trituration and sifting, dissolves easily in water. On distilling the aqueous solution till the boiling point rises to 100° , and mixing the distillate with potassium carbonate, an oily liquid rises to the surface consisting of allyl alcohol. The action of the sodium is therefore simply to remove the chlorine from the dichlorhydrin:

Hydrogen also appears to remove the chlorine from dichlorhydrin without replacement (Hübner a. Müller).

Action of Ammonia (Claus, *Ann. Ch. Pharm.* clxviii. 29). Dichlorhydrin heated with alcoholic ammonia yields ammonium chloride and chlorhydrinimide, $C^3H^3N^2ClO$. This compound is a white amorphous mass, insoluble in water, alcohol, ether and concentrated acids, not acted upon even by boiling with sulphuric acid, aqua regia, or strong potash-ley. In hot water it swells up enormously and yields a perfectly transparent jelly. It appears to be identical with the compound which Reiboul obtained by the action of alcoholic ammonia on epichlorhydrin. Heated to redness with slaked lime, it yields an oily distillate containing a resin and basic compounds.

The formation of chlorhydrinimide is represented by the equation:

The structural formula assigned to it by Claus is:

8. The formation of chlorhydrinimide in the quantity indicated by the preceding

equation takes place only when 9 mol. ammonia are used to 4 mol. dichlorhydrin and the alcohol contains about 4 per cent. of ammonia. When the solution contains only about 1 p. c. ammonia, no chlorhydrinimide is obtained, but the product consists of the hydrochlorides of two new bases, together with sal-ammoniac.

(1). *Diamidohydrin Hydrochloride*, $C^3H^4N^2O.2HCl$. This is a very hygroscopic substance, partially decomposed, with formation of ammonium chloride, when the alcoholic solution obtained in the process just described, is filtered from the sal-ammoniac and evaporated. On dissolving it in absolute alcohol and adding platonic chloride, transparent prisms or needles are deposited, having the composition of diamidohydrin platino-chloride, $C^3H^4N^2O.2HCl.PtCl^4$.

(2). *Glycidamine Hydrochloride*, $C^3H^7NO.HCl$, is obtained in crystals by precipitating the same alcoholic solution with ether: it is also very hygroscopic, but appears to be more stable than the preceding hydrochloride.

The *platinochloride*, $2(C^3H^7NO.HCl).PtCl^4$, crystallises in transparent glistening needles. Glycidamine appears to be identical with the glyceramine of Berthelot and De Luca.

The constitution of these bases and the mode of formation of their hydrochlorides may be represented by the following equations:—

Trichlorhydrin, $C^3H^2Cl^3$. According to Berthelot (*Ann. Ch. Pharm.* clv. 105) the bodies having this composition which are not directly allied to glycerin, are for the most part only isomeric with the true trichlorhydrin obtained from that body (i. 804). To establish the identity of any such compound with trichlorhydrin, he considers it necessary to show that the body in question may be reconverted into glycerin, by substitution of 3OH for 3Cl , under the same circumstances as trichlorhydrin itself. It is true that this transformation is difficult, even in the case of the true trichlorhydrin, not being produced by the action of alkalis, or with certainty even by that of moist silver oxide. It may, however, be satisfactorily effected by heating the chloride in a digestion-tube to 160° for 25 to 30 hours with pure water; part of it is then converted into insoluble polyglycerin derivatives, but the greater part into glycerin. Trichlorhydrin is further characterised by boiling at 155° , and by being converted by potash into epidichlorhydrin $C^3H^4Cl^2$, boiling at 101° , which in its turn may be transformed into the liquid compound C^3H^4Cl , boiling at 164° . By these tests, Berthelot has examined the following isomerides of trichlorhydrin:

1. $C^3H^4Cl^3$ from *Acetone*. Acetone was treated with phosphorus pentachloride, whereby the compound $C^3H^4Cl^3$ was formed, and this was treated at 0° with dry chlorine. The product separated on distillation into $C^3H^4Cl^3$ boiling at 140° - 145° , and $C^3H^4Cl^3$ boiling at 161° - 166° . Neither of these compounds yielded glycerin when heated with water; and the same negative result was obtained with the compound $C^3H^4Cl^3Br^2$ produced by direct combination of $C^3H^4Cl^3$ with bromine. That the above-mentioned acetone derivatives are merely isomeric with those obtained from propylene chloride is seen from their boiling points:

	$C^3H^4Cl^3$	$C^3H^4Cl^3$	$C^3H^4Cl^3$
The propylene compounds boil at	104°	170°	195° - 200°
The corresponding acetone derivatives boil at	70°	140°	165°

2. $C^3H^4Cl^3$ from *Isopropyl Iodide*. This iodide was first converted by the action of chlorine on the corresponding chloride C^3H^4Cl , and the latter was further chlorinated. Two compounds were thus obtained, namely $C^3H^4Cl^3$ boiling at 150° - 160° , and a camphoroidal body $C^3H^4Cl^3$ of sp. gr. about 1.55, melting at 145° and boiling at 180° - 190° .

The former when heated with water did not yield a trace of glycerin.

3. $C^3H^5Cl^3$ from Propane. This hydrocarbon, prepared by heating ethyl cyanide with hydriodic acid to 180° was chlorinated by Schorlemmer's method (1st Suppl. 958), whereby two chlorides were obtained, namely $C^3H^5Cl^2$, boiling at 200° , and $C^3H^5Cl^3$, boiling at $150^\circ-160^\circ$. The former was further chlorinated and the product, together with the trichloride just mentioned, was submitted to the action of water. The results were doubtful, as only small quantities of material were employed.

From these facts Berthelot concludes that there are at least five series of isomeric compounds C^3H^5X (where $X = Cl, H$), namely, those derived: 1. from Propane; 2. from Propylene hydrochloride or Isopropyl chloride; 3. from Normal propylene chloride; 4. from the Acetone derivative $C^3H^5Cl^2$; 5. from Trichlorhydrin; to which perhaps may be annexed as special series, the corresponding derivatives of Allyl chloride, the two Hydrochlorides of Acrolein, the two Hydrochlorides of Allylene, &c.

On the physiological action of trichlorhydrin, see Romansky (*Pflüger's Archiv. für Physiologie*, v. 365: *Chem. Soc. J. x.* 902).

Epichlorhydrin, C^3H^5ClO . This compound unites with sulphuric acid, with great evolution of heat, and forms a thick oil, $C^3H^5ClO \cdot SO^3H^2$ or $CH^2OH \cdot CH(SO^3H)$, from which the sulphuric acid may be removed by potash (Oppenheim, *Deut. Chem. Ges. Ber.* iii. 735).

Chlorobromhydrin, $C^3H^5(HO)BrCl$, is prepared by the action of fuming hydrobromic acid on epichlorhydrin. When oxidised by chromic acid, it yields a product which boils at $176^\circ-188^\circ$, and solidifies in ice-cold water. On expressing the water from this product, and recrystallising it from ether free from alcohol, crystals of chlorobromacetone C^3H^5BrClO are obtained, which melt at $31^\circ-35.5^\circ$, have a very pungent odour, dissolve easily in alcohol and ether, sparingly in water, and unite with sodium bisulphite (Tegarten, *Deut. Chem. Ges. Ber.* vi. 1212).

Chloriodhydrins.—*Dichloriodhydrin*, $C^3H^5Cl^2I$, obtained by acting on chloriodhydrin with phosphorus pentachloride, is a colourless liquid, with a faint ethereal smell, boiling at 205° . It is neutral, but soon becomes acid in the moist state (L. Henry, *Deut. Chem. Ges. Ber.* iv. 701).

Chlorobromiodhydrin, C^3H^5ClBrI , obtained by acting with phosphorus pentabromide on chloriodhydrin, is a substance with similar properties, but decomposed on boiling, free iodine and acid vapours being given off (Henry).

Chloronitrins (L. Henry, *Ann. Ch. Pharm.* clv. 164). The mono- and di-halogen-hydrins, as well as the epi-halogen-hydrins of glycerin, are acted on by pure hydrogen nitrate, HNO^3 , in such a manner that the OH and O contained in them are replaced by equivalent quantities of the nitric acid residue NO^2 , provided that the only halogens present are chlorine and bromine; with the chloriodo- and bromiodohydrins, the reaction takes place somewhat differently, the iodine as well as the hydroxyl being then replaced by NO^2 . The method of preparing the nitro-halogen-hydrins, is essentially the same as that employed for the preparation of nitroglycerin.

To prepare mono- and di-nitrochlorhydrins, monochlorhydrin, or dichlorhydrin is gradually added to a cooled mixture of equal volumes of fuming nitric and strong sulphuric acid, with vigorous stirring in order to bring the two liquids (which do not mix perfectly) into intimate contact. The reaction takes place very quietly, especially in the case of the dichlorhydrin. When it is complete, the whole is poured into cold water, and the heavy oil produced is washed with solution of sodium carbonate and dehydrated with calcium chloride.

The product consists of monochlorodinitrin $C^3H^5Cl(NO^2)^2$, or dichloromononitrin $C^3H^5Cl^2NO^2$. The former of these compounds may also be prepared from epichlorhydrin C^3H^5ClO , by adding the latter very carefully, so as to avoid even local heating, to fuming nitric acid cooled with ice, and pouring the mixture into cold water, whereupon the chloronitrin separates as an oil. To ensure complete conversion, the product is treated with a mixture of nitric and sulphuric acids, and the process is completed in the manner above described when mono- or dichlorhydrin is used as the starting point. The reaction is supposed to consist, first, in the addition of the elements of nitric acid to the epichlorhydrin, forming the compound $C^3H^5Cl.OH.NO^2$, and, secondly, in the replacement of the water-residue OH by NO^2 .

Dichloromononitrin, $C^3H^5Cl^2NO^2$, is a colourless oil having a faintly pungent nitrous odour and a saccharine taste, slightly soluble in water, easily in alcohol and ether, and having a specific gravity of 1.465 at 10° . It distils, with partial decomposition at $180^\circ-190^\circ$, therefore, like other nitric ethers, at a temperature differing but slightly from the boiling point of the corresponding alcohol (dichlorhydrin). Heated on platinum foil, it burns quickly with a white flame. Aqueous potash does not act

upon it, but *alcoholic potash* attacks it, even in the cold, forming potassium nitrate, potassium chloride and epichlorhydrin, and finally reducing it to glycerin. From aqueous *hydriodic acid* it eliminates iodine. *Ammonium sulphhydrate* in alcoholic solution reduces it quickly, forming an oil which appears to be the thio-compound $\text{C}^2\text{H}_2\text{Cl}^2\text{SH}$, analogous to dichlorhydrin.

Monochlorodinitrin, $\text{C}^2\text{H}_2\text{Cl}(\text{NO}^2)^2$, is very much like the preceding compound; it has a specific gravity of 1.5112 at 0° , and appears to be non-volatile. Neither of these chloronitrins can be exploded by pressure or percussion.

In the series of the chloronitrins, the specific gravity increases with the proportion of NO^2 , thus:—

Hydrin containing	Cl^2	$\text{Cl}^2(\text{NO}^2)$	$\text{Cl}(\text{NO}^2)^2$	$(\text{NO}^2)^2$
Sp. gr.	1.347–1.417	1.465	1.5112	1.595–1.606.

Chlorobromonitrin, $\text{C}^2\text{H}_2\text{Cl.Br}(\text{NO}^2)$, formed by adding chlorobromhydrin in small quantities to a mixture of nitric and sulphuric acids, is a thick colourless liquid, having a pungent odour and a bitter taste.

CHLORINE. *Preparation.*—Deacon's process for preparing chlorine by passing a mixture of hydrogen chloride and oxygen over cupric sulphate or other copper salt heated to 700° – 750° F. (1st Suppl. 436), has been explained by its author in a lecture delivered before the Chemical Society on June 20, 1872 (see *Chem. Soc. J.* [2] x. 725–759); abstr. *Chem. News*, xxv. 307). The paper contains an account of numerous experiments both on the laboratory and on the manufacturing scale, the chief results of which are as follow:—

1. The heated mixture of hydrochloric acid gas and oxygen or air does not yield chlorine, except in presence of some substance capable of being attacked by the hydrochloric acid, amongst which the copper-compounds are eminently active. For economic reasons, the sulphate is the salt mostly employed.

2. With the same mixture of gases at the same temperature, the amount of hydrochloric acid decomposed by the aid of a molecule of the copper salt in a given time, depends upon the number of times the molecules of the mixed gases are passed through the sphere of action of the copper salt.

3. There is a certain small range of temperature between the limits of which the percentage of hydrochloric acid decomposed varies greatly; this percentage is higher for the sulphate of copper than for the chloride, but is the same whether solid cupric sulphate is used, or merely pieces of brick saturated with it: hence the amount of action appears to depend upon the surface rather than the mass of the copper salt present.

In experiments on the large scale, the critical temperature is always lower than in laboratory experiments, usually 100° or 150° ; and when the mixed gases are passed through a series of parallel tubes coated internally with cupric sulphate, an increased velocity in the flow of gas yields only about one-third the increase in the amount of chlorine produced, that an irregular porous surface does under the same circumstances.

4. Other conditions remaining the same, the percentage of hydrochloric acid decomposed varies with the square root of the proportionate volume of oxygen to hydrochloric acid.

5. The cupric chloride formed bears no definite proportion to the amount of chlorine produced.

De Lalande a. Frudhomme (*Bull. Soc. Chim.* [2] xvii. 290) find that when a mixture of silica with the chloride of an alkali-metal, alkaline earth-metal, or earth-metal is heated to redness and subjected to the action of a current of air or oxygen gas, chlorine is evolved and the chloride is converted into a silicate: e.g.

When hydrochloric acid gas is passed, together with oxygen, over the mixture of silica and chloride, the hydrochloric acid reproduces the metallic chloride at each instant by decomposing the silicate:

In this manner a continuous evolution of chlorine is obtained.

The water-vapour formed in the preceding reaction gives rise to two secondary reactions:

1. The water is decomposed by the chlorine:

2. The chloride is decomposed by the water:

2nd Sup.

Y

Boric, stannic, and phosphoric acids, alumina, pumice-stone, fragments of brick, &c., cause the evolution of chlorine quite as well as silica.

The temperature of the reaction is higher than in Deacon's process, but the quantity of chlorine evolved is the same.

On the action of Light on Chlorine, and on the Absorption of Light by Chlorine and its Compounds, see LIGHT.

Detection and Estimation.—For Beilstein's method of detecting chlorine, bromine, and iodine in organic substances by heating them with cupric oxide in a gas-flame, see BROMINE (p. 210).

In estimating these elements in organic bodies by Carius's method, it is found that bulbs of ordinary glass are not available, since they lose considerably in weight when heated to 160°–220° with nitric acid of sp. gr. 1.2. Bulbs of Bohemian glass, on the contrary, are scarcely altered.

Estimation in Bleaching Powder.—G. E. Davis (*Chem. News*, xxvi. 25) takes advantage of the comparatively easy solubility of arsenious acid in glycerin, to prepare a solution of arsenious acid for chlorometric purposes. He states that it possesses all the advantages and none of the disadvantages of the solution prepared according to Penot's method (4.44 grams of arsenious oxide and 13 grams of crystallised sodium carbonate dissolved in a litre of water). The standard solution is thus prepared: 13.95 grams of powdered arsenious oxide are dissolved by the aid of heat in 40 c.c. of glycerin, and the solution is diluted to one litre. Every 10 c.c. corresponds to 0.1 gram of chlorine. A drop of solution of indigo sulphate is used as an indicator, and the bleaching liquor is run into the arsenic solution until the blue colour of the indigo is destroyed or changed to a brownish yellow. The results obtained by this method are found to agree with those obtained by the use of a solution of arsenious oxide in acid or alkali, and with those of Bunsen's iodometric method.

J. B. Herreshoff (*Chem. News*, xxiii. 29) has given a method for the determination of available chlorine in bleaching powder based upon the fact that when bleaching powder is made to act upon an excess of stannous chloride in strongly acid solutions, stannic chloride is formed at the expense of all the available chlorine of the bleaching powder:

The amount of stannous chloride is afterwards estimated by means of a standard solution of potassium dichromate, and deducted from the amount originally employed:

1 gram of bleaching powder triturated with water is added to 20 cub. cent. of a titrated solution of stannous chloride (30 grams SnCl_2 dissolved in water with addition of hydrochloric acid, and diluted to 1000 c.c.) and afterwards 10 or 12 c.c. of hydrochloric acid. The reaction is energetic and complete, and yields a perfectly colourless solution. This liquid is then treated with a few drops of starch-paste and potassium iodide, and the excess of stannous chloride is determined with potassium dichromate (13.8738 grams in 1000 c.c.) added till a permanent blue colour is produced.

G. Lunge (*Chem. News*, xxiv. 5) regards this method as unsatisfactory, on the ground that the strength of the tin-solution is very variable. He gives the preference to Mohr's method of estimation with arsenious acid (i. 904), and replies to certain objections urged by Herreshoff against it, namely, that it is difficult to ascertain the purity of the arsenious acid employed; that the dissolution of this acid in sodium carbonate takes a long time; and that the solution thus formed does not remain of constant strength. Lunge, on the other hand, finds that the purity of any sample of arsenious acid is easily tested by sublimation; if pure, it will sublime completely and yield a perfectly white sublimate (sulphides of arsenic, if present, would give the sublimate a reddish tinge); further that the arsenious acid dissolves very quickly in aqueous sodium carbonate, if the proportions recommended by Mohr and by Fresenius are followed; and lastly, that a solution of pure arsenious acid will preserve its strength unaltered for years. Lunge titrates it with iodine, and recommends that the arsenious acid be poured into the iodine-solution.

A. H. Massey (*Chem. News*, xxiv. 271) examined three samples of bleaching powder by Herreshoff's method and by the arsenic method, and found that in each case the two methods gave concordant results.

According to J. Smyth (*ibid.* 75) the milky solution of chloride of lime is not so well adapted for chlorimetry as a clear solution obtained by dissolving the bleaching powder in an alkaline liquid. 10 grams of chloride of lime are added to a solution of 20 grams of sodium carbonate; the liquid is filtered from the precipitated calcium carbonate; the precipitate washed till the wash-water no longer bleaches indigo; and

the liquid is diluted to a litre. The resulting solution is well adapted for chlorimetry, and presents the further advantage of an easy estimation of the lime by precipitation with a titrated solution of sodium carbonate.

In the method of chlorimetry depending on the oxidation of ferrous sulphate by a hypochlorite (i. 904), it has been proposed to substitute ammonio-ferrous sulphate for the simple ferrous sulphate, inasmuch as it is more easily obtained and kept in a perfectly definite state. According to E. Biltz, however (*Arch. Pharm.* [2] cxlvi. 97), the double salt does not give exact results, because the chlorine acts on the ammonia as well as on the ferrous salt, as is shown by the evolution of gas which takes place on adding the ammonia salt to chlorine water. The error thence ensuing, which in the most favourable case entails a loss of $\frac{1}{2}$ p. c. of the chlorine present, is not constant, but varies considerably according to the quantity of water added to the solution of the double salt.

CHLORITE. From a discussion of the published analyses of the several varieties of chlorite, including pennine and clinocllore, Konngott (*Jahrb. pr. Chem.* ci. 17) infers that they may all be included under the general formula $RO.H^2O + 2(RO.SiO^2)$, assuming that the group $RO.SiO^2$ may be more or less replaced by Al^2O^3 .

A mineral called diabantachronny, which gives the colour to the green diabases of the Vorgtland and the Frankenwald, was examined by K. Liebe (*Jahrb. f. Mineralogie*, 1870, i.; *Jahrb.* 1870, 1307), and regarded by him as a distinct species. Konngott, however (*Jahrbuch f. Mineralogie*, 1871, 51) has shown from Liebe's analyses, that it is a variety of chlorite. Seven analyses of carefully selected specimens of diabantachronny gave the following results:—

	SiO^2	Al^2O^3	Fe^2O^3	MgO	FeO	H^2O
I.	30.27	11.16	—	21.22	26.94	10.20
II.	29.37	12.00	—	21.01	25.63	11.27
III.	29.85	9.07	—	17.92	26.60	15.81
IV.	31.25	10.03	3.47	19.73	23.52	11.37
V.	31.69	12.22	—	22.05	21.26	12.47
VI.	31.38	11.89	—	22.91	22.72	10.91
VII.	31.56	12.08	—	22.44	21.61	11.78

These numbers yield the following ratios:—

	I.	II.	III.	IV.	V.	VI.	VII.
Silica	5.05	4.89	4.97	5.21	5.28	5.23	5.26
Alumina	1.08	1.16	0.88	0.97	1.19	1.15	1.17
Ferric oxide	—	—	—	0.22	—	—	—
Magnesia	5.30	5.25	4.48	4.93	5.51	5.73	5.61
Ferrous oxide	3.74	3.56	3.60	3.27	2.95	3.16	3.00
Water	5.67	6.26	8.78	6.32	6.93	6.06	6.54

If now we resolve the alumina into AlO^2 and AlO , and add these to the SiO^2 and RO respectively, the same being done in IV. with the ferric oxide, we have—

	I.	II.	III.	IV.	V.	VI.	VII.
$SiO^2 + AlO^2$	6.13	6.05	5.85	6.40	6.47	6.3	6.43
$RO + AlO$	10.12	9.97	9.05	9.39	9.65	10.0	9.78
$2H^2O$	2.83	3.13	4.39	3.16	3.46	3.03	3.26
Or,							
$SiO^2 + AlO^2$	2.00	2.00	2.00	2.00	2.00	2.00	2.00
$RO + AlO$	3.30	3.30	3.09	2.03	2.98	3.16	3.04
$2H^2O$	0.92	1.03	1.50	0.97	1.07	0.95	1.01

These proportions agree for the most part with the chlorite formula. The disparity in III. of 1.50 instead of 1(2H²O) doubtless arises from an error in analysis, the exact estimation of the water presenting considerable difficulty.

CHLOROCODIDE. See CODEINE.

CHLOROFORM, CHCl³.—This compound is formed by the action of phosphorus pentachloride on iodoform:

There is also formed a very small quantity of a liquid containing a large proportion of iodine, and decomposing quickly, with rise of temperature, on exposure to the air (Gautier, *Bull. Soc. Chim.* [2] xiii. 127). The action of phosphorus pentachloride on iodoform was first studied by Serullas, who obtained an iodised product, regarded by Butlerow as methylene iodide (CH²I²) (iii. 311, 1006).

According to Bolohoubek (*Ann. Ch. Pharm.* clxv. 240), pure methyl alcohol, obtained from the crystalline oxalate, does not yield chloroform when treated with bleaching powder and water. Neither is chloroform obtained by treating acetic acid with aqueous bleaching powder. Now Lieben has shown that pure methyl alcohol and acetic acid yield no iodoform, although ethyl alcohol, aldehyde, and acetone do yield that compound under the influence of certain reagents. Probably, therefore, bodies which do not yield iodoform are likewise incapable of producing chloroform. The formation of chloroform by heating dry acetates with bleaching powder, is probably due to the acetone formed in the first instance.

Chloroform heated with bromine to 200° for six or eight hours yields a product from which, by fractional distillation, bromotrichloromethane CBrCl² is obtained, together with a small quantity of a liquid of higher boiling point, probably CBr²CCl (Paternò, *Gazzetta chimica italiana*, i. 593.—Friedel a. Silva *Bull. Soc. Chim.* [2] xvii. 537). The compound CBrCl² is a mobile colourless liquid becoming coloured on exposure to light. It has a pleasant ethereal odour, dissolves in alcohol and ether, boils at 104.3° under a pressure of 757.9 m.m. (Paternò); at 103°–104° under a pressure of 752 m.m. (F. and S.) Its specific gravity is 2.063 at 0°, 2.016 at 25°. When it is mixed with ether and acted upon by sodium, its chlorine and bromine are slowly attacked; sodium alone does not act upon it even when heated, but potassium produces a violent explosion (F. and S.).

Chloroform heated to 150° for three hours with 3 parts bromine and 1 part iodine in sealed tubes, which are opened occasionally to allow escape of gas, yields a liquid from which by fractional distillation are obtained tribromochloromethane CBr³Cl, melting at 70° and tetrachloromethane or carbon tetrachloride, melting at 76° (Bolas a. Groves, *Chem. Soc. J.* [2] ix. 779).

In like manner when chloroform is heated to 160°–170° in a sealed tube with iodine monochloride, tetrachloromethane is obtained, together with a small quantity of trichloro-iodomethane, the latter being doubtless the first product, and being converted into the former by the further action of the iodine monochloride:

and

(Friedel a. Silva, *loc. cit.*)

Chloroform may be converted into chloropierin, C(NO²)Cl³, by heating 7 vol. of it with 16 vol. hydrogen nitrate (HNO³), containing much nitrogen tetroxide, in sealed tubes to 90°–100° for 120 hours. The digesting tubes should be at an angle of about 30° with the bottom of the bath, as a more nearly horizontal position is found to involve the destruction of any nitro-compound that may be formed, while an upright position causes the reaction to proceed very slowly. When the digestion is ended, the apparent volume of the chloroform is much greater than before, on account of the liquefied gases, especially nitrogen tetroxide, which it now holds in solution. The tubes are best opened by means of a flame, and allowed to stand about 12 hours; their contents are then poured into water (with which they are washed), and are afterwards dried over calcium chloride and fractionally distilled.

In the course of the distillation, much chloroform comes over first, and is followed by a very small quantity of chloropierin.

Pure nitric acid not containing nitrogen tetroxide attacks chloroform with much greater difficulty and it is very doubtful whether any chloropierin is formed. This observation, taken in connection with the fact that chloroform dissolves nitrogen tetroxide much more readily than nitric acid does, raises a fair presumption that the tetroxide is the actual agent of nitration (E. J. Mills, *Chem. Soc. J.* [2] ix. 443).

Detection of Chloroform.—To detect small quantities of chloroform, especially in

presence of etheral compounds closely allied to it, and possessing similar properties, advantage may be taken of its behaviour with the *monamines* in presence of alcohol and sodium hydrate. The odour of isonitrils thereby produced is an infallible sign of the presence of chloroform. The experiment is performed by adding the liquid to be tested to a mixture of aniline—any other primary monamino, fatty or aromatic, serves equally well—and alcoholic soda. If chloroform is present, a violent reaction takes place, either immediately or on warming gently, and the peculiar-smelling vapour of the isonitril is evolved. Bromoform and iodoform, of course, behave like chloroform: the reaction occurs, moreover, with all bodies capable of yielding chloroform, bromoform, or iodoform by the action of alkalis. For example, on adding a solution of chloral in aniline to alcoholic potash, the vapour of an isonitril is immediately evolved in abundance. *Chlorethylidene* treated with alcoholic potash and aniline, yields no isonitril, and is therefore easily distinguished from chloroform. The reaction here recommended is so delicate, that one part of chloroform dissolved in 5,000 to 6,000 parts of alcohol may be detected by it with certainty (A. W. Hofmann, *Deut. Chem. Ges. Ber.* iii. 769).

On the detection of alcohol in chloroform, see ETHYL ALCOHOL.

CHLOROPHYLL. Absorption-spectrum.—In the spectrum of light transmitted through a concentrated solution of chlorophyll, all the light is absorbed, except the least refrangible red, near the line B. On gradually diluting the solution, the green first makes its appearance, then the yellow, the orange, and part of the red, forming a very characteristic spectrum containing—I, a broad dark band close behind B, which is darkest between B and C; II, a second absorption-band in the orange between C and D; III, a third a little behind D; and a fourth, IV, in the green close before F. Of these bands, I, is by far the darkest, making its appearance even in very dilute solutions, whilst II, III, and IV, gradually diminish in intensity. The whole of the more refrangible portion of the spectrum is also absorbed, but just before G the absorption is somewhat weaker, increasing again behind G; and in the green behind δ , is a band V, which does not appear in fresh solutions of leaf-green, but only in those which have been modified by the action of light.

When a solution of chlorophyll is illuminated by a pure sun-spectrum, the red fluorescent light is seen over all the spectrum with the exception of the extreme red, beginning just before B, and extending with varying intensity to the ultra-violet. In this spectrum seven bright bands may be observed: the first between B and C; the second between C and D, rather nearer to D; the third close behind D; the fourth immediately before E; the fifth, which is seen only in the modified solution, behind δ ; and the sixth and seventh, beginning behind F, cover the rest of the spectrum. Of these, the first, between B and C, and the sixth and seventh are the brightest. These bright fluorescent bands correspond both in position and intensity with the dark absorption-bands, showing the intimate relation between fluorescence and absorption. The red fluorescent light, when concentrated and examined spectrally, is found to consist entirely of red rays corresponding in refrangibility with those between B and C.

The absorption-spectrum of solid chlorophyll has a great resemblance to that of the solution, a thick layer of green leaves absorbing all the rays of the spectrum from B to the violet end. A thinner layer shows a dark band beginning before B and reaching to behind C; it transmits the red, orange, yellow, and green light between C and E; just behind E the spectrum begins to darken, and from the middle point between F and G it is opaque. The dark bands II, III, and IV, of the solution do not appear, powerful absorption only being found in the violet, and in the red between B and C. As solid chlorophyll does not exhibit the phenomenon of fluorescence, the red rays between B and C can only be indirectly absorbed (Lommel, *Pogg. Ann.* cxl. iii. 568).

Modification of Chlorophyll by Light. a.—It has long been known that a chlorophyll solution when exposed to light becomes changed in colour, and Stokes (*Pogg. Ann. Erg.* iv. 128) has found that this chlorophyll, precipitated from its alcoholic solution and again dissolved in ether, undergoes no further change when exposed to diffused light. This modified chlorophyll has a somewhat different spectrum from the fresh, the dark band III, being lighter and displaced towards the more refrangible end of the spectrum, whilst there is a bright band between δ and F, so that, in the modified chlorophyll, there are five dark bands between a and F, whilst in the fresh there are only four. In order to investigate this change more thoroughly, Gerland (*Pogg. Ann.* cxliii, 585) has examined the absorption-spectra of various chlorophyll solutions, both prior to exposure, and at intervals during insolation.

1. **Alcoholic Solution of fresh Chlorophyll.**—This solution, which was simply an alcoholic extract of the leaves of *Urtica dioica*, previously boiled in water, showed the band III, very distinctly and stronger than IV, which was very feeble. Exposed to

sunlight it had perceptibly changed colour in five minutes, in ten it was olive green, in fifteen brown, and after the lapse of an hour it had become bright yellow, and no longer showed any signs of fluorescence. During this change the absorption-bands gradually became more indistinct, and disappeared in their order, I. being the most stable; eight days' insolation rendered it almost colourless in thin layers, but in thicker layers it appeared of a brownish yellow, and gave the same absorption-spectrum as Fülho's yellow (*Ann. Chim. Phys.* [4] xiv.). The same change took place in diffused light, but more slowly. The alcoholic solution of the leaves of *Urtica dioica* which had been previously treated with cold water, as also that prepared from *Sambucus nigra*, which had been boiled with water, gave the same spectrum, although the solutions differed slightly in colour.

2. *Alcoholic Solution of half-modified Chlorophyll.*—A solution which had been prepared from the leaves of *Brassica oleracea* in December 1870, and exposed to a diffused light for about two months, gave a spectrum between that of fresh and that of modified chlorophyll. Its colour was brownish-green, and gave the dark band III. but weakly, whilst V. was scarcely distinguishable. Exposed to insolation, it gradually faded, but more slowly than the freshly prepared solution; for even after being exposed to sunshine for eight hours, and to daylight during several days, it still showed all the dark bands except III., but much more faintly than before. After another eight hours' sunshine and several days more of diffused light, I. was still very faintly visible, and even when it was submitted to insolation for six hours more, a considerable thickness of the solution showed traces of the band I. A solution, prepared in 1863, and kept in the dark for 3½ years, gave the same results.

3. *Completely modified Chlorophyll.*—An ethereal solution of modified chlorophyll becomes faded, but very slowly; after 42 hours' insolation, a stratum of the solution 15 m.m. thick had the same colour as one of the original solution 2.5 m.m. thick, but all the bands were visible, and even after forty days' exposure to light, I. was still faintly visible, and the solution distinctly fluorescent. An alcoholic solution behaved in the same way, but the change took place much more rapidly.

4. *Ethereal Solution of Fresh Chlorophyll.*—This was obtained from *Urtica dioica* in a similar manner to the alcoholic solution, and had the same spectrum, but the bands, with the exception of I. being darker, rendered it more characteristic. Exposed to the sun's rays, it faded much more slowly than the corresponding alcoholic solution, being only slightly changed. After one and a-half hour's action, and although it now showed the bright band of modified chlorophyll, the dark band III. was not displaced. The latter, however, was much broader, so that it occupied the space covered by the dark bands both in modified and in fresh chlorophyll. On continuing the insolation, a more rapid change took place, the colour became browner, and after a time III. disappeared, giving the spectrum of the incompletely modified chlorophyll.

5. *Solid Chlorophyll*, precipitated on paper from its alcoholic or ethereal solution, fades completely and rapidly in sunlight, but more slowly in diffused daylight. The chlorophyll cells in a leaf of *Sambucus nigra*, from which the epidermis had been removed, became colourless on exposure to sunlight.

6. *Ethereal Solution of Frémy's Phylloxanthin* (1st Suppl. 443), when submitted to insolation, behaved precisely like modified chlorophyll.

7. *Alcoholic Solution of Fülho's Green* (*Ann. Chim. Phys.* [4] xiv.) became completely faded by long-continued insolation, showing no trace of absorption or fluorescence. When the solution is evaporated, it leaves a colourless waxy substance which froths with sulphuric acid, but not with hydrochloric acid or nitric acid. This green behaves in the same manner whether prepared from dried or from fresh leaves.

As the chlorophyll in plants is evolved from a yellow colouring substance, so does it again become yellow on fading, and therefore it is possible that the yellow residue which is left in autumn leaves, may be faded chlorophyll.

8.—Hitherto no distinction has been made between modified and faded chlorophyll, so that the theories respecting its fading and decolorisation are very contradictory.

Jodin (*Compt. rend.* lix. 859) found that an alcoholic solution of chlorophyll exposed to sunlight absorbed oxygen, whilst Timiriaseff (*Botan. Zeit.*, xxvii. 886), states the fading to be a process of reduction. The latter view appears to be borne out by the observation made by Rauwenhoff and Gerland, that in one instance there was an odour of aldehyde in the alcoholic solution from which modified chlorophyll had been precipitated. Gerland has since frequently repeated this experiment, but has not again been able to detect aldehyde, and has therefore endeavoured to settle this point by insulating two exactly similar test-tubes of chlorophyll solution through one of which oxygen or ozonified air was passed, but it faded with nearly equal rapidity in both cases.

As neither the ether nor the alcohol employed as solvent undergoes any change when the chlorophyll fades, if the fading is due to oxidation, the oxygen must be taken from the air or from that dissolved in the alcohol. When strongly ozonified air was passed into a boiled alcoholic solution of chlorophyll standing over mercury, a small quantity of gas was at first absorbed, and the solution became somewhat darker, but after that no further absorption took place. The presence of oxygen is necessary, however, to start the action, for both the alcoholic and ethereal solutions which had been sealed up in glass tubes from which the air had been expelled by boiling the liquid, could be exposed to the sun's rays without undergoing any change, but directly the air was admitted and they were submitted to insolation, the colour of the solutions began to fade. It would seem, therefore, that both oxygen and light are necessary to produce chemical change in chlorophyll, so that when the solution is exposed to light and air, oxygen first combines with the chlorophyll which begins to be modified, and then, if the insolation be continued, it fades, but if it is exposed only to a feeble light, the oxidation at first set up continues and the chlorophyll becomes modified.

III.—As the dark bands disappear when chlorophyll fades and becomes decolorised, it seems probable that the rays absorbed by the solution are employed in producing chemical action. To test the accuracy of this view, a chlorophyll solution was first submitted to the action of the rays of different parts of the spectrum, but no satisfactory result was obtained. Sach (*Handbuch Exper. Phys. Pflanz.*) had observed that when a chlorophyll solution is exposed to light which has previously passed through another stratum of the same fluid, it does not begin to fade until the other is much changed. Gerland, on repeating the experiment, found that when the protected or test solution began to fade, the band I. in the spectrum of the protecting solution had become foggy and indistinct, whilst the dark bands II. and III. had completely vanished. As therefore light of a refrangibility corresponding with the dark bands II., III., IV. and V. had produced no effect upon the test-solution, it could only be the rays of the same refrangibility as I., and the blue, that caused the solution to fade. When the protecting solution was a concentrated ethereal solution of modified chlorophyll, no change took place in the test-solution even after several days' insolation. On examining this protecting solution spectroscopically, the band I. was seen to be quite black, whilst the red and yellow rays on each side of it were freely transmitted. From the results of this series of experiments, it seemed that the obscure heat-rays took no part in causing the chlorophyll to fade, and in order to confirm this, a solution of chlorophyll was exposed to bright sunshine from which the heat-rays had been excluded by passing it through a stratum of water 130 mm. thick. The colour of the solution, however, faded as quickly as that of one exposed to the direct rays of the sun. In order to ascertain whether it was the red rays corresponding with the band I. or the blue and violet from G to II, or both of these, which caused the change, solutions of chlorophyll were exposed behind red glasses (coloured with copper oxide), and an ammoniacal solution of copper sulphate respectively. The colour of the solution slowly faded in both cases; but on exposing the solution to the light transmitted through green glasses (consisting of the green and a few yellow and blue rays) no change took place: hence it is inferred that chlorophyll fades only when exposed to light of the same refrangibility as that which it absorbs.

It has been shown by Filhol that chlorophyll is composed of two substances, one green the other yellow, which may be separated from one another by filtration through animal charcoal or by the action of oxalic or tartaric acid (*1st Suppl.* 444). This result has been confirmed by Gerland & Rauwenhoff (*Pogg. Ann.* cxliii. 231), who find however, in accordance with Schön and other observers, that these two colouring matters are not the phylloxanthin and phyllocyanin described by Frémy; the phylloxanthin of this chemist appears indeed to be nothing but modified chlorophyll. Neither are the substances in question identical with the yellow and green colouring matters which Kromayer obtained by treating chlorophyll with alcoholic potash (*Jahresber.* 1861, 738). Neither these two substances nor those obtained by Frémy are capable of reproducing chlorophyll by their union.

In leaves which become yellow, the chlorophyll disappears either by being absorbed, or by being converted into the yellow compound (Gerland & Rauwenhoff).

J. Chautard (*Compt. rend.* lxxv. 1836) observes that the dark band in the red of the chlorophyll spectrum is very persistent even under great dilution. The spectrum is considerably altered by adding hydrochloric acid to the solution, but the band in the red is still seen even after great dilution. An alcoholic solution prepared from dried leaves gives a spectrum like that of the acidified solution of fresh leaves. The solution of fresh chlorophyll is also rapidly changed by exposure to sunshine, and more slowly by diffused light, so as to give a spectrum like that of acidified chlorophyll. Other colouring matters do not mask the presence of chlorophyll; and metallic salts do not affect its spectrum before precipitation takes place.

An alcoholic solution of chlorophyll mixed with a few drops of solution of caustic potash or ammonia is very little changed. But by boiling with solution of caustic potash, the characteristic absorption-band in the red is divided into two, whilst the rest of the chlorophyll bands disappear almost entirely. These two bands reunite on acidifying the liquid with acetic acid, and may be again separated by adding ammonia, (Chautard, *ibid.* lxxvi. 570).

According to F. A. Hartsonn (*Chem. Centr.* 1872, 524), chlorophyll in the leaves of plants is generally accompanied by a yellow crystalline body. This substance, called *chrysophyll*, and perhaps identical with Frémy's *phyloxanthin*, is obtained, (together with chlorophyll) in small crystals, having a gold-yellow colour, by treating the leaves, previously freed from water by means of alcohol, with ethereal alcohol, pouring off the liquid after 24 hours' standing, and allowing it to evaporate spontaneously. The residue while still moist is treated with petroleum or boiling caustic potash, which dissolves only the chlorophyll, and the remaining *chrysophyll* is recrystallised from ether.

The green mass obtained by evaporation of the ethereal extract from leaves, yields, with hydrochloric acid, a greenish solution, from which, on addition of water, a black substance called *melanophyll* is precipitated.

Chlorophyll is carried down from its solution together with many precipitates, as barium sulphate, calcium oxalate, silver chloride, &c.

CHLOROPICRIN, $C(NO^2)Cl^2$. *Trichloronitromethane*.—This substance may be prepared by direct nitration of chloroform with strong nitric acid (Mills, p. 324). Cossa (*Gazzetta chimica italiana*, ii. 181) follows the same process, with addition of oil of vitriol.

In preparing chloropicrin by the action of calcium hypochlorite on picric acid (Stenhouse's method, i. 223), Cossa recommends that the mixture of picric acid with perfectly fresh and dry calcium hypochlorite, be passed through a sieve to retain any lumps, which often cause explosion. The best temperature for the reaction is 45° . The chloropicrin thus obtained boils at 112.8° , at 743 mm. pressure, and distils without decomposition. When it is suddenly heated at a temperature above its boiling point, and the vapour is passed through a red-hot tube, it decomposes without explosion, as is also the case when sodium or potassium is fused in it. Chloropicrin readily dissolves iodine, the colour of the solution being deeper than that of iodine in chloroform. It also dissolves cinnamic and benzoic acid, resins, and most substances rich in carbon, including that modification of dinitronaphthalene which is difficultly soluble in alcohol. It is miscible in all proportions with benzene, amyl alcohol, carbon sulphide, and absolute alcohol. At 11° , 1 vol. of 80.5 p. c. alcohol dissolves 3.7 vols., and 1 vol. 78 p. c. alcohol 1.3 vol. chloropicrin; 1 vol. ether dissolves only 0.3 vol.

The reaction which takes place when ammonium sulphide is added to chloropicrin, or when hydrogen sulphide is passed into a solution of chloropicrin in ammoniacal alcohol, is very energetic, and affords the best means of detecting small quantities of chloropicrin in very dilute alcoholic solution. The liquid becomes hot, a deep red colour is produced, sulphur is set free, and much ammonium chloride formed.

Chloropicrin has a more violent action on the respiratory mucous membrane than either chlorine or nitrous fumes, causing suffocation and spitting of blood.

CHOLESTERIN, $C^{26}H^{44}O$. This substance is contained in the grease of sheep's wool. F. Hartmann (*Inaug. Diss.* Göttingen, 1868) by boiling the grease with alcoholic potash and crystallising the unsaponified residue from alcohol, obtained crystals which exhibited the reactions of cholesterol, but differed considerably from it in appearance, melting point, and composition. Hartmann regarded these crystals as a mixture of cholesterol with unaltered cholesteryl ethers. By heating them with potash-solution in a sealed tube, he obtained crystals which appeared to be purer cholesterol and melted at 137° .

These results have been fully confirmed by E. Schulze (*Zeitschr. f. Chem.* [2] vi. 453), who has obtained the cholesterol in the pure state. 120 grams of the wool-grease were boiled for some hours with potash-solution in a porcelain dish, common salt then added, and the boiling continued for half-an-hour longer. After cooling, the semifluid mass of soap and unsaponified fat was separated from the liquid, and freed from unsaponified fat by digestion with ether. This unsaponified fat, amounting to about 70 p. c. of the original grease, was heated with alcoholic potash for 20 hours to 100° in a closed stone-ware bottle; the contents then poured out; the alcohol evaporated; the greater part of the potash dissolved out of the residue by water; and the undissolved substance stirred up with water and agitated in a glass cylinder with ether. The ethereal layer, when left to evaporate, yielded a faintly yellow fatty substance, a very concentrated solution of which in hot ether solidified on cooling to a mass of needles.

shaped crystals, and a solution of the same in hot alcohol deposited on cooling a considerable quantity of crystalline laminae and white flocks.

The substance thus obtained is a mixture of cholesterol with one or two substances containing less carbon and melting at lower temperatures; by fractional crystallisation from ether-alcohol it yields pure cholesterol in thin shining plates, having exactly the appearance and composition of cholesterol from gall-stones, exhibiting similar reactions, and melting at 144.5° . On triturating it with a little concentrated sulphuric acid and then adding chloroform, a blood-red solution is formed, which, on addition of strong nitric acid, becomes violet, blue, and afterwards colourless. On triturating it with a drop of a mixture of 3 vol. strong hydrochloric acid and 1 vol. solution of ferric chloride, and slowly evaporating to dryness, the particles which have remained undissolved assume a violet-red colour, changing to blue. A small portion of the crystals treated with a drop of strong nitric acid and slowly evaporated, leaves a yellow spot turned red by ammonia (compare 1st Suppl. 447).

The reaction of cholesterol with sulphuric acid is best exhibited by dissolving a few centigrams of cholesterol in about 2 c. c. of chloroform, and then shaking it with its own bulk of strong sulphuric acid. The chloroform quickly becomes blood-red, and then cherry-red or purple, a colour which it retains for several days. A few drops poured into a basin become blue, green, and then yellow. This change seems to be due to traces of moisture, and the original colour may be restored by sulphuric acid. The sulphuric acid under the chloroform presents a distinct green fluorescence. When dropped into glacial acetic acid, the liquid, in about half an hour, becomes violet, or, if much diluted, rose-coloured, with a green fluorescence, and exhibits such a resemblance to the liquid obtained by diluting Pottenkofer's test for bile-acids with glacial acetic acid, that it is often impossible to distinguish between them. The spectra they present are also very much alike, but the spectrum of each is somewhat variable. That of the cholesterol solution indicates that it consists of two substances, whose proportions vary. Water takes up from the chloroform solution a sulpho-acid, which forms crystallisable salts with barium. The reaction of cholesterol with sulphuric acid is slightly modified when only traces of cholesterol are present, and it is best in that case to dissolve a few granules in 1 c. c. of chloroform, and warm gently with an equal volume of sulphuric acid, occasionally shaking. The chloroform quickly acquires a rose or violet colour. The sulphuric acid becomes lemon-yellow, with a distinct green reflection. By dilution with glacial acetic acid, a liquid is obtained of a faint red colour, with green fluorescence (E. Salkowski, *Pflüger's Archiv f. Physiologie*, vi. 207).

Cholesterol, boiled for twelve hours with sulphuric acid and potassium dichromate, becomes oxidised, yielding a white amorphous acid product having the composition of oxycholic acid $C^{24}H^{40}O^6$, together with small quantities of several of the lower terms of the fatty acid series, probably acetic, propionic, and butyric. Oxycholic acid is not affected by sodium-amalgam in alkaline solution, and is but slowly oxidised by fusion with potassium hydrate, yielding only secondary products of decomposition, viz., inflammable gases, a brown fatty substance, and some of the lower fatty acids (L. Henry, *Deut. Chem. Ges. Ber.* v. 569).

Cholesteryl acetate, $C^{26}H^{42}.C^2H^3O^2$, is produced by treating cholesterol with acetyl chloride; it crystallises in small colourless needles, melting at 92° (Henry); compare 1st Suppl. 448.

Cholesterylamine, $C^{26}H^{42}.NH^2$.—The chloride obtained by the action of phosphorus pentachloride on cholesterol is readily converted into this compound by digestion with alcoholic ammonia. It crystallises in small plates melting at 104° (Henry).

The following cholesterol derivatives are now known:—

$C^{26}H^{42}.OH$:	:	:	:	Cholesterol.
$C^{26}H^{42}.ONa$:	:	:	:	Sodium cholesterylato.
$C^{26}H^{42}.OC^2H^3O$:	:	:	:	Acetyl-cholesteryl.
$C^{26}H^{42}.Cl$:	:	:	:	Cholesteryl chloride.
$C^{26}H^{42}.NH^2$:	:	:	:	Cholesterylamine.

Cholesterol treated with phosphorus trichloride yields neutral phosphoretted bodies, which are difficult to purify, and resemble the so-called myelin (Grupe-Besanes, *Ann. Ch. Pharm.* clvii. 284).

The substances above mentioned as obtained together with cholesterol, by the saponification of wool-grease, consists chiefly of an isomeride of cholesterol, which separates from alcohol in white flocks. The portion of wool-grease which does not dissolve in alcohol consists of ethers of cholesterol and ischolesterol; the portion soluble in alcohol contains free cholesterol, and probably free ischolesterol, together with fatty ethers of both these alcohols (Schulze). See ISCHOLESTERIN.

CHOLIC ACID, $C^{22}H^{40}O^3$ (Baumstark, *Deut. Chem. Ges. Ber.* v. 1185, 1377).—This acid is diatomic and monobasic, two of its hydrogen-atoms being replaceable by alcohol-radicles, but only one by metals.

Ethyl cholate, $C^{22}H^{42}(C^2H^5)O^3$, is prepared by passing hydrochloric acid-gas into a solution of cholic acid in ethyl alcohol, precipitating with water, heating the precipitate with solution of sodium carbonate, and dissolving the portion not thereby taken up, in ether. On evaporating the ether, ethyl cholate remains as a soft unctuous mass, which, when placed over sulphuric acid and frequently stirred, dries up to a resin resembling colophony. [Hoppe-Seyler (*J. pr. Chem.* lxxxix. 272) describes both ethyl and methyl cholates as well crystallised compounds.] It is insoluble in water, very soluble in alcohol and in ether. Caustic alkalis in the cold, and alkaline carbonates with the aid of heat, do not extract from it anything precipitable by acids; but when heated with caustic soda to 120° in a tube, it yields sodium cholate and ethyl alcohol.

It has not been found possible to prepare a diethylic cholate by heating the monethylic ether, or the acid itself, with ethyl chloride.

Ethyl-Benzoyl Cholate, $C^{22}H^{42}(C^2H^5)(C^7H^5O)O^3$, is produced by heating ethyl cholate with benzoyl chloride in a flask with reversed condenser; and may be purified in the same way as the preceding ether, excepting that it must be heated for some time to 130° to remove adhering benzoic acid. It is a resinous mass, insoluble in water, easily soluble in alcohol and in ether, resolved by heating with alkalis into benzoic acid and ethyl alcohol.

Cholamide, $C^{22}H^{40}O^4.NH^2$, is formed by heating ethyl cholate with alcoholic ammonia to 120° (according to Hoppe-Seyler the product consists of ammonium cholate). Prepared in this way, or by heating ammonium cholate in an oil-bath as long as water continues to escape, it is a yellowish resinous mass, insoluble in water, moderately soluble in acids, easily in alcohol and ether, decomposing at high temperatures.

Products of Decomposition of Cholic Acid.—This acid, subjected to gradual oxidation, yields a condensed acid which appears to contain not less than 96 atoms of carbon, and is, perhaps, the acid which has been described as choloic acid.

By dry distillation cholic acid yields a small quantity of a substance exhibiting the properties of phenol.

Cholates distilled with excess of alkali yield volatile products passing over from 150° to 280° , and all exhibiting Pettenkofer's bile reaction with sugar and sulphuric acid.

According to Gorup-Bosanez (*Ann. Ch. Pharm.* clvii. 282) cholic acid melted with potassium hydrate, yields acetic and propionic acids, together with a brown insoluble substance exhibiting the characters of dyslysin.

Reactions with Phosphorous Chloride.—When powdered cholic acid is digested in phosphorous chloride, much hydrochloric acid is evolved, and a thickish liquid is obtained, from which water precipitates a white resinous mass. When heated with water to boiling, this mass melts and forms on cooling an easily pulverisable lump, which may be purified by boiling it with successive portions of water till the water no longer acquires an acid reaction, dissolving it in warm sodium carbonate, and precipitating it with hydrochloric acid, repeating this several times, and finally digesting it with ether. The product is a peculiar acid containing phosphorus; when dry it presents the appearance of a fine dusty white powder, and, on microscopic examination, is seen to consist of highly refracting granules without any trace of crystals. It has a slightly bitter taste, no smell, is insoluble in water either cold or boiling, soluble in alcohol and chloroform, sparingly soluble in ether. When heated on platinum foil, it melts, becomes brown, takes fire and burns with a greenish flame and emission of thick white fumes, leaving a cinder which burns with difficulty and has a strong acid reaction due to the presence of phosphoric acid. It gives Pettenkofer's reaction with sugar and sulphuric acid.

The numbers obtained from analyses of different portions of the acid nearly correspond with the empirical formula $C^{22}H^{44}P^2O^{13}$. If this formula were correct the reaction might be—

There is, however, no guarantee for the purity of the acid, as neither it nor its salts can be obtained in the crystalline state. The probable formation of this body by the union of three molecules of cholic acid is extremely interesting when considered in connection with the very high molecular weight by which all the compounds of bile and nerve at present known, are distinguished. It would appear that with the action of tri- or quinquivalent phosphorus, several molecules of non-phosphorised compounds unite to form a condensed molecule containing phosphorus.

CHOLINE, $C^9H^{14}NO^2$. This base is formed, together with margaramido, glycerophosphoric acid, and small quantities of oleic and margaric acids, when lecithine is left for a month in contact with an equal weight of ammonia (Gobley, *Compt. rend.* **LX.** 1207).

CHONDRIEN, or **CHONDROGEN**. Tissues yielding chondrin when boiled with water have been found in the *Brachiopoda*, *Holothuridae*, and *Tunicata*. The mantles of animals of the last-named class, when boiled for some time in a Papin's digester, yield an opalescent solution which, however, does not gelatinise. It is precipitated by acetic acid, the precipitate being insoluble in excess; also by lead-acetate, basic and neutral, and gives a bulky precipitate with alum. The residue left on evaporating the aqueous solution, after treatment with dilute hydrochloric acid and washing with alcohol and water, gives by analysis 14.99 p.c. nitrogen, which agrees nearly with the quantity found in chondrin by Mulder and Scherer (Schüfer, *Ann. Ch. Pharm.* **clx.** 330).

CHONDRODITE. See HUMITE.

CHROME IRON-ORE. On the analysis of this mineral, see *Chem. News*, **xxiii.** 284; **xxiv.** 304; *Chem. Soc. J.* [2] **ix.** 177).

CHROMIUM. In the preparation of this metal by Wöhler's method of reducing chromic chloride with zinc (*1st Suppl.* 910), E. Zettnow (*Pogg. Ann.* **cxliii.** 477) uses as a flux, instead of the mixed chlorides of potassium and sodium recommended by Wöhler, a double chloride of chromium and potassium. He forms this double salt from red potassium chromate, by reducing it with hydrochloric acid in presence of alcohol, and adding chloride of potassium to the boiling liquid, which is then evaporated to dryness. The residue, after being carefully dried, is mixed with finely granulated zinc, and this mixture is introduced by successive portions into a red-hot Hessian crucible, in which, after the last portion has been added, it is heated for half to three-quarters of an hour, and then allowed to cool slowly. The soluble salts are dissolved out by water, the zinc by dilute nitric acid.

Chromium Trioxide. Chromic Anhydride, CrO^3 .—For the preparation of this compound in the pure state, the following process is recommended by Zettnow (*Pogg. Ann.* **cxliii.** 474) as the easiest and most economical:—

300 grams of pulverised commercial potassium dichromate are warmed with 500 c.c. of water and 420 c.c. of sulphuric acid, until dissolved; and the solution is left at rest for 10–12 hours, in which time the acid potassium sulphate crystallises out. The mother-liquor is decanted and allowed to drain for an hour or two, the salt being washed with 10–12 c.c. of water. The solution is heated to 80° – 90° , mixed with 150 c.c. of sulphuric acid, and afterwards gradually with the same quantity of water, until the precipitated chromic acid is re-dissolved. The solution is then evaporated until crystals begin to appear. After standing for 10 to 12 hours, the chromic anhydride is precipitated in small, brownish-red crystals. The mother-liquor is decanted from the crystals, again evaporated, and left at rest, whereby a second crop is obtained of rather larger feathery crystals, and in a similar manner a third crop of long scarlet-red needles. These crystals are freed from mother-liquor by draining in a funnel, in the apex of which is placed a piece of thin platinum-foil pierced with very small holes, and finally dried on a porous tile.

To purify the crystallised chromic anhydride thus obtained, it is introduced into a porcelain crucible, and treated gradually with 50 c.c. of pure nitric acid of sp. gr. 1.46 (weaker acid would dissolve the chromic acid), the mixture being thoroughly stirred with a glass rod; it is then placed on a dry tile. If, after standing thus for 12 hours, the chromic anhydride is found to be not thoroughly freed from potash and sulphuric acid, it is sufficient to repeat the operation with 25 c.c. of the nitric acid to remove these impurities. The nitric acid is readily expelled from the crystals by heating on a sand-bath, first gently, then more strongly, until no more acid fumes are evolved.

By this method Zettnow obtained an average of 84.8 p.c. of the theoretical quantity of pure and dry chromic anhydride. By using the green mother-liquor decanted after the third crystallisation, in place of fresh sulphuric acid, a considerable saving is effected, whilst the quantity of chromic anhydride thus procured is about 90.3 p.c. of the theoretical quantity, instead of 84.8 p.c.

Specific gravity of Chromic Anhydride and of Chromic acid solutions (Zettnow, *Pogg. Ann.* **cxliii.** 274).—The specific gravity of chromic anhydride was determined by means of commercial benzene, freed from water by digestion with calcium chloride. The dried benzene, whether hot or cold, does not dissolve the smallest quantity of chromic acid.

The sp. gr. of the solid chromic anhydride, as determined by six experiments at 17.5°, was 2.775, 2.777, 2.787, 2.785, 2.804, and 2.800 respectively, the mean being 2.788.

Specific gravity of Aqueous Chromic acid.

Percentage of CrO ³ dissolved	Specific gravity of solution	Percentage of CrO ³ dissolved	Specific gravity of solution

Action of Chromic acid on Carbon compounds.—Chromic acid in aqueous solution is recommended by Bertholot (*Ann. Chem. Phys.* [4] xxiii. 212) in many cases for the oxidation of organic compounds, instead of the ordinary mixture of potassium dichromate and sulphuric acid, because it acts less violently; in fact, when this mixture is used, the chromic anhydride parts with half its oxygen, producing chrome-alum:

whereas, when aqueous chromic acid is used, only one-fifth of the oxygen of the anhydride is given off, with formation of a chromate of chromium:

By the use of the dilute aqueous acid, *acetylene* is oxidised to acetic acid, and *allylene* to propionic acid. If, however, only a small quantity of water is present, the action on acetylene becomes violent, and the products are formic and carbonic acids.

Carbon monoxide, passed through a series of U-tubes filled with pumice-stone moistened with concentrated chromic acid is slowly oxidised to dioxide. *Hydrogen* is also slowly converted into water, when a gypsum-ball steeped in the concentrated acid is introduced into the gas standing over mercury. *Marsh-gas* withstands the action of chromic acid even in the concentrated state. *Ethylene* at ordinary temperatures is completely oxidised to carbon dioxide and water by concentrated solution of chromic acid, and very slowly by dilute solutions (E. Ludwig, *Ann. Ch. Pharm.* clxii. 47).

Chromates. *Barium chromates.*—The *dichromate* $\text{BaCr}^2\text{O}^6 = \text{BaO} \cdot 2\text{CrO}^3$ separates as a yellowish powder from a solution of the normal chromate in boiling aqueous chromic acid. No other acid chromate of barium appears to exist (Zettnow, *Pogg. Ann.* cxlv. 167).

Chromic Chromate, $\text{Cr}^2\text{O}^3 \cdot \text{CrO}^3$ or *Chromium Dioxide* CrO^2 , is obtained in the hydrated state by mixing a cold solution of potassium dichromate with sodium thiosulphate:

hyposulphuric (dithionic) acid being probably formed in the first instance, and afterwards resolved into sulphurous and sulphuric acids. If the action be completed by aid of heat, and the product washed till the wash-water no longer appears yellow, the compound $2(\text{Cr}^2\text{O}^3 \cdot \text{CrO}^3) + 9\text{H}^2\text{O}$ is obtained. When dried at a gentle heat, it is a light, bulky, deep-brown powder. It dissolves easily, especially with aid of heat, in dilute sulphuric or hydrochloric acid, forming a green solution; in dilute acetic acid it is less soluble. Nitric acid dissolves it with deep brown colour; strong hydrochloric acid dissolves it, when heated, with evolution of chlorine. From its solutions in dilute sulphuric and hydrochloric acids, ammonia throws down green chromic oxide, while ammonium chromate remains in solution, generally retaining a little chromic oxide. By boiling it with alkaline carbonates, green chromic oxide is separated and an alkaline chromate is dissolved. The compound, when slowly heated, first gives off its water of hydration, and is then resolved, with vivid incandescence, into oxygen and chromic oxide of a fine green colour (O. Popp, *Ann. Ch. Pharm.* clvi. 90).

Mercury-salts.—Normal mercurous chromate $(\text{Hg}^2)^2\text{CrO}^6$ is best prepared by

precipitating mercurous nitrate with potassium dichromate; the precipitate is not decomposed by washing with water. On the contrary, the precipitate thrown down by potassium dichromate from *mercuric nitrate* retains the composition of the normal chromate only when washed with dilute nitric acid; if washed with water it loses chromic acid. The only basic mercuric chromate that seems to exist is the tribasic salt $3\text{HgO} \cdot \text{CrO}_3$ (Freese, *Zeitschr. f. Chem.* [2] vi. 30).

Nickel-salts.—Freese (*loc. cit.*), by precipitating a boiling solution of nickel sulphate with neutral potassium chromate, obtained the salt $3\text{NiO} \cdot \text{CrO}_3 + 6\text{H}_2\text{O}$. According to E. A. Schmidt (*Zeitschr. f. Chem.* [2] vii. 31), this salt is formed only when the precipitate is thrown down in presence of excess of nickel-salt, as for instance, on mixing boiling solutions of 2 mol. nickel sulphate and 1 mol. potassium chromate. When, on the other hand, the chromate is in excess, precipitates containing less nickel are thrown down under otherwise similar conditions; with 2 mol. potassium chromate and 1 mol. nickel sulphate, Schmidt obtained the salt $5\text{NiO} \cdot 2\text{CrO}_3 + 12\text{H}_2\text{O}$, and with 4 mol. of the chromate to 1 mol. of nickel sulphate, the salt, $2\text{NiO} \cdot \text{CrO}_3 + 6\text{H}_2\text{O}$. No salt containing less nickel than the last was obtained; on the contrary, by employing 10 or 12 mol. potassium chromate to 1 mol. nickel sulphate, precipitates were thrown down, the composition of which lay between $5\text{NiO} \cdot 2\text{CrO}_3$ and $2\text{NiO} \cdot \text{CrO}_3$. When basic nickel chromate, still moist, is triturated to a thin pulp with ammonia, and gaseous ammonia is passed in till the brown colour completely disappears, *ammonio-nickel chromate* is deposited in the form of a yellowish-green crystalline powder. Further quantities of the same salt are obtained by placing a few crystals of neutral ammonium chromate in the mother-liquor. Large and well-formed prismatic crystals are produced when the ammoniacal solution is covered with a layer of alcohol; they are yellowish-green, dichroic by transmitted light, and undergo decomposition in the air, and more rapidly on warming, giving off ammonia. Malaguti and Sarzeau assign to this salt the formula $\text{NiO} \cdot \text{CrO}_3 \cdot 3\text{NH}_3 + 4\text{H}_2\text{O}$; but Schmidt found it to be anhydrous, and to have the composition expressed by the formula $\text{NiO} \cdot \text{CrO}_3 \cdot 3\text{NH}_3$.

Potassium salts.—The *dichromate* heated with 2 pts. of strong nitric acid forms a liquid which, on cooling, deposits splendid crimson tabular crystals containing nitric acid, and yielding by analysis 36.4 p.c. chromium, whence may be deduced the formula $\text{CrO}_2 \cdot \text{OK} \cdot \text{CrO}_3$, which requires 36.7 p.c. The salt, when heated, gives off red fumes and melts to a blackish-brown liquid. Its aqueous solution yields, on evaporation, not the original salt, but potassium dichromate. An excess of nitric acid appears to convert the salt into $\text{CrO}_2 \cdot \text{OK} \cdot 2\text{CrO}_3$ (Darmstädter, *Deut. Chem. Ges. Ber.* iv. 167).

The dichromate, heated with *phosphorous chloride* to 166° in a sealed tube, is decomposed, yielding potassium chlorochromate, brown oxide of chromium (chromic chromate), and other products (Michaelis, *Jenaische Zeitschrift*, vii. 110):

Potassium Chlorochromate, $\text{KCl} \cdot \text{CrO}_3$, may be obtained in long needles by dissolving the dichromate in three or four parts of warmed strong hydrochloric acid, and recrystallising the product from hot hydrochloric acid; it is partially decomposed by heat, and must be dried *in vacuo*. Dry pure ammonia gas produces with the dry compound, ammonium chloride and a salt crystallisable from hot water, and having

the formula $\text{CrO}_2 \cdot \text{OK}$; its reactions seem to be identical with those of ordinary chromates.

The corresponding *ammonium salt* $\text{CrO}_2 \cdot \text{ONH}_4$ is produced by passing ammonia gas into a solution of chromyl dichloride, CrO_2Cl_2 , in chloroform. It is a brown amorphous powder, difficultly soluble in water, insoluble in alcohol, ether, chloroform, and glacial acetic acid, but readily soluble in mineral acids, from which solutions it separates again as an amorphous powder.

Ether and dry ammonia gas transform potassium chlorochromate into *potassium anido-chromate* $\text{CrO}_2 \cdot \text{OK} \cdot \text{NH}_2$, crystallisable from water; cold caustic soda-solution does not decompose this body, but on boiling for some time, ammonia is given off in quantity; on heating it with water to 100° for some hours, the following reaction takes place:—

Similarly nitrous acid gives nitrogen, water, and potassium dichromate. Neither platinum chloride, mercury chloride, nor silver nitrate combines with it.

Together with the amidochromate, a body is formed giving numbers agreeing not very closely with the formula $\text{Cr}^2\text{O} \cdot \text{NH}^2$; it is a chocolate-coloured powder insoluble in water, alcohol, ether, chloroform, and carbon sulphide. Acids and alkalis dissolve it on prolonged heating, the latter with evolution of ammonia. The amount of this body formed is but small, but is increased by allowing the action of the ethereal ammonia to take place under a pressure of 1-2 decimeters of mercury J. Heintze, *J. pr. Chem.* [2] iv. 58, 211).

Potassium chlorochromate and potassium cyanide yield gaseous cyanogen chloride and potassium monochromate; with nitrogen tetroxide, the chlorochromate yields nitryl chloride NO^2Cl . The corresponding bromide NO^2Br is obtained by the action of nitrogen tetroxide on potassium bromochromate formed by dissolving potassium dichromate in bromine-water (Heintze).

Silver Chromates.—Two only of these salts appear to exist. The normal chromate, Ag^2CrO_4 , is always formed when solutions of potassium monochromate and silver-nitrate are mixed, though the appearance of the precipitate varies considerably according as one or the other salt is added in excess. In like manner solutions of potassium dichromate and silver nitrate always yield the pure dichromate of silver $\text{Ag}^2\text{Cr}_2\text{O}_7$, or $\text{Ag}_2\text{O} \cdot 2\text{CrO}_3$, whether the chromium solution is added in excess or in a mere trace. When silver oxide is heated for some time with solution of normal potassium chromate, the greyish black product, after washing with hot water, consists wholly of silver monochromate. Silver oxide treated in like manner, with solution of potassium dichromate yields pure silver dichromate (Freese).

On the action of Chromates on Ammonia salts. See AMMONIA (p. 61).

Chromium Oxychlorides.—Chromyl dichloride, CrO^2Cl_2 , is strongly attacked by phosphorous chloride, producing a hissing noise and emission of light.

The reaction is:

(Michaelis, *Jenaische Zeitschrift*, vii. 110).

Chromyl dichloride dissolves in glacial acetic acid, and in chloroform, and ammonia gas passed into the latter solution produces the ammonium salt CrO^2ONH^4 , already mentioned, (p. 335).

The chromium chromatochloride, or trichromyl dichloride, described by Thorpe, (1st Suppl. 456) may be regarded as the chloride analogous to this, and represented

by the formula CrO^2Cl (Heintze, *J. pr. Chem.* [2] iv. 211).

Zettnow (*Pogg. Ann.* cxliii. 328), by heating potassium chlorochromate with sulphuric acid has obtained—together with chromyl dichloride—a brown compound, which after distillation and drying over sulphuric acid, appears to be identical with Thorpe's compound.

Ammoniacal Chromium Compounds. P. T. Cleve (*Sill. Am. J.* [2] xlix. 251), has obtained the following ammonio-chromic compounds, in addition to those previously described (1st Suppl. 452):

$\text{Cr}^2\text{Cl}^2\text{Br}^2 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Chlorobromide.
$\text{Cr}^2\text{Br}^2 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Bromide.
$\text{Cr}^2\text{Br}^2\text{Cl}^2 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Bromochloride.
$\text{Cr}^2\text{Cl}^2\text{I}^2 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Chloriodide.
$\text{Cr}^2\text{I}^2 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Iodide.
$\text{Cr}^2\text{Br}^2\text{O}^2 \cdot 8\text{NH}^3 \cdot 2\text{SO}^2 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Bromosulphate.
$\text{Cr}^2\text{Cl}^2\text{O}^2 \cdot 8\text{NH}^3 \cdot 2\text{CrO}^2 \cdot \text{H}^2\text{O}$	Tetramine-chromic Chlorochromate.
$\text{Cr}^2\text{Cl}^2\text{O}^2 \cdot 8\text{NH}^3 \cdot 2\text{N}^2\text{O}^2 \cdot 2\text{H}^2\text{O}$	Tetramine-chromic Chloronitrate.

Of heptamine-dichromic compounds, only the two following double salts have been obtained:

Of salts of the triamine series, two also have been obtained, viz.

The salts of the heptamine and triamine series closely resemble the tetramine salts. The nitrate of the heptamine series is obtained by the action of silver nitrate on tetramine-chromic chloride; the oxalate of the triamine series by the action of oxalic acid on the same chloride.

Besides these three series, Cleve describes the following salts:

but it is doubtful whether they have been obtained in the pure state, inasmuch as they could not be made to crystallise.

CHROMO-WULFENITES. See WULFENITES.

CHRYSAMMIC ACID, $\text{C}^4\text{H}^2\text{N}^2\text{O}^8$, or $\text{C}^4\text{H}^2\text{N}^2\text{O}^{12} = \text{C}^4\text{H}^2(\text{NO}^2)_2(\text{HO})_2\text{O}^2$. Tetranitro-dioxyanthraquinone (1st Suppl. 457). Tilden (*Pharm. J. Trans.* [3] ii. 845) prepares this acid by the action of cold fuming nitric acid on barbaloin, the aloin obtained from Barbadoes aloes, (p. 52). The product is a mixture of aloetic, chrysammic, oxalic and picric acids, the two latter of which are easily dissolved out by cold water, the aloetic and chrysammic acids remaining undissolved. The aloetic acid is finally converted into chrysammic acid by prolonged boiling with nitric acid, and the crystalline precipitate of chrysammic acid, after purification by washing with water, is converted into the potassium salt, which is further purified by recrystallisation. Barbaloin thus treated yields more than one-third of its weight of pure potassium chrysammate.

The acid is obtained by dissolving the potassium salt in boiling water, and strongly acidifying the liquid with acetic acid. It crystallises in thin, yellow, fern-shaped crystals, somewhat resembling picric acid, but more lustrous.

The chrysammates of lead and barium have been described by Schunck and Mulder as red powders, the former containing variable proportions of lead. They may, however, be obtained in a crystalline and perfectly definite state by mixing a solution of the potassium salt with solution of lead or barium acetate acidified with acetic acid. The crystals of the lead salt exhibit a magnificent bronze reflection and strongly polarize transmitted light. The analysis of these salts leads to the formulæ $\text{C}^4\text{H}^2\text{Pb}(\text{NO}^2)_2\text{O}^4 + 4\text{H}^2\text{O}$ and $\text{C}^4\text{H}^2\text{Ba}(\text{NO}^2)_2\text{O}^4 + 4\text{H}^2\text{O}$.

If chrysammic acid has the constitution of tetranitro-dioxyanthraquinone, the substance hitherto called *chrysamide*, which is produced by the action of ammonia on chrysammic acid (i. 955), may be regarded as the ammonium salt of a monobasic acid $\text{C}^4\text{H}^2(\text{NO}^2)_2(\text{O}^2)^- \left\{ \begin{smallmatrix} \text{NH}^3 \\ \text{OH} \end{smallmatrix} \right.$, which may be called *chrysamidic acid** (tetranitramido-oxyanthraquinone).

The so-called chrysamide is formed according to the equation:

Chrysammic acid.

Ammonium Chrysamidate.

When dry ammonia gas is passed over chrysammic acid, 4.4 p. c. water is given off, according to Mulder; the equation just given requires 4.3 p. c. Strong acids convert the so-called chrysamide into chrysammic acid, whereas by treating it with dilute acids, a body is formed containing more nitrogen than chrysammic acid, evidently free chrysamidic acid (Graebe & Liebermann, *Zeitschr. f. Chem.* [2] vi. 262).

Hydrochrysamide (iii. 191), obtained by reduction of chrysammic acid, was regarded by Schunck as $\text{C}^4\text{H}^3\text{N}^2\text{O}^4$, or rather $\text{C}^4\text{H}^{11}\text{N}^2\text{O}^4$. But from his analyses and from the reactions of this body, it appears rather to consist of $\text{C}^4\text{H}^{10}\text{N}^2\text{O}^4$, that is to say of *triamido-nitro-dioxyanthraquinone* $\text{C}^4\text{H}^3(\text{NH}^2)_2(\text{NO}^2)(\text{O}^2)^-(\text{OH})^+$. The colourless body formed from chrysamide by further reduction will accordingly be *triamido-nitro-tetraoxyanthracene* $\text{C}^4\text{H}^3(\text{NH}^2)_2(\text{NO}^2)(\text{OH})^+$; it is reconverted into hydrochrysamide by oxidation in the air (Graebe & Liebermann).

CHRYSANISIC ACID, $\text{C}^4\text{H}^3\text{N}^2\text{O}^4$. Cahours, who first obtained this body by treating nitranisic acid† with fuming nitric acid, and exhausting the product with ammonia in order to separate it from simultaneously formed di- and trinitroanisol,

* Not the same as Schunck's chrysamidic acid (i. 955).

† In the translation of Cahours' paper in *Lieber's Annalen* it is said that Cahours used 'anilic acid,' and the same mistake occurs in *Gmelin's Handbook*, and in the first volume of this Dictionary (p. 267); but Salkowski finds that only nitranisic acid can be converted into chrysanisic acid, and that anilic acid does not yield a trace.

assigned to it the formula, C^6H^5NO , and regarded it as methylated picric acid. Beilstein and Kellner found afterwards that the true formula of this acid is $C^6H^5NO_2$ (1st Suppl. 458), but their researches do not give any clue to its constitution.

The recent researches of H. Salkowski (*Ann. Ch. Pharm.* clxiii. 1) have shown, however, that it has the constitution of dinitro-amido-benzoic acid $C^6H^2(NO_2)_2(NH^2).COOH$. This appears from the following reactions:—

(1). By reduction with tin and hydrochloric acid it is converted into triamido-benzoic acid, $C^6H^2(NH^2)_3CO^2H$, which by the action of heat is resolved into carbon dioxide and triamidobenzene, $C^6H^2(NH^2)_3$.

(2). By heating chrysanisic acid with fuming hydrochloric acid, it is converted into trichlorobenzoic acid, $C^6H^2Cl^3.CO^2H$.

(3). By the action of nitrous acid, a dinitro-oxybenzoic acid, $C^6H^2(NO_2)_2(OH)CO^2H$, is obtained; and the same transformation is effected by the action of caustic alkalis.

Chrysanisic acid is not a direct product of the action of nitric acid upon nitranisic acid; it is formed by the action of ammonia on the crude product of the reaction which contains dinitranisic acid, as may be shown by exhausting this crude product with solution of sodium carbonate, precipitating with hydrochloric acid, and recrystallising from alcohol, whereby dinitranisic acid is obtained in pale yellow crystals melting at $171^\circ-173^\circ$. This acid dissolves without decomposition in dilute aqueous ammonia, but when boiled for a few minutes with strong ammonia, it is completely converted into chrysanisic acid:

Chrysanisic is therefore *dinitro-para-amido-benzoic acid*, inasmuch as anisic acid is methyl-para-oxybenzoic acid.

Pure chrysanisic acid, prepared according to Cahours' method, melts at 259° , and not, as Cahours states, at a gentle heat. It crystallises from alcohol in small shining rhombic plates, and from hot water in hair-like fasciculated needles. It is very slightly soluble in cold water, but insoluble in dilute acids.

By adding a small quantity of chrysanisic acid, or of one of its salts, to an alcoholic potash solution, an almost black colour is produced, which disappears on standing and quickly on addition of water. This reaction may be used for the detection of the acid; the dark compound formed is perhaps $C^6H^2(NO_2)_2NHK.CO^2K$.

Methyl chrysanisate is obtained by heating the silver salt with methyl iodide; it crystallises from alcohol in small plates, melting at 144° , and having a metallic-golden lustre.

Dinitro-amidosalylic, Dinitro-anthranilic, or more shortly *Chrysalylic acid*, the ortho-isomeride of chrysanisic acid, is produced by the following series of reactions:—

Gaultheria oil treated with a mixture of nitric and sulphuric acids yields methyl dinitrosalyicylate $C^6H^2(NO_2)_2.OH.CO^2OCH^3$; the ammonium salt of this compound mixed with silver nitrate yields the silver salt $C^6H^2(NO_2)_2.OAg.CO^2CH^3$; and by treating this salt with ethyl iodide, the ether $C^6H^2(NO_2)_2.OC^2H^5.CO^2CH^3$, is obtained in well-defined monoclinic crystals melting at 80° .

This ether treated with hot ammonia forms a yellow-red solution, together with a solid yellow mass, which, when recrystallised from boiling alcohol, is converted into yellow laminae melting at 165° . The yellow-red solution contains the ammonium salt of dinitro-amido-salylic acid $C^6H^2(NO_2)_2.NH^2.CO^2H$, which may be precipitated from it by acids, while the yellow laminae consist of its methyle ether, $C^6H^2(NO_2)_2.NH^2.CO^2CH^3$; the latter may be obtained as sole product of the reaction by using alcoholic instead of aqueous ammonia.

Dinitroamidosalicylic acid is converted into dinitrosalyicylic acid, with evolution of ammonia, by boiling with soda. Its ethylic ether melts at 135° , the methyle ether at 165° . It bears a great resemblance to its isomeride, chrysanisic acid, and has almost the same melting point (256°), but the methyl and ethyl derivatives melt at about 21° higher than the corresponding chrysanisic derivatives (114° and 144°). Again, the ammonium salt contains one molecule of water, driven off at 100° , whereas that of chrysanisic acid is anhydrous (Salkowski, *Deut. Chem. Ges. Ber.* iv. 870).

CHRYSENE, $C^{18}H^{12}$ (Liebemann, *Ann. Chem. Pharm.* clviii. 209). This hydrocarbon was discovered by Laurent in crude anthracene (i. 958), and further examined by Berthelot, who has produced it synthetically from benzene (1st Suppl. 459). It may be extracted from the mixture of solid hydrocarbons which have a higher boiling point than anthracene, and form the latter portion of the distillate from coal-tar by

treating this mixture with successive quantities of cold carbon sulphide, which dissolves the pyrene and similar hydrocarbons, leaving 18 to 19 per cent. of a yellow powder melting at 240° . By crystallising this powder from coal-oil (boiling at 150°) the chrysene is obtained in bright yellow glistening scales, from which the colour cannot be completely removed, even by repeated crystallisation from ether, or by the insolation of its solutions. It is however obtained colourless by heating the yellow crystals with hydriodic acid and amorphous phosphorus to 240° ; also by boiling them with alcohol and a small quantity of nitric acid. It cannot be sublimed without decomposition, and when submitted to distillation in a current of gas, its melting point is lowered sometimes as much as 10° .

Chrysene is very slightly soluble in cold alcohol, ether, benzene, and glacial acetic acid, but somewhat more soluble in carbon bisulphide. It is moderately soluble in coal-oil of high boiling point when hot, and in boiling glacial acetic acid, from both of which it separates in the crystalline state on cooling. It melts at 248° – 250° , and its boiling point lies above the range of the mercurial thermometer. The yellow chrysene dissolves in a large quantity of hot sulphuric acid, with a dirty violet colour, forming sulpho-acids, whilst colourless chrysene forms a pure blue solution. Chlorine acts upon it very little in the cold, but on heating, a substance is formed which sublimes in white needles with partial decomposition. It forms a *picrate*, $C^{18}H^{12}.C^6H^2(NO_2)^3O.H$, crystallising in orange coloured needles, which are decomposed by the action of cold alcohol, being converted into pseudomorphs of chrysene.

By oxidation with chromic acid it is converted into chrysoquinone $C^{18}H^{10}O^2$, and by prolonged action into phthalic acid.

Bromochrysenes. On adding bromine to chrysene suspended in carbon sulphide, hydrobromic acid is evolved, and a substance is obtained which crystallises from benzene in colourless needles, and appears by analysis to be a mixture of di- and tri-bromochrysene.

Decachlorochrysene, $C^{18}H^2Cl^{10}$, is formed by heating chrysoquinone (*infra*) for twelve hours with a large excess of phosphorus pentachloride; it is a yellowish uncrystallisable substance soluble in carbon sulphide.

Nitrochrysenes.—*Mononitrochrysene*, $C^{18}H^{11}NO^2$, is produced by boiling yellow chrysene with alcohol and a little nitric acid of sp. gr. 1.4. The solution slowly acquires an orange colour from formation of nitrochrysene; and if, after 24 hours' digestion, it be separated from unaltered chrysene, concentrated by distillation, and allowed to cool, then filtered and mixed with water, an orange-red precipitate of nitrochrysene is formed, which may be purified by crystallisation from boiling alcohol. The chrysene remaining undissolved in the above operation is much less readily acted upon by nitric acid than before, and when boiled with potash and recrystallised, yields colourless chrysene.

Tetranitro-chrysene, $C^{18}H^5(NO_2)^4$.—On dissolving chrysene in fuming nitric acid in the cold, and adding water after some hours, this substance is precipitated as a yellow, difficultly soluble powder. By treatment with chromic acid it is in great part destroyed, and when heated to 170° with nitric acid, it forms a volatile acid containing nitrogen.

Chrysoquinone, $C^{18}H^{10}(O^2)^2$. On oxidising crystallised chrysene suspended in glacial acetic by the careful addition of one and a half times its weight of chromic acid, and finally heating to boiling to complete the reaction, a solution is obtained from which the quinone may be precipitated by addition of water, as an orange-red powder. To purify this substance, it is dissolved in concentrated sulphuric acid, filtered through asbestos to separate unaltered chrysene, and precipitated by water; repeated crystallisation from benzene renders it quite pure. It is moderately soluble in hot alcohol, benzene, and glacial acetic acid, and crystallises from the former in long rhombic plates. It is but slightly soluble in ether and carbon sulphide, melts at about 220° , and when more strongly heated, sublimes with partial decomposition. It dissolves in cold concentrated sulphuric acid with a fine pure blue colour, and is precipitated unchanged by the addition of water. The production of this blue colour affords a very characteristic test for chrysene. If a mixture of solid hydrocarbons, on oxidation with chromic acid, and subsequent treatment with sulphuric acid, gives the blue reaction, the presence of chrysene may be safely inferred. The quinone of idrialin heated in the same manner gives a red-brown colour. Chrysoquinone yields phthalic acid when treated with potassium permanganate, or subjected to the prolonged action of chromic acid. When it is heated with zinc-powder, chrysene is regenerated.

Dichlorochrysoquinone, $C^{18}H^8Cl^2O^2$.—When 1 mol. of chrysene is heated for a short time to 200° with 2 mols. of phosphoric chloride and an excess of phosphorus oxychloride, a green uncrystallisable substance is formed, which is soluble in carbon

sulphide and phosphorus oxychloride, but almost insoluble in alcohol, ether, and benzene. The contents of the tubes, when gradually added to alcohol, give a bright yellow flocculent precipitate of dichlorochrysoquinone.

Tetranitrochrysoquinone, $C^{14}H^2(NO^2)_4O^2$.—Chrysoquinone dissolves in cold concentrated nitric acid, and after it has been allowed to stand for some hours, water precipitates tetranitrochrysoquinone as an orange-yellow powder, which is but little soluble in most solvents. It deflagrates slightly when heated.

Chrysohydroquinone, $C^{14}H^{10}(OH)^2$.—Chrysoquinone boiled with zinc-powder and caustic potash-solution, dissolves to a yellow liquid, from which acids precipitate colourless flocks of chrysohydroquinone, which can be easily reoxidised to the quinone. This change takes place when the hydroquinone is heated to 200° with access of air, or when it is dissolved in concentrated sulphuric acid and agitated with air, the solution then acquiring the characteristic blue colour of chrysoquinone.

Constitution of Chrysene.—The properties of the derivatives of chrysene, and its conversion into phthalic acid by oxidation, clearly show that it is a member of the naphthalene-anthracene series; and, moreover, the absence of any fatty group is rendered manifest by the formation of the quinone and its reversion into chrysene. Strecker (*Lehrbuch der Organ. Chemie*, 762) has pointed out that its constitution is probably analogous to that of naphthalene and anthracene, and if the substance prepared synthetically from benzene by Berthelot be identical with chrysene, the structure of this hydrocarbon may be represented by the following formula, which indicates that it is formed by the union of three benzene molecules, with elimination of hydrogen:—

CHRYSOCOLLA. Cupric Silicate.—This mineral appears to occur on a gneissoid gangue in South Africa, rich in Muscovite and quartz, as a blue layer in botryoidal forms, and carrying here and there a green incrustation. The blue mineral appears also in some places in fibres, apparently crystals, generally mixed with smaller blue crystals. Its analysis gave:

SiO^2 (soluble)	As^2O^3	P^2O^5	SO^3	CO^2	CuO	Fe^2O^3	Al^2O^3	Gangue	Water
18.82	9.79	11.75	3.45	1.00	32.15	4.36	2.27	10.92	6.41 = 99.92.

It is probably chrysocolla mixed with two minerals, one belonging to the trochantite group, probably langite, the other a cupric arsenophosphate (Maskelyne & Flight, *Chem. Soc. J.* [2] x. 1052).

CHRYSOPHANIC ACID and CHRYSOPHANINE. These compounds are contained, according to Bourgoin, in crude cathartin from senna (p. 270).

Chrysophanic acid is reduced by zinc-dust to anthracene. Whether its formula is $C^{14}H^{10}O^4$ or $C^{14}H^8O^4$ is not yet decided. The formula $C^{14}H^{10}O^4$ is in accordance with the analyses both old and new of chrysophanic acid itself; the formula $C^{14}H^8O^4$, on the other hand, is supported by De La Rue and Müller's analyses of diacetyl-chrysophanic acid (*1st Suppl.* 460) and by Palz's analysis of diacetyl-chrysophanic acid. If the formula $C^{14}H^{10}O^4$ should be corroborated by further investigations, it will, perhaps, be better to interpret this formula as dioxanthraquinone-dihydrate $C^{14}H^8(O^2)(OH)^2.H^2$, rather than as tetraoxyanthracene $C^{14}H^8(OH)^4$: first, because chrysophanic acid contains only 2 atoms of hydrogen replaceable by acid radicals; secondly, because, it is an acid of quinonic character, and is converted by reducing agents—e.g. by treating its solution in alkalis with sodium-amalgam—into a colourless substance which again

becomes oxidised and coloured on exposure to the air (Graebe u. Liebermann, *Zeitschr. f. Chem.* [2] vi. 261).

CIMBEX. The larvæ of *Cimbex variabilis* (living on the leaves of *Alnus incana*) have on both sides of their bodies a series of orifices, from which, on being touched, they squirt a green fluid, which is tasteless and inodorous, has an alkaline reaction, and consists of a moderately concentrated solution of a proteid having great resemblance to albumin.

The nature of the colouring matter (perhaps chlorophyll) has not been ascertained; alkalis change the colour into a yellowish green. The fluid from the larvæ of two other species of cimbex feeding on birch leaves, gave the same results (A. J. von Rossum, *Zeitschr. f. Chem.* [2] vii. 423).

CIMICIFUGA. The active principle of Black Snake-root (*Cimicifuga racemosa*) appears to be a neutral, crystallisable body. The fresh root bruised and treated with alcohol produces a tincture which, after the separation of the resin, tannin, &c., by acetate of lead, leaves, on spontaneous evaporation, a powder which may be purified from fatty matter by benzene. The powder freed from the odour of benzene, washed with water, dried, dissolved in alcohol, mixed with pure alumina, and evaporated spontaneously, yields a light dry mass. This mass exhausted with hot alcohol affords a solution which, on evaporation, leaves a crystalline substance having a light yellow colour, and presenting under the microscope an appearance similar to that of rock-candy. The crystals are slightly soluble in ether, more so in alcohol and chloroform, but quite insoluble in benzene, turpentine-oil, and bisulphide of carbon. This substance does not possess the character either of an acid or an alkalioid. It has little taste, on account of its extreme insolubility in the liquids of the mouth, but its solution in alcohol has the intensely acrid and sharp taste which characterises recent cimicifuga (T. B. Courard, *Pharm. J. Trans.* [3] i. 866).

CINCHONA BARKS (O. Hesse, *Deut. Chem. Ges. Ber.* iv. 818).—To distinguish between genuine and false cinchona barks, Grahe heats a small piece in a test-tube which is held horizontally; the genuine barks yield a carmine-red tar, but the false barks do not (1st *Suppl.* 461). Batka has shown that this red product is always formed when a cinchona base is heated with cellulose, and this test is therefore very well adapted to prove the existence of alkalioids in the bark; but it cannot be used as a means of distinguishing between genuine and false barks, because there exist genuine barks containing no bases, and false barks in which alkalioids are present. Thus a genuine bark in Hesse's collection (probably from *Cinchona pubescens*) does not contain a trace of any alkalioid, whilst a false bark, which was formerly often found amongst the 'soft bark' (*Cinchona lancifolia* var. *obovata*), and is now found in larger quantities in the market, gives the above reaction, because it contains cinchona bases.

This bark, which Flückiger calls *China cuprea*, has a fine red colour, and gives with ammonia a purple solution, which imparts to filter-paper a fine pink colour after exposure to the air. Nitric and sulphuric acids produce in this solution an amorphous reddish brown precipitate. On filtering, a yellow solution is obtained, which, on adding ammonia, assumes a violet colour, and, after some time, purple amorphous flakes separate out, no doubt a product of decomposition of the tannic acid of the bark. This tannic acid is different from that contained in genuine barks and in *China nova*, as it gives an intense green coloration with ferric chloride. Milk of lime gives, with the bark, a deep yellowish red solution, from which, on exposure to the air, a red lime-compound (cinchona-red lime?) separates. On adding an excess of acetic acid to the filtrate, a gelatinous precipitate is obtained, which cannot be distinguished from that which the genuine barks give under the same circumstances. On filtering from this precipitate and adding basic lead acetate, a copious precipitate of basic lead quinate is formed. The following percentages of bases are contained in this bark:—

	1.	2.	3.	4.
Quinine	1.33	1.28	1.20	1.26
Cinchinine (?)	—	—	0.46	0.28
Cinchonine	—	—	0.22	0.24
Amorphous bases	—	—	0.37	0.37

The amorphous bases in this bark gave the same reactions as quinine; quinidine and quinidine were not found in it.

Flückiger (*Chem. Centr.* 1872, 152) further points out that *paytine*, a crystallisable alkalioid differing from cinchonine only by the addition of one atom of carbon, is obtained from a so-called false bark, *Quina blanca*.

Distribution of Alkalioids in Cinchona barks.—An examination of several species of

cinchona bark by P. Carles (*Pharm. J. Trans.* [3] iv. 643) has led to the conclusion that quinine exists in all parts of the bark, but in a much larger proportion in the external or cortical layers than in the internal or liber layers: in the intermediate layers the proportion diminishes pretty regularly from the exterior to the interior. The seat of the cinchonine has not been so clearly established; it appears, however, in most species, to be more abundant in the outer than in the inner layers.

CINCHONA BASES. Separation and Estimation.—J. E. de Vrij (*Pharm. J. Trans.* [3] ii. 624) has given a process for this purpose, based upon the following facts:—

1. The great solubility of quinine and amorphous alkaloid in ether, and the relative insolubility of quinidine, cinchonine, and cinchonidine in this liquid.

2. The great solubility of the iodosulphate of amorphous alkaloid in alcohol, and the very slight solubility of the iodosulphate of quinine (herapathite) in the same.

3. The difference of solubility in water between the tartrate of cinchonidine and the tartrates of cinchonine and quinidine.

4. The difference in solubility between the hydriodide of quinidine and the hydriodide of cinchonine in water and alcohol.

The application of these facts to the determination of the respective cinchona alkaloids is conducted in the following manner:—

5 grams at least of the pulverised mixed alkaloids are digested with 50 grams of ether, and filtered, whereby the alkaloids are separated into two groups.

A. Part soluble in Ether.—The ether is evaporated, the residue dissolved in 10 parts of proof spirit acidulated with one-twentieth of sulphuric acid, and alcoholic iodine added until a precipitate is no longer formed. The quinine is thus precipitated as herapathite. One part of herapathite washed, and dried at 100°, represents 0.565 parts of pure quinine. The liquid separated from the herapathite is mixed with an alcoholic solution of sulphurous acid, then neutralised with caustic soda, heated on a water-bath to expel alcohol, and mixed with an excess of soda. The precipitate consists of amorphous alkaloid, with, perhaps, traces of quinidine and cinchonidine.

B. Part insoluble in Ether.—The insoluble alkaloids are dissolved in 40 parts of hot water with the aid of a little dilute sulphuric acid, the acid being so adjusted that the solution shall preserve a faint alkaline reaction. To this liquid a solution of Rochelle salt is added, and the whole allowed to remain for twelve hours. The cinchonidine will be found separated as tartrate, which may be collected and dried at 100°. One part of this tartrate represents 0.804 parts of cinchonidine. The filtrate is mixed with a solution of potassium iodide, which precipitates the quinidine as a sandy crystalline powder, provided that the quinidine be not very small in quantity relatively to the cinchonine; otherwise the precipitate is often resinous. One part of the hydriodide dried at 100° represents 0.718 parts of anhydrous quinidine.

The liquid separated from the quinidine is precipitated by caustic soda, whereby the cinchonine is obtained; it is collected and dried as in the previous instances.

The substance designated as 'amorphous alkaloid' is the dextrogyrate base soluble in ether, probably identical with Pasteur's quinine.

On the application of Molecular Rotation to the Estimation of Cinchona bases, see de Vrij (*Pharm. J. Trans.* [3] ii. 1; *Chem. Soc. J.* [2] ix. 857).

Periodides of the Cinchona Bases (Jørgensen, *J. pr. Chem.* [2] iii. 146).

The tri-iodide of methylquinine, $C^{20}H^{24}N^2O^2.CH^3I^3$, is obtained by adding a solution of 2 atoms of iodine in alcohol to a hot alcoholic solution of the hydriodide of methylquinine. By slow cooling of the liquid the tri-iodide is formed in beautiful black needles, having an adamantine lustre and melting at 159–160°. This body is moderately soluble in alcohol; the brown solution is decolorised by sulphurous acid, sulphuretted hydrogen, and mercury. The tri-iodide, boiled with a large quantity of water, gradually loses the 2 atoms of iodine, and is reduced to methylquinine hydriodide. It does not appear to be decomposed by boiling with strong aqueous ammonia or by cold caustic soda-solution, but it is easily and completely decomposed by solution of silver nitrate.

The following periodides are prepared by corresponding processes and exhibit similar properties:—

Tri-iodide of:

		Melting point.
Ethyl-cinchino . . .	$C^{20}H^{24}N^2O^2.C^2H^5I^3$, like the last . . .	150–151°
Cinchonine . . .	$C^{20}H^{24}N^2O.H.I^3 + aq.$ brown rhombic tables . . .	80–82°
Methyl-cinchonine . . .	$C^{20}H^{24}N^2O.CH^3.I^3$ brown adamantine laminae . . .	161–162°
Ethyl-cinchonine . . .	$C^{20}H^{24}N^2O.C^2H^5.I^3$ dark brown prisms . . .	141–142°
Methyl-quinidine . . .	$C^{20}H^{24}N^2O^2.CH^3.I^3$ brown adamantine laminae . . .	164–165°
Methyl-cinchonidine . . .	$C^{20}H^{24}N^2O.C^2H^5.I^3$ brown hemispherical groups . . .	

Quinine and Cinchonine. *Optical properties.* The specific rotatory power of pure quinine in alcoholic solution is for the yellow ray:

$$\begin{aligned} a_f &= -165.79 \text{ at } 15^\circ \\ &= -162.46 \text{ at } 25^\circ. \end{aligned}$$

Thus the sulphate gives for the yellow ray the values—

$a_y = -191.47$ in alcoholic solution
 $a_y = -228.78$ dissolved in 6 molecules of H_2SO_4 diluted till $SO_3 = 4$ per cent. of the volume:

$\alpha_y = -220.43$ in alcoholic solution,
 $\alpha_x = -264.66$ in excess of sulphuric acid.

$a_v = -264.30$ in alcoholic solution,

With excess of acid, the mono-acid sulphate gives higher values--

With 1 molecule SO_3 , α_{y} for contained quinine = - 277.23
 " 3 " " = - 280.77

$$\alpha_{\gamma} = -287.62.$$

Crystallised $\text{C}^{20}\text{H}^{21}\text{N}^2\text{O}^2 \cdot 2\text{HCl} + 2\text{H}_2\text{O}$, dissolved in alcohol gave—

in water with large excess of acid $a_y = -166.41$,
 $a_x = -247.39$.

In alcoholic solution	$\alpha_f =$	226.48
Neutral sulphate in alcoholic solution		244.12
" with 1 mol. free acid		261.40
" " 6		255.86
Hydrochloride in alcoholic solution		203.68
" in strong acid aqueous solution		233.12

Reactions.—The green coloration produced by *chlorine* and *ammonia* in quinine solutions, is capable of indicating the presence of 1 part of quinine in 4,000 to 8,000 parts of liquid.

Bromine vapour, with subsequent addition of ammonia, also produces a green colour, which is perceptible when the solution contains only $\frac{1}{10,000}$ of quinine.

Vogel's red reaction, obtained by the successive addition of *chlorine, red, or yellow prussiate of potash, and ammonia*, is less delicate, being capable of indicating only about 1 part in 2,500.

Pure quinine hydrochloride dissolves in dilute nitric acid without any marked change of colour, but if it is mixed with 5 p. c. of morphine hydrochloride, an orange-tint is produced; 1 p. c. gives a dark yellow colour, whilst 0.2 p. c. produces a marked change in the tint produced. The acid should contain 20 p. c. HNO_3 by volume (Hosue, *Ann. Ch. Pharm.* cxlvi. 217).

When cinchonine sulphate is heated in sealed tubes with concentrated hydrochloric acid for some hours to 140°-150°, the contents of the tubes yield crystals not unlike those of cinchonine sulphate, but differing therefrom essentially in their insol-

bility in acids. After one recrystallisation these crystals do not contain a trace of sulphuric acid; their solution is strongly acid, but is no longer fluorescent. They are anhydrous, and contain 3 atoms of chlorine, two of which are readily and completely removed by silver nitrate, the third with difficulty. The mother-liquor from these crystals yields, on further evaporation, a second crop of different aspect, but also free from sulphuric acid.

Quinine sulphate similarly treated gives crystals, which also do not contain any sulphuric acid; they yield a strongly acid solution, which is non-fluorescent, and coloured only very slightly green on addition of chlorine water and ammonia. Potassium ferrocyanide produces a yellow precipitate, insoluble in excess, but soluble on boiling. The base thus formed is precipitated by ammonia, and is readily soluble in ether, also in excess of ammonia and in boiling water. In its behaviour with ammonia and chlorine-water, and with ferrocyanide, it resembles cinchonine; like quinine, it is readily soluble in ether, but differs from both by its solubility in ammonia and in boiling water.

Action of Quinine in arresting Molecular Movements and Organic Decomposition.—The active movements in water of fine particles of Indian ink, pure charcoal, finely ground cinnabar, ground parts of plants, fine earth, or, best of all, of the pigment granules of the choroid, observed to go on for days together, are rapidly arrested by a neutral solution of quinine, and the particles are thus caused to subside. A neutral or slightly basic solution of quinine, even in very small quantities, is nearly as powerful in causing this phenomenon of subsidence as alum, more powerful than alum neutralised with sodium carbonate, and still more so than the other officinal salts of the alkaloids. Slight alkaliescence retards the process. It has but little influence over the movements of powdered gamboge.

Quinine also possesses in a remarkable degree the property of preventing the occurrence of certain forms of decomposition. It materially retards the conversion of cane-sugar into glucose, and checks the acid fermentation of flour. The effect of quinine salts, however, in checking acid fermentation does not appear to be due to any peculiar property of the quinine, but to the fact that its neutral salts give off acid. Sulphate of quinine checks the process, but not to a materially greater extent than the corresponding potassium and sodium salts. On the other hand, quinine hydrochloride, like potassium or sodium chloride, rather hastens the process.

Quinine has no effect upon the saccharifying action of saliva; but it energetically checks putrefaction, alcoholic fermentation, and the formation of lactic and butyric acids by the fermentation of sugar.

According to von Boeck, the lessened rate of destruction of albumin in the living body caused by quinine must be ascribed to its direct influence upon (vegetative) cells. The contents of the red blood-corpuscles appear to be influenced by quinine in a similar manner. Quinine is also a muscle-poison (C. Binz, *N. Rep. Pharm.* xxi. 407).

On the Influence of Quinine on Oxidation in the Blood, see BLOOD (p. 197).

Oxidation and Denitrogenation.—Cinchonine yields by oxidation two compounds containing nitrogen, one of which is an acid, crystallisable, and capable of forming beautifully crystallised salts. This acid treated with nascent hydrogen gives up its nitrogen and becomes changed into another strong tribasic acid, free from nitrogen, crystallisable, and very like certain plant-acids in its general properties. The second compound formed by the oxidation of cinchonine is also crystallisable, but it has not been much examined.

These compounds are different from all the oxidation-products of cinchonine hitherto described. From their composition it seems to follow that cinchonine $C^{20}H^{21}N^2O$, is composed of two atomic groups, one containing C^{11} the other C^9 ; and that the acid whose nitrogen is removable is derived from the C^{11} group, the other from the C^9 group,—which also contains the same number of carbon-atoms as chinoline (H. Weidel, *Deut. Chem. Ges. Ber.* vi. 555).

When quinine is distilled with zinc and zinc-sodium, a distillate is obtained which is free from nitrogen, and smells like cumin oil, while sodium cyanide is found in the residue. Similar results are obtained with cinchonine (J. Boeko, *ibid.* 488).

Hydrobromides of Quinine and Cinchonine. Neutral Quinine Hydrobromide, $C^{20}H^{21}N^2O \cdot 2HBr + 3H^2O$, is obtained by mixing 10 parts of quinine sulphate with 50 parts alcohol (85 p. c.), adding the mixture, after warming, to a solution of 8 parts potassium bromide, 20 parts water, and 10 parts dilute sulphuric acid (1 mol: 100), heating the whole to boiling, filtering after a few minutes, and then evaporating a little. Part of the salt then crystallises on cooling and the rest may be obtained by leaving the solution to evaporate. It forms white, opaque or translucent nacreous crystals, very soluble in water, and in alcohol, and having an acid reaction. A basic salt is obtained by using 5 parts potassium bromide and 5 parts dilute

sulphuric acid (1 : 100) to 10 parts quinine sulphate. It is likewise formed from the neutral salt by dissolving 1 part of the latter in 10 parts of dilute alcohol (equal volumes of alcohol and water), mixing the warmed solution with ammonia to slight alkaline reaction, and then with a solution of $\frac{1}{2}$ part of the neutral salt. On heating the liquid to boiling and leaving it to cool, the basic salt separates in radiate groups of crystals having the lustre of asbestos. It is very soluble in alcohol, less soluble in water: the solution is alkaline.

Neutral Cinchonine Hydrobromide, $C^{20}H^{21}N^2O \cdot 2HBr$, may be prepared by double decomposition, better however, by the method described for the quinine salt (10 parts basic cinchonine sulphate, 50 parts alcohol, 8 parts potassium bromide, 10 parts water, and 20 parts dilute sulphuric acid); a small quantity of basic salt which forms at the same time, must be removed by filtration. The neutral hydrobromide forms rhombohedral crystals, very soluble in water and in alcohol, but less so than the quinine salt; it has an acid reaction. A *basic cinchonine hydrobromide* is prepared in the same manner as the corresponding quinine salt. The evaporated alcoholic solution is mixed with a little water, and the salt which separates is crystallised from hot water. Or $\frac{1}{2}$ of a solution of the neutral salt is neutralised with ammonia, and the remaining third then added. The basic hydrobromide forms long shining needles which dissolve easily in alcohol, and have an acid reaction.

Solubility of Cinchonine in Alcohol and Chloroform.—According to Oudemans (*Zeitschr. anal. Chem.* xi. 287) cinchonine is much less soluble in pure alcohol and pure chloroform than in mixtures of the two. At 17° a mixture of 4 parts alcohol and 1 part chloroform takes up a maximum quantity, which is seven times as large as that taken up by absolute alcohol, and twenty times as large as that dissolved by pure chloroform.

• *Quinine Sulphates*. *Normal quinine sulphate* crystallises from water with $7\frac{1}{2}H^2O$; probably, however, it contains $8H^2O$, but is very efflorescent; from alcohol it crystallises with only $2H^2O$.

Mono-acid quinine sulphate contains $C^{20}H^{21}N^2O^2 \cdot H^2SO^4 + 7H^2O$. Six-sevenths of the water of crystallisation is given off in the exsiccator; the last seventh at 100° – 115° ; the salt dissolves in 11 parts of water at 13° , and is less soluble in alcohol. The *di-acid sulphate* contains $C^{20}H^{21}N^2O^2 \cdot 2H^2SO^4 + 7H^2O$ (Hesse. *Ann. Ch. Pharm.* clxvi. 217).

Cinchonidine. For the optical rotatory power of this base, Hesse finds the following values:

- $\alpha_D = -112.49$ for the base dissolved in alcohol,
 -178.47 for that contained in the sulphate dissolved in alcohol.

The presence of free sulphuric acid slightly diminishes the rotation.

For the hydrochloride:

- $\alpha_D = -162$ in alcoholic solution,
 $= -169.29$ with excess of acid.

The *hydrochloride* crystallises in monoclinic double pyramids containing 1 mol. water; this form is not exhibited by the hydrochloride of any other cinchona alkaloid. By evaporation of the solution at a moderate heat, or by crystallisation from a very concentrated solution, asbestos-like crystals of a dihydrate, $C^{20}H^{21}N^2O \cdot HCl + 2H^2O$, are obtained; but these, when left for a considerable time in the mother-liquor, gradually disappear, and the solution afterwards deposits the more compact crystals of the monohydrate.

Cinchonidine sulphate crystallised from alcohol has the composition $2C^{20}H^{21}N^2O \cdot H^2SO^4 + 2H^2O$.

Quinidine or Conchinine (Hesse), $C^{20}H^{21}N^2O^2$. This alkaloid may be prepared from quinoidine by a method depending on the difficult solubility of its acid tartrate, 100 grams of quinoidine are dissolved in 200 grams of water holding in solution 50 grams of tartaric acid, and the liquid, after brisk agitation is set aside for several days. A mass of crystals then forms which is to be pressed between folds of linen, dissolved in 14 times its weight of water, and the solution filtered while hot. Acid tartrate of quinoidine then crystallises out, and is easily purified (De Vrij, *Chem. Cent.* 1872, 152).

According to Hesse (*Ann. Chem. Pharm.* clxvi. 237) the product thus obtained contains a mixture of the tartrates of several cinchona alkaloids, from which however the quinidine may be separated by recrystallising the crude product from boiling water, dissolving the resulting crystals in hot water, and neutralising with ammonia. The

solution on cooling deposits neutral tartrate of cinchonidine, sometimes mixed with neutral tartrate of quinine, while the quinidine remains in the mother-liquor, and may be precipitated therefrom by heating with potassium iodide.

For the optical rotatory power of quinidine Pasteur found $\alpha_D = + 250.75$ at 13° , which is equivalent to $\alpha_D = + 327$. According to Hesse, it is much smaller, viz.

$$\alpha_D = + 260.65.$$

The sulphate $2C^{20}H^{21}N^2O^7 \cdot 2H^2SO + 2H^2O$, gives for the alkaloid contained in it nearly the same value, viz.:

$$\alpha_D = + 261.18,$$

but in presence of 1 and 6 molecules of acid, it gives the values:

$$\alpha_D = + 323.06$$

and

$$\alpha_D = + 324.54.$$

The hydrochloride gives for the rotatory power of the alkaloid contained in it:

In alcoholic solution	$\alpha_D = + 270.03$
In aqueous solution with excess of dilute acid	$\alpha_D = + 312.47$
Dissolved in fuming acid	$\alpha_D = + 257.52.$

Quinicine and Cinchonine. These bases, isomeric with quinine and cinchonine respectively, were discovered by Pasteur, who obtained them by heating the sulphate or other salt of quinine, quinidine, cinchonine or cinchonidine. He observed, however, that to make the transformation complete, and prevent decomposition, the heat must be moderate and the salt must be kept for some time in a viscous or resinous state, and that the change is best effected by heating the sulphate to 120° – 130° with a little water and sulphuric acid (i. 971; v. 13). These observations have lately been confirmed by D. Howard (*Chem. Soc. J.* [2] x. 102), who finds that the action of heat on a solution of a salt of cinchona alkaloid in water in sealed tubes, even when exposed to a higher temperature than is required under favourable circumstances to convert it wholly into the isomeric modification, is very slight indeed; if however, a considerable excess of acid be present, the alkaloid, is, under the same circumstances, slowly changed, but far less readily than when Pasteur's conditions are observed. On the other hand, a mixture of glycerin and neutral cinchonine sulphate exposed to the needful heat, is converted into sulphate of cinchonine at the same rate as with a mixture of the salt with acid. Quinine sulphate when heated with glycerin showed no signs of the formation of quinicine, owing apparently to the slight solubility of the salt in that medium.

The change in the alkaloids is accompanied in all cases by the development of a yellow colour, which seems inherent in the resulting alkaloid; if more heat is used than is absolutely needed, especially when atmospheric air is present, a further decomposition takes place, with formation of a darker colour; this may be in great part prevented by heating in an atmosphere of carbonic anhydride.

Quinicine is contained in the impure quinine salts which crystallise from the mother-liquors of the manufacture of quinine sulphate, and is most conveniently prepared by purifying the alkaloids contained in the mother-liquor from the recrystallisation of those impure products, by solution in ether, then evaporating the ether, dissolving the residue together with oxalic acid, in the smallest possible quantity of water, and leaving the solution to crystallise.

The base separated by potash or soda from the oxalate thus obtained is a yellowish oil, which cannot be obtained pure in the solid state, for it will not bear heat without decomposition, and holds water too strongly for drying in a vacuum. It has a peculiar bitter taste, much less intense and permanent than that of the other cinchona-alkaloids; is very soluble in alcohol, soluble to a large extent in ether, from which it separates as an oil when the ether is allowed to evaporate. It is a strong base; the salts are neutral to test-paper; a small excess of the base strongly restores the colour of reddened litmus. Ammonia precipitates its solutions but imperfectly, whence it would appear to be even a stronger base than quinine.

Chlorine-water, followed by ammonia, produces in solutions of its salts the green colour and precipitate of dallocchin which distinguishes quinine and quinidine. Strong acids, even in the cold, produce a change of colour, and even when diluted with a considerable quantity of water; heat renders the action much more rapid. This coloration is strongest when nitric acid is used, an excess of which, with the aid of heat, develops a strong yellow-green colour, even in a weak solution. In this reaction, as well as in the persistent colour of its salts, quinicine shows a strong resemblance to aricine.

Quinicine salts are very soluble and difficult to crystallise, but the platino-chloride, oxalate, and acid tartrate, crystallise with comparative facility and can be obtained

pure. The salts of quinine prepared from quinine are exactly similar in their properties to those prepared from quinidine; in fact, there is but one quinine, from which ever of the isomeric bases it is derived.

The *platino-chloride*, $C^{20}H^{24}N^2O^2 \cdot 2HCl \cdot PtCl_4$, precipitated from a hot solution, forms a crystalline powder; from a hot acid solution it separates, on cooling, in definite crystals. The *oxalate* $2C^{20}H^{24}N^2O^2 \cdot C^2H^2O^4 + 9H^2O$ crystallises easily, but is difficult to purify completely, on account of the facility with which it changes under the influence of air, light, or heat. It is extremely soluble in water, the wet crystals melting at 100° , but much less so in cold water; insoluble in ether, but very soluble in alcohol, and to a less degree in amyl alcohol, from hot concentrated solutions in either of which solvents it crystallises freely on cooling. The water of crystallisation is partially given off *in vacuo*, and entirely at 100° after previous drying; if the salt is at once heated to 100° without previous exsiccation, it is apt to fuse.

The *acid tartrate*, $C^{20}H^{24}N^2O^2 \cdot C^4H^4O^6 + 6H^2O$, crystallises freely from strong solutions in radiated needles, which melt easily at 100° . By gradual drying at about 50° it loses 4 mols. water, and at 140° the remaining 2 mols. are expelled, with fusion and slight discoloration.

The *sulphate*, *citrate*, *hydrochloride*, *phosphate*, and *acetate* are all exceedingly soluble in water; on evaporation *in vacuo* they form semi-crystalline masses. The *hydrobromide* and *ferrocyanide* obtained by double decomposition form oily strata at the bottom of the solution, soluble in an additional quantity of water, but show no sign of crystallisation even on long standing. The *hydriodide* also forms an oily stratum in strong solutions, but on standing it becomes semi-solid by formation of crystals; weaker solutions also deposit a small quantity of flocculent crystals, but in neither case can they be separated from the mother-liquor. The *sulphocyanate* also forms an oil when in concentrated solutions, but crystallises from a somewhat larger quantity of water in long silky needles, almost white, very soluble, and readily decomposed by heat.

The leaves of *Cinchona succirubra* have been found by J. E. Howard to contain minute quantities of an alkaloid which is soluble in ether, and is precipitated in the crystalline form by an alcoholic solution of oxalic acid. Whether this alkaloid is identical with quinine must be decided by further investigation.

Cinchonidine and its salts are very similar to quinine and its salts; the base is soluble in ether, separating, like quinine, as an oily layer at the bottom of the solution as the ether evaporates. Its salts are somewhat more soluble than the corresponding quinine salts. The same similarity is observed between those prepared from cinchonine and those from cinchonidine that is found between the salts of quinine prepared from quinine and from quinidine.

The *platinochloride* has the composition $C^{20}H^{24}N^2O^2 \cdot 2HCl \cdot PtCl_4$.

The *oxalate*, $2C^{20}H^{24}N^2O^2 \cdot C^2H^2O^4 + 7H^2O$, differs from the oxalate of quinine by containing only 7 mols. of water; it very readily loses a portion of this water, and is therefore difficult to dry for analysis; the whole is given off at 100° . No definite point of hydration is reached by drying in a vacuum. It is somewhat more soluble than the quinine salts.

The *acid tartrate*, $C^{20}H^{24}N^2O^2 \cdot C^4H^4O^6 + H^2O$, crystallises in crusts composed of short prisms, which lose their water at 120° without fusion.

The action of these alkaloids on polarised light also shows the identity of the alkaloid produced by the action of heat on the isomeric alkaloids, the different action on the polarised ray disappearing with the other characteristic distinctions. Quinine, either from the strongly levogyrate quinine, or from the dextrogyrate quinidine, exhibits a comparatively feeble right-handed rotation, identical within the limits of errors of observation.

The observed molecular rotatory powers of these alkaloids for the yellow ray are as follows:—

In a spirituous solution of the alkaloid—

Quinine from quinine gives . . .	$\alpha_D = +39^\circ$
Quinine from quinidine . . .	$\alpha_D = +39^\circ$
Quinine from quinoidine . . .	$\alpha_D = +39.3^\circ$

Oxalate of quinine in an acid solution—

Prepared from quinine . . .	$\alpha_D = +13.4^\circ$
Prepared from quinidine . . .	$\alpha_D = +14^\circ$
Prepared from quinoidine . . .	$\alpha_D = +14^\circ$

Cinchonidine in a spirituous solution—

Prepared from cinchonine . . .	$\alpha_D = +48^\circ$
Prepared from cinchonidine . . .	$\alpha_D = +48.4^\circ$

Oxalate of cinchonine in an acid solution—

From cinchonino	$\alpha_D = +18^\circ$
From cinchonidino	$\alpha_D = +17.0^\circ$

The rotatory power in both cases is much less in an acid solution than in a spirituous solution of the alkaloid.

Amorphous Alkaloid of Cinchona bark.—It is not known with certainty whether this alkaloid, sometimes called quinoïdino (v. 26), is quinine or another alkaloid really uncrystallisable. Hitherto the most careful purification has failed to obtain crystalline salts from it such as have been described. When quinine is present, it will, as has been stated, crystallise out of the mixture, but the bulk of the quinoïdine, however carefully purified, refuses to crystallise, even after many months' standing. It seems highly improbable, though of course it is possible, that this is owing to some impurity which hinders the crystallisation: for we find that quinicinacalts prepared from crystallisable alkaloid crystallise entirely with comparative freedom, even when the heat used in its formation has been considerably above the point needed, and sufficient to decompose a portion, and there is no sign of any amorphous modification being formed.

Quinoïdine closely resembles quinine in other respects. When purified, as far as possible, by fractional precipitation and solution in ether, it forms a readily fusible yellow resin. The platinumchloride precipitates as an amorphous powder, readily fusible, slightly soluble in hot water, and much more so in hot dilute hydrochloric acid, from its solution in which it is deposited, on cooling, as an amorphous powder which, under the microscope, appears to consist of globules without any sign of crystallisation.

The salt precipitated from a cold solution contains 26.59 p.c. of platinum, and after solution in dilute acid 26.28 p.c.; it is, therefore, isomeric with quinine and quinine.

It is difficult to speak with certainty of the optical properties of this alkaloid, on account of the great difficulty of insuring absolute purity from the other alkaloids of higher rotatory power, a very small percentage of which would evidently vitiate the results. The specimen, the analysis of the platinum salt of which is given above, showed a specific rotatory power of $+33^\circ$; other specimens gave higher results, but their purity was more doubtful (Howard).

See further, Hesse (*Ann. Ch. Pharm.* clxvi. 273).

Quinamine, $C^{20}H^{27}N^2O^2$. (Hesse, *Deut. Chem. Ges. Ber.* iv. 985).—This alkaloid occurs, together with paricine and several others, in the bark of *Cinchona succirubra*, now extensively cultivated in India. The quantity of it contained in the bark is, however, extremely small, so that its preparation is very difficult.

The whole of the alkaloids contained in the bark are first extracted by the ordinary methods, then dissolved in dilute sulphuric acid; the warm solution is neutralised with ammonia, and potassium-sodic tartrate is added, which throws down cinchonidine and quinine, if present, in the form of neutral tartrate. The filtered solution is treated with ammonia to liberate the bases, and then shaken with ether, which takes up the quinamine, together with the amorphous substances, including paricine, but leaves the greater part of the cinchonine undissolved. The separated ethereal solution left to evaporate slowly in a tall glass vessel, first deposits short prisms of cinchonine, then very long delicate prisms of quinamine, and finally leaves an amorphous mass which must be removed as completely as possible by inverting the vessel while it is still fluid, afterwards breaking off the neck, and removing the adhering amorphous particles from the sides with filter-paper.

The crystalline mass thus obtained is rinsed with dilute alcohol, the residue dissolved in dilute hydrochloric acid, and platinum chloride added as long as it produces a permanent precipitate. From this precipitate the quinamine may be directly separated by ammonia; but it is better to remove the platinum by hydrogen sulphide, and then, after expelling the excess of that gas, to precipitate the quinamine by ammonia. It is finally purified by recrystallisation from boiling alcohol. The quantity obtained is for the most part very small, rarely amounting to 0.1 p.c. of the bark; in one case, 0.3 p.c. was obtained.

Quinamine crystallises in delicate, asbestiform, anhydrous prisms, easily soluble in strong alcohol, ether, and light petroleum oil, slightly soluble in dilute alcohol, insoluble in water and in alkaline solutions. Its alcoholic solution is alkaline and neutralises acids. Quinamine melts at 172° and crystallises again, on cooling, in radiated masses. Continued heating, however, renders it brown and amorphous. Its optical rotatory power is $\alpha_D = +106.8$.

Hydriodide of quinamine, $C^{20}H^{27}N^2O^2$, forms colourless anhydrous prisms easily soluble in boiling, sparingly in cold water; the neutral sulphate is easily soluble in water and crystallises with difficulty in six-sided prisms and short laminae. The

hydrochloride, acetate, neutral and acid tartrate, mercurio-chloride, mercurio-iodide, and auro-chloride, are amorphous; the platino-chloride is extremely soluble in water, so that it is only in very highly concentrated solutions of the hydrochloride that a precipitate is formed by platine chloride.

Paricine (Hesse, *Ann. Ch. Pharm.* clxvi. 283).—This alkaloid, first found by Winkler in 1845, in a false cinchona bark said to be imported from Peru, afterwards in the bark of a true cinchona, viz. *C. lutea*, occurs also in the bark of *C. succirubra*. When the alkalis have been separated from this bark in the usual way, and the aqueous solution of the mixed sulphates is treated with strong nitric acid, paricine nitrate is thrown down in yellowish flocks. To separate the base, this precipitate, which becomes resinous, is kneaded with nitric acid, the mass drained with alcohol, ammonia added to decompose the nitrate, and the solution treated with hot petroleum oil, which abstracts the alkaloid from the alcoholic solution. The petroleum oil is then evaporated off, the residue dissolved in dilute hydrochloric acid, and the solution, after purification with animal charcoal, is mixed with ammonia, which throws down a yellowish-white flocculent precipitate of pure paricine.

Paricine dissolves easily in ether, alcohol, and light petroleum oil, but is nearly insoluble in water and ammonia. It cakes together at 100° , and melts at 116° . It dissolves easily in strong sulphuric acid. Strong nitric acid converts it into a dark-green resin, which dissolves with deep yellow colour on warming. Its solution in acetic acid gives, with nitric acid or sodium nitrate, a yellowish-white precipitate of paricine nitrate. The same solution gives precipitates with sodium chloride and potassium iodide. The chlorides of gold, mercury, and platinum produce flocculent precipitates in the solution of paricine in hydrochloric acid.

Paricine has not yet been obtained in sufficient amount for quantitative analysis.

Aricine. The existence of this alkaloid, obtained, according to Pelletier & Corriol, from a white cinchona bark from Arica (*1st Suppl.* 357), is regarded by Hesse as still doubtful (*Ann. Ch. Pharm.* clxxvi. 259).

Paytine, $C^{21}H^{24}N^2O$. Hesse (*Ann. Ch. Pharm.* cliv. 287; clxvi. 272). This is an alkaloid obtained from a white cinchona bark from Payta in Peru. It is prepared by exhausting the bark with alcohol, evaporating, supersaturating the residue with sodium carbonate, and then agitating it with ether. The ethereal solution is treated with dilute sulphuric acid to convert the base into a sulphate, and the acid solution, after being nearly neutralised with ammonia, is mixed with potassium iodide, whereby the base is precipitated as a hydriodide, which is decomposed by sodium carbonate and agitated with ether. On leaving the ethereal solution to evaporate, the base remains in beautiful crystals containing $C^{21}H^{24}N^2O.H^2O$.

Paytine has a bitter taste; it is not poisonous; its optical rotatory power is $\alpha_D = -49.5$. It dissolves easily in ether, benzene, chloroform, light petroleum oil, and alcohol, sparingly in water, potash, and ammonia. From alcohol it crystallises in beautiful colourless rhombic crystals exhibiting the combinations $OP \cdot \infty P \cdot \infty P\infty$, with $mP\infty$ subordinate; the alcoholic solution reddens blue litmus-paper. Paytine melts at 156° and at a higher temperature gives off a colourless oil, and leaves a carbonaceous residue. When distilled with soda-lime, it gives off a non-azotised body, paytone, which sublimes in colourless laminae or needles, dissolves easily in alcohol and ether, and reacts indifferently with dilute sulphuric or nitric acid, potash-solution, and alcohol.

Paytine forms salts with dilute acids. The hydrochloride, $C^{21}H^{24}N^2O.HCl$, forms colourless prisms soluble in 16.6 parts of water at 15° ; it is easily soluble also in alcohol, but insoluble in ether.

The platino-chloride is a dark yellow amorphous precipitate which must be rapidly filtered and washed, as it is very liable to decompose.

The mercurio-chloride is a yellowish amorphous powder. The hydriodide crystallises in white prisms soluble in water nearly insoluble in alcohol. The nitrate crystallises in needles, and can be prepared only by double decomposition with the hydrochloride and silver nitrate.

Paytine gives various coloured reactions. The platinum precipitate, heated with hydrochloric acid, dissolves with brown-red colour, quickly changing to blue, a blue precipitate being formed at the same time; auric chloride colours the solution of the hydrochloride purple-red and forms a precipitate of the same colour. Solution of bleaching powder produces in the acid solution, first a dark red, then a blue colour, which quickly disappears, the liquid then turning pale yellow and depositing a white amorphous body.

White cinchona bark yields also an amorphous alkaloid which Hesse regards as amorphous paytine.

CINNAMIC ACID, $C^9H^8O^2$, is formed by heating benzoic aldehyde with acetic acid and a small quantity of gaseous hydrogen chloride, or with zinc chloride, to 160° :

The quantity of cinnamic acid thus obtained is but small. If a larger quantity of hydrochloric acid is used, or greater heat applied, a certain quantity of metacinnameno is always formed by the action of the hydrochloric acid on the cinnamic acid (H. Schiff, *Zeitschr. f. Chem.* [2] vi. 700).

Crude cinnamic acid prepared from storax always contains a rosin, sometimes also benzoic acid. It may be purified by adding water and ammonium carbonate, stirring the liquid, leaving it to stand for some time, then precipitating with hydrochloric acid, and distilling the dried precipitate. Benzoic acid then volatilises first, and afterwards (between 280° and 290°) cinnamic acid, which may be freed from an adhering oily substance by pressure between filter-paper, or recrystallisable from alcohol (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] vii. 489).

Nitro-cinnamic acids.—Cinnamic acid yields two isomeric nitro-acids which may be obtained from it by the action of fuming nitric acid. The *para-acid* is easily obtained pure, and it is very sparingly soluble in alcohol. It forms slender needles melting at 165° . The other modification is much more soluble in alcohol, and was formerly mistaken for a mixture of benzoic acid, nitrobenzoic acid, and other oxidation-products of cinnamic acid.

The *barium salt of the para-acid*, $Ba[C^9H^7(NO^2)O^2]^2 + 3H^2O$, crystallises from water in microscopic yellow needles, sparingly soluble in cold water, and giving off nearly all their water over oil of vitriol, the last portion ($\frac{1}{4}H^2O$) at 150° . The *calcium salt* $Ca[C^9H^7(NO^2)O^2]^2 + 2H^2O$ forms short flat shining needles. The *ethylic ether* $C^9H^7(NO^2)(C^2H^5)O^2$ crystallises from alcohol in fine, very thin, slightly yellowish needles: it melts at 138.5° (at 136° according to Mitscherlich), dissolves very slightly in boiling ether, scarcely at all in cold ether.

By dissolving para-nitrocinnamic acid in sodium carbonate and passing chlorine into the liquid, β *nitro-phenyl-chlorolactic acid* $C^9H^7(NO^2)ClO^2$ is formed; this acid melts at 166° , and is more soluble in water and more stable than chlorophenyl-lactic acid (Beilstein a. Kuhlberg).

Nitro-hydrocinnamic acid, which, according to Glaser and Buchanan, softens when heated, and becomes perfectly liquid at 153° , is a mixture of two isomerides, of which the *para-acid* can be easily obtained pure by recrystallisation from water, being less soluble than the other nitro-acid. It forms small flat needles melting at 163° – 164° . The *barium salt* of the crude acid forms a semi-fluid mass, whereas that of the pure *para-acid* crystallises in microscopic needles, containing, like the calcium salt, 2 molecules of water. The *ethylic ether* $C^9H^7(NO^2)(C^2H^5)O^2$ forms long, flat crystals melting at 33° – 34° .

Para-nitro-cinnamic and para-nitro-hydrocinnamic acids are converted by oxidation with chromic acid mixture into para-nitrobenzoic acid (Beilstein a. Kuhlberg).

CITRACONIC ACID, $C^8H^8O^4$. *Barium salt.*—When neutral ammonium citraconate and barium acetate are mixed together in the cold, an amorphous precipitate is thrown down, which becomes crystalline by prolonged heating. The same salt is obtained by heating aqueous citraconic acid with barium acetate. In the crystalline state, it is quite insoluble in water, and has the composition $2C^8H^7BaO^4.5H^2O$ (Kümmerer, *Ann. Ch. Pharm.* clxx. 191).

Brominated Derivatives.—Citraconic anhydride heated to 140° with dry bromine, is converted into bromocitraconic anhydride, $C^8H^7BrO^4$. The same compound is produced, together with bromoxaform (p. 213), by the action of bromine on pyrotartaric acid. The action is very slow at ordinary temperatures, but when 13 parts pyrotartaric acid, 24 parts bromine, and 10 cub. cent. of water are heated together to 120° , the bromine disappears after two hours, and on cooling, there is obtained a pale yellow liquid and usually a white crystalline mass of bromocitraconic anhydride. On mixing the liquid with 4 or 5 times its volume of water, crystals of bromoxaform separate after a while, and the liquid filtered therefrom yields, on agitation with ether, an additional quantity of bromocitraconic anhydride, which by recrystallisation from water, pressure, and final crystallisation from ether, may be obtained in the form of white crystals. Its formation appears to be due to the splitting up of dibromopyrotartaric acid (the formation of which has not, however, been actually observed) according to the equation:

It is also formed, together with a dark-coloured unctuous substance, when pyro-

taric acid is heated to 100° with dry bromine (Lagermark, *Zeitschr. f. Chem.* [2] vi. 299).

Bromocitraconic anhydride melts at 97° – 98° , begins to volatilise a little above its melting point, distils with aqueous vapour, and boils without decomposition at about 200° (Lagermark), 225° (Kekulé). It is soluble in water, hydrobromic acid, alcohol, ether, carbon sulphide, and chloroform, and crystallises unaltered from hydrobromic acid, ether, or carbon sulphide, in large six-sided apparently rhombic plates (Lagermark). It dissolves slowly in cold, quickly in warm water, with formation of bromocitraconic acid, $C^3H^3BrO^4$; but from boiling water it separates without alteration in shining laminae; this results from the facility with which bromocitraconic acid splits up into water and the anhydride, this decomposition taking place even when the acid is evaporated over oil of vitriol (Kekulé).

When bromocitraconic anhydride is heated with water and sodium-amalgam, the liquid contains pyrotartaric acid, together with the unaltered anhydride (Lagermark).

Ammonium Bromocitraconate, $C^3H^3Br(NH^4)^2O^4$, is anhydrous, easily soluble in water, insoluble in ether and in absolute alcohol. The potassium salt $C^3H^3BrK^2O^4$, is a white deliquescent mass insoluble in absolute alcohol. The barium salt $C^3H^3BrBaO^4$ forms tufts of microscopic prisms; the calcium salt $C^3H^3BrCaO^4 + 2H^2O$, gives off part of its water at 140° , the rest at 160° , and remains undecomposed at 180° . The silver salt $C^3H^3BrAg^2O^4$ is formed as a white, quickly crystallising precipitate, when a solution of bromocitraconic anhydride, neutralised with ammonia, is mixed with silver nitrate (Kekulé). According to Lagermark, it blackens at 100° and turns dark brown when boiled with water.

By the action of bromine and water on pyrotartaric acid, Lagermark obtained, besides bromoxanform and bromocitraconic anhydride, a nearly colourless acid which agreed very nearly with bromocitraconic acid, but could not be obtained pure. It melted more easily, and decomposed at the boiling point of the anhydride. A tarry substance was also formed.

CITRIC ACID, $C^3H^3O^7$. This acid is found in large quantity in the leaves of the wild cherry, *Cerasus acida* (Tochleder, *Zeitschr. f. Chem.* [2] vi. 176.)

Citric acid crystallises from a solution which has not been heated above 100° with one molecule of water, which it loses in the air, or more quickly at 130° . When the substance dried at 130° is re-dissolved in water, or when an aqueous concentrated solution of the acid is boiled for some time, anhydrous crystals are obtained, which appear to be an isomeric modification of common citric acid. By heating ordinary ethyl citrate, $C^6H^5(C^2H^3)^2O^7$, with alcoholic ammonia to 70° – 110° for 24 hours, citramethane, $C^6H^5(NH^2)^2(C^2H^3O)^2O^4$, is formed as a dark green amorphous and hygroscopic powder, which is soluble in water and alcohol, but not in ether, and may be used as a colouring matter (Sarandinaki, *Deut. Chem. Ges. Ber.* vi. 496).

Action of Hydrobromic acid (Mercadante, *Gazzetta chimica italiana*, i. 248). When pulverised citric acid dried at 100° is dissolved in three times its weight of hydrobromic acid boiling at 126° , and heated for 12 hours in a flask with reversed condenser, a crystalline product is obtained, free from bromine, and yielding, when dissolved in alcohol and treated with gaseous hydrochloric acid, a product which is resolved by water into a heavy oil and an aqueous solution of citric acid. No brominated acid is obtained by this reaction.

The oil dried with calcium chloride and distilled, boils almost constantly at 275° ; it is slightly yellow, has a characteristic aromatic odour, and yields by analysis 55.09 p.c. C., and 7.19 H., numbers agreeing nearly with the formula of aconitic ether $C^8H^{11}O^6$, which requires 55.81 C., 6.97 H., and 37.22 O. Aconitic ether is said, however, by Crasso (i. 55) to boil at a much lower temperature, viz., at 236° . But Mercadante, on preparing aconitic ether by saturating a solution of aconitic acid in absolute alcohol with hydrochloric acid gas, obtained an oily liquid which began to boil at 255° , and passed over for the most part between 270° and 275° , this latter portion exhibiting all the characters of the product obtained as above by the action of hydrobromic acid on citric acid. It is probable that the aconitic ether examined by Crasso was mixed with itaconic ether, inasmuch as, in preparing aconitic acid by the action of heat on citric acid, it is impossible to obtain a product quite free from itaconic acid.

The action of hydriodic acid on citric acid does not yield definite results. Dessaignes has shown that aconitic acid is formed by boiling citric acid for a long time with hydrochloric acid.

The formation of aconitic acid by the action of hydracids on citric acid consists in the elimination of a molecule of water, and may be represented by the following equations:—

Action of Permanganates.—Citric treated with potassium permanganate, forms a solution which leaves an uncrystallisable syrup on evaporation. No acetone is formed, as is the case when citric acid is decomposed in presence of free acid (A. Fleischer, *Dent. Chem. Ges. Ber.* v. 350).

Distinction of Citric acid from other Fruit-acids. Kümmerer (*Zeitschr. anal. Chem.* viii. 298) detects citric acid in presence of tartaric or malic acid, by means of the barium salt to be described further on. The solution of the acids is mixed with excess of barium acetate, and the amorphous precipitate is heated for several hours with the liquid in a covered vessel on the water-bath. The precipitate, which is bulky at first, usually diminishes greatly in volume in about two hours, becoming heavy and granular, and being completely converted into the microcrystalline salt, $\text{Ba}^2(\text{C}^3\text{H}_5\text{O}_7)^2 + 7\text{H}^2\text{O}$. The filtrate, mixed with lead acetate, does not yield any precipitate of lead citrate. Any bases that may be present in the liquid, such as lime, iron oxide, &c., must be removed, and the filtrate neutralised, before adding the barium acetate. Very dilute solutions must be evaporated to a small bulk, after precipitation with the barium salt; otherwise the needle-shaped salt $\text{Ba}^2(\text{C}^3\text{H}_5\text{O}_7)^2 + 5\text{H}^2\text{O}$ will be formed instead of the preceding. 50 grams of a solution of 1 gram sodium acetate, $(2\text{Na}^+\text{C}^2\text{H}_3\text{O}_2^- + 11\text{H}^2\text{O})$, mixed with barium acetate, did not give an immediate precipitate; but on heating the liquid, an amorphous precipitate was formed which, in a short time became aciculate-crystalline, and after further concentration passed into the characteristic monoclinic form.

Neutral ammonium citrate added to a hot solution of *basic ferric chloride* throws down a light yellow precipitate which redissolves completely in excess of the citrate; hence it is that solutions of citrates often give no precipitate with ferric chloride. Sodium citrate reacts in the same manner as the ammonium salt; the yellow iron-compound is often formed only after some minutes, and still increases after several hours. Hence it follows that citric acid and aconitic acid cannot be distinguished from one another by their behaviour with ferric chloride; still less can they be separated by this re-agent, since the ferric citrate precipitated is always mixed with aconitate (Kümmerer).

Lead citrate, precipitated from the sodium salt with excess of lead nitrate, melts in the boiling liquid to a single kneadable lump, which, on prolonged heating or on cooling, is resolved into a powder of $\text{Pb}^2(\text{C}^3\text{H}_5\text{O}_7)^2 + 3\text{H}^2\text{O}$, having a vitreous lustre. Diammonio tartrate and the corresponding sodium salt form, with lead nitrate, precipitates which behave in a similar manner when quickly heated. From malate of lead, the citrate and tartrate differ only by not forming a clear liquid. If, however, the malic acid is not quite pure, its lead salt exactly resembles the citrate or tartrate (Kümmerer).

Examination of Citric acid for Crystals of Tartaric acid.—The following methods for this purpose are given by Lager (*Dingl. polyt. J.* cxi. 387):—1. A solution of 4 grams potassium hydrate in 60 c.c. water is mixed with 30 c.c. of 90 p.c. spirits of wine, and poured on one or two glass plates, so that the liquid stands not less than 6 mm. high. Small and large crystals of the citric acid to be tested are now placed in the solution, about 3 to 5 centimeters distant from one another. The plates are on no account to be disturbed. In two or three hours the citric acid crystals are nearly, if not quite dissolved, and in each of their places is left a small, delicate, white, powdery patch. The tartaric acid crystals, on the contrary, appear dissolved to a small extent only, whitish and opaque, and with either an enclosure of white acicular crystals, or surrounded by an aggregate of small crystalline groups lying one upon another. The citric acid crystals, after being subjected for several minutes to the action of the alkaline solution, appear clearer and more transparent, the tartaric acid crystals remain and whitish.

2. The crystals are placed, with the same precautions, in a dilute, transparent solution of potassium permanganate, made strongly alkaline by addition of fused potassium hydrate. After one or two hours, tartaric acid crystals, which as a rule are not quite dissolved, will be found to have left a yellow or colourless spot. Citric acid, on the contrary, gives a green colour, with a tinge of blue; the crystals are usually dissolved. The first plan is the best and safest; in either case the mode of procedure described must be strictly adhered to, or the results will be considerably modified. Perfectly pure citric acid gives no whitish spots, but the commercial acid never fails to do so.

Quantitative estimation.—J. Crouse (*Pharm. J. Trans.* [3] ii. 547) gives a process for the estimation of citric acid, depending upon the precipitation of an alkaline citrate by barium acetate, the resulting barium citrate being perfectly insoluble in alcohol of sp. gr. .805, while the alkaline acetates and barium acetate are freely soluble in that liquid. The presence of alkaline acetates does not in any way interfere with the reaction. If the citric acid is already in combination with an alkali, one or two grams of the salt are dissolved in 20 c. c. of water, and the solution exactly neutralised with ammonia or acetic acid as may be required; a slight excess of barium acetate is then added, and afterwards twice its volume of alcohol of 95°. The whole is then allowed to remain undisturbed for 24 hours. The barium citrate, which at first resembles a thick jelly, has by that time become denser and easier to wash. The precipitate is then thrown on a filter, washed with alcohol of 63°, and dried at a moderate heat.

To obtain accurate results, it is necessary to estimate the barium in the precipitated citrate. The filter is therefore burnt, and the ashes, together with the precipitate, gently ignited with a few drops of sulphuric acid, until a constant weight is obtained. Every three molecules of barium sulphate obtained represent one molecule of citric acid.

* When it is required to estimate the citric acid of a non-alkaline citrate, soluble or otherwise, a certain weight of the salt is first heated carefully with a solution of caustic potash, the heat being applied long enough to decompose the salt thoroughly, but not to such an extent as to alter the citric acid. The liquid is then filtered, and the filtrate, after neutralisation with acetic acid, treated as a solution of an alkaline citrate.

Crouse likewise describes briefly a peculiar class of citrates in which an alkaline citrate plays the part of a base, a certain metallic salt, the part of an acid: thus, phosphate hypophosphite, valerate of iron, &c., were found to dissolve readily in solutions of the alkaline citrates, losing thereby, more or less completely, their special characteristics as salts of iron.

Metallic Citrates (Kümmerer, *Ann. Ch. Pharm.* cxlviii. 294; clxx. 176).—The trisodic salt $2Na^+C^3H^3O^7 + 11H^+O$, which usually crystallises in large rhombic prisms, has also been obtained by Kümmerer in fine, silky, concentrically grouped needles. All attempts to prepare sodio-potassic citrates by saturating citric acid with mixtures of the corresponding carbonates were unsuccessful, the trisodic salt always crystallising out, while the deliquescent tripotassic salt remained in solution.

Barium salts.—By precipitating sodium citrate with calcium chloride or by saturating citric acid with laryta water, an amorphous precipitate is formed which has the composition $Ba^+(C^3H^3O^7)^2 + 7H^+O$, and when heated in the water-bath with a large quantity of water, is converted into the microcrystalline salt $Ba^+(C^3H^3O^7)^2 + 5H^+O$, consisting of uniformly thin, concentrically grouped needles. The same salt is gradually deposited in microscopic, short, thick prisms, from a solution of 2 mols. trisodic citrate and 3 mols. barium acetate in a quantity of water such that 150 grams of water are present to 1 gram of the barium acetate. By heating the pentahydrated salt with water, or either of the preceding salts with aqueous ammonia, the *hebario salt* $Ba^+(C^3H^3O^7)^2 + 7H^+O$ is obtained in well-defined microscopic monoclinic prisms. The same salt is formed as an amorphous precipitate on mixing free citric acid with barium acetate in a solution diluted to the degree above mentioned.

Strontium salts.—When 2 grams of trisodic citrate and 8 grams of strontium acetate are dissolved in 500 grams of water at ordinary temperatures, a precipitate begins to form after 24 hours, goes on increasing for several days, and settles at the bottom of the vessel in loose lumps or a network of silky microscopic needles having the composition $Sr^+(C^3H^3O^7)^2 + 5H^+O$. It is not altered by digestion with aqueous ammonia.

When citric acid is heated for some time with strontium acetate and water, the precipitate, which is at first amorphous, becomes crystalline, and appears under the microscope to consist of monoclinic tablets. The salt thus obtained has the composition $Sr^+H^+(C^3H^3O^7)^2$ or $2Sr^+(C^3H^3O^7)^2 + 11H^+O$. When this salt is heated for several hours with strong acetic acid, the residue contains short microscopic prisms

having the same composition, while the acetic acid solution deposits the salt $2\text{S}_2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^1 + 5\text{H}^2\text{O}$, apparently in the amorphous state.

Calcium salts.—By precipitating sodium citrate with calcium chloride, or saturating citric acid with lime-water, a precipitate of the salt $\text{Ca}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 4\text{H}^2\text{O}$ is obtained which does not appear distinctly crystalline under the microscope, but, when heated in the water-bath, is converted, without change of composition, into a mass of transparent microscopic needles. The same change takes place on dissolving the amorphous precipitate in acetic acid, and leaving the solution to evaporate. This salt dissolves in aqueous ammonia and separates from the solution unaltered, even after prolonged digestion in the water-bath.

A solution of 1 part calcium acetate in 300 parts water, mixed with half the quantity of sodium citrate necessary to precipitate the whole as trisodic salt, slowly deposits the salt $\text{Ca}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 7\text{H}^2\text{O}$ in the form of a precipitate having an almost gummy aspect, but appearing under the microscope to consist of short prisms. It gives off 4 mols. water over sulphuric acid, and 6 mols. at 210° . The tetrahydrated salt above described gives off the whole of its water at 200° .

Magnesium salts.—The salt $\text{Mg}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 8\text{H}^2\text{O}$, or $\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)$, $\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 8\text{H}^2\text{O}$, is obtained by digesting a boiling solution of citric acid with excess of magnesium carbonate. By mixing the solutions of magnesium sulphate and trisodic citrate, or by boiling magnesium acetate and citric acid together in alcoholic solution, the salt $\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 9\text{H}^2\text{O}$ is obtained in microscopic six-sided prisms, with pyramidal summits; and by dissolving this salt in hot water and evaporating, oblique prisms are obtained having the composition $2\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 11\text{H}^2\text{O}$.

By mixing magnesium acetate and citric acid in aqueous solution and adding alcohol, the salt $\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 14\text{H}^2\text{O}$ described by Heldt (1st Suppl. 998) is obtained as a tenacious precipitate, which gradually solidifies to crystalline crusts.

Solutions of sodium citrate and magnesium acetate mixed and evaporated, yield an acid solution and a tenacious mass, which is very soluble in water and has an alkaline reaction. This solution, heated in a closed vessel, deposits a microcrystalline precipitate containing $\text{Mg}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 13\text{H}^2\text{O} = 4\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 3\text{H}^2\text{O}$.

Trimagnesium citrate dissolves in hot aqueous ammonia and separates from the solution on evaporation as a crystalline precipitate containing $\text{Mg}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 9\text{H}^2\text{O}$, and the filtrate, on further concentration, yields the salt $\text{Mg}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 3\text{H}^2\text{O}$, or $2\text{Mg}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 3\text{H}^2\text{O}$.

Zinc salts.—The salt $\text{Zn}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 2\text{H}^2\text{O}$, described by Heldt as a crystalline powder, was obtained by Künmerer in microscopic monoclinic prisms. A basic salt $\text{Zn}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2$, similar to the last-mentioned magnesium salt, was obtained by dissolving the trimetallic salt in aqueous ammonia and evaporating. By prolonged contact with acetic acid it is gradually converted into the crystalline trimetallic salt. From all the zinc citrates the zinc is but imperfectly precipitated by sodium carbonates, even after prolonged heating.

Cadmium salts.—When a hot solution of trisodic citrate is poured into a hot solution of cadmium sulphate till a permanent precipitate is formed, this precipitate, which is at first amorphous, melts under the hot liquid to a soft mass, which, after several hours heating in the liquid, is converted into microscopic prisms of the salt $2\text{Cd}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + \text{H}^2\text{O}$, perfectly insoluble in cold water. Cold solutions of the same two salts yield an amorphous precipitate which, when left under the liquid, changes into microscopic rhombic prisms. The amorphous salt melts when heated with water; the crystalline salt does not. This salt has the composition $\text{Cd}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 10\text{H}^2\text{O}$; at 150° it gives off the greater part of its water, and is converted into the former hydrate $2\text{Cd}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + \text{H}^2\text{O}$; at 200° it becomes anhydrous. By concentrating the filtrate, crystalline deposits are obtained which, under the microscope, appear to consist partly of needle-shaped prisms, partly of monoclinic prisms, very much like the two forms of the barium salt $2\text{Ba}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 7\text{H}^2\text{O}$. By treatment with ammonia, the trisodic citrate is converted into the basic salt $\text{Cd}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2$, with 18 and 27 mols. of water, the latter crystallising from the mother-liquor of the former.

Copper salts.—The solution of cupric carbonate in citric acid deposits, on boiling, a green crystalline precipitate consisting of $2\text{Cu}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 8\text{H}^2\text{O}$. When cupric carbonate is treated with cold aqueous citric acid, and the filtered solution is mixed with alcohol, a faintly greenish-blue bulky precipitate is formed, which, after drying between filter-paper, is still quite soluble in water. Its formula is $\text{Cu}^2\text{H}^2(\text{C}^2\text{H}^4\text{O}^7)^2 + 15\text{H}^2\text{O}$. The dry salt turns green at 100° , is converted into acetonate at 160° , and decomposes quickly on further heating. It also decomposes gradually if kept in the alcoholic liquid in which it has been formed. On heating the aqueous solution, the whole of the copper is thrown down in the form of the dicupric salt above mentioned.

the supernatant liquid becoming quite colourless, and exhibiting a strong acid reaction. The pentacupric salt decomposes gradually also, even when kept in the dry state in perfectly closed vessels, changing its colour and being resolved into the dicupric salt, free citric acid, and water.

When 1 mol. citric acid is heated with 2 mols. cupric sulphate in very dilute solution, a considerable quantity of the dicupric salt is precipitated; and, on filtering, after the liquid has begun to bump violently, and heating the filtrate, a further quantity of the salt is precipitated. This precipitation may be repeated several times, the reaction taking place as represented by the equation:

The ammoniacal solution of the dicupric salt yields, by evaporation, blue easily soluble crystalline crusts, the aqueous solution of which quickly gives off ammonia when heated, and leaves the original salt.

Lead salts.—The salt $Pl^2(C^3H^4O^7)^2 + 3H^2O$ is obtained by adding sodium citrate to lead acetate, and digesting the precipitate with water or acetic acid, or more quickly and in larger crystals having a vitreous lustre, by precipitating sodium citrate with a large excess of lead nitrate. When the precipitate formed in the cold is heated with the supernatant liquid, it melts to a soft coherent mass, like malate of lead, and, after longer heating, is resolved into a mass of highly lustrous crystals having the same composition. The triplumbic salt, heated with ammonia, is converted into the amorphous diplumbic salt $Pl^2(C^3H^4O^7) + 2H^2O$.

Iron salts.—A *ferrous citrate* $FeH^2(C^3H^4O^7) + H^2O$ is produced by boiling metallic iron with citric acid; it forms a heavy white powder consisting of microscopic rhombic tablets. By mixing an aqueous solution of ferric acetate with citric acid and alcohol, a light yellow precipitate of *ferric citrate* is obtained, easily soluble in water, but not deliquescent.

Manganese salts.—The salt $MnH(C^3H^4O^7) + H^2O$, described by Holdt, is easily obtained by digesting manganous carbonate with a slight excess of citric acid. The *trimanganous salt* $Mn^3(C^3H^4O^7)^3 + 9H^2O$ crystallises in distorted rhombic prisms of a light rose colour. At 130° it gives off its water, and is immediately converted into aconitate. If it be then heated to 150° , it detonates, whereas in its original state it may be heated to 210° without decomposition. From the filtrate of citric acid, saturated in the cold with manganous carbonate, the salts $Mn^3H^3(C^3H^4O^7)^3 + 15H^2O$, or $Mn^4(C^3H^4O^7)^4 \cdot Mn^2(C^3H^4O^7) + 15H^2O$, crystallises on evaporation in microscopic monoclinic tablets. From the mother-liquors of trimanganous citrate, the salt $Mn^4H^4(C^3H^4O^7)^4 + 18H^2O$, or $Mn^4(C^3H^4O^7)^4 \cdot 2Mn^2(C^3H^4O^7) + 18H^2O$ may be prepared. The pure *dimanganous salt* $Mn^2(C^3H^4O^7)$ appears also to exist.

The composition of many of the citrates above described, affords further evidence of the tetrabasic character of citric acid (see 1st Suppl. p. 473).

CITRON and CITRONELLA OILS. See OILS, VOLATILE.

CITRUS LIMONUM. See LEMON.

CLADONIC ACID. This name is given by Stenhouse (*Ann. Ch. Pharm.* clv. 50) to the acid obtained from *Cladonia rangiferina*. This acid was formerly regarded as identical with usnic acid till Hesse (*ibid.* cxvii. 346) showed that it differs therefrom by its melting point, which is 176° . Hesse named it β -usnic acid. Stenhouse finds that it yields, by dry distillation, β -orcin, which is not obtained from usnic acid.

CLANDESTINA. The flower-buds of *Clandestina rectiflora*—a plant which flowers in early spring at the foot of the Pyrenees—yield to ether two crystalline substances, one yellow, and resembling cholesterol in other respects, the other called clandestinin, white, soluble in alcohol, quite insoluble in water and in dilute acids (Hartsen, *Chem. Centr.* 1872, 524).

CLAY. *Estimation of the Fire-resisting qualities of Clays.*—E. Richters (*Dingl. polyt. J.* exel. 50, 150, 229; *Jahresh.* 1860, 1074) estimates the fire-resisting qualities of clays by determining how much alumina must be added to a comparatively fusible clay, and how much silica to a refractory clay, so that at certain temperatures (as high as possible) it may exhibit the properties of a normal clay. (The criterion adopted is that the samples, after being heated for two hours to the melting point of wrought iron, shall appear but slightly glazed). The degree of fire-resisting power thus determined is represented by the quantity of quartz or alumina, expressed in tenths of the weight in clay, required to produce the result above mentioned, the addition of alumina being denoted by the sign —, and that of quartz by +.

2nd Sup.

A A

The following are the results of experiments made by this method:—

1. In white clay from Saarau (in Middle Silesia) containing on the average 53 p.c. of quartz-sand removable by levigation, the fire-resisting power was found equal to — 2 (this clay served for the preparation of the normal clay, by adding to it $\frac{2}{10}$ of its weight of pure alumina obtained in the preparation of soda from cryolite).
2. The same clay after levigation; + 2.
3. Blue clay from Saarau; + 2.
4. Another blue clay from the same locality; \pm to — 1.
5. A clay from Valendar near Coblenz; — 1; (the last three on account of their great cohesion could not be levigated).
6. Clay from Mirow (Poland) with 12·7 p.c. sand; — 3.
7. Clay from Grojecc (Poland) with 8·2 p.c. sand; — 3 to 4.
8. Clay from Poremba (Poland) with 20·03 p.c. sand; — 4.
9. Clay from Bielschowitz (Upper Silesia) with 27·7 p.c. sand; — 4.
10. Clay from Czielze with 15·94 p.c. sand; — 5 to 6.
11. Clay from Tillendorf (Silesia) with 30·11 p.c. sand; — 3.
12. Whitish-grey clay from Comprachezütz with 35·91 p.c. sand; — 4 to 5.
13. Blue clay from the same locality with 31·24 p.c. sand; — 6;
14. Blue clay from Brieg, with 26·15 p.c. sand; — 6.
15. White-grey clay from the same locality with 33·34 p.c. sand; — 5.
16. Argillaceous schist from Mettkau (Silesia), with 74·81 p.c. sand; various according to the fineness of the powder.

The chemical analysis of these clays gave the following results, the fine quartz-powder removed, together with the clay, by levigation, being reckoned with the sand:—

C. Bischof gives two methods of estimating the fire-resisting qualities of clays: 1. By determining the quantity of a normal mixture of pure silica and alumina which must be added to the clay, to render it infusible at a certain high temperature (*Diag. polyt. J. exciv. 420; excviii. 396*).

2. By Chemical Analysis (*ibid.* cc. 110 and 280).

(1). The first method is similar in principle to that of Richters, but is regarded by Bischof as more accurate. Small cylinders of the clay to be examined, are twice heated to the melting point of platinum; the cylinder is then weighed, crushed, and mixed with a test-substance consisting of 2 parts of pure alumina and 1 part of pure silica. This test-substance is added in proportions of $\frac{1}{10}$ of the weight of the cylinder.

the cylinder being heated to the melting point of platinum after each addition. This treatment is repeated until the cylinder remains unglazed and the structure becomes granulated. The pyrometric value of the clay is estimated by the quantity of the test-material required, this quantity varying from $\frac{3}{10}$ to $\frac{10}{10}$ of the weight of the cylinder.

(2). In judging of the fire-resisting qualities of clays from their chemical composition regard must be had: 1. To the proportion of the alumina and fluxes (*i.e.* the alkalis, alkaline earths, and ferrous oxide); 2. To the proportion of alumina and silica—

A clay is more refractory the greater the quantity of alumina which it contains in proportion to the fluxes, and the smaller the quantity of silica in proportion to the alumina. A simple expression for the relative pyrometric value may be obtained by dividing the number (A) which expresses the proportion of the silica and alumina taken together—*i.e.* of the aluminium silicate or true clay—to 1 part of the fluxes, by the number (B) which expresses the proportion of silica to 1 part of alumina.

The following table exhibits the composition of seven kinds of fire-clay, together with their relative fire-resisting powers, as directly determined by the first method; and, lastly, the quotients calculated from the chemical composition by the method just explained:—

Composition and Fire-Resisting Power of Clays.

	Formula	Fire-resisting power	Quotient $\frac{A}{B}$
CLASS I.			
a. Clay from Saarau, selected: purest and most refractory variety	$19.25(Al_2O_3 \cdot 1.38SiO_2) + RO$	100	$\frac{19.25}{1.38} = 13.95$
b. Average sample of clay from the same locality	$16.59(Al_2O_3 \cdot 1.69SiO_2) + RO$	100	$\frac{16.59}{1.69} = 9.70$
CLASS II.			
Levigated Kaolin from Zettlitz in Bohemia .	$12.82(Al_2O_3 \cdot 1.35SiO_2) + RO$	70—60	$\frac{12.82}{1.35} = 9.49$
CLASS III.			
a. Crude Kaolin from Saarau	$14.15(Al_2O_3 \cdot 5.01SiO_2) + RO$	50	$\frac{14.15}{5.01} = 2.82$
b. Belgium clay, from Strudmolsereul, near Ardennes	$6.86(Al_2O_3 \cdot 1.63SiO_2) + RO$	50	$\frac{6.86}{1.63} = 4.21$
CLASS IV.			
Clay from Mühlheim, near Coblenz; best average sample . .	$5.96(Al_2O_3 \cdot 1.51SiO_2) + RO$	45	$\frac{5.96}{1.51} = 3.95$
CLASS V.			
Clay from Grünstadt, in the Pfalz	$3.65(Al_2O_3 \cdot 1.54SiO_2) + RO$	30	$\frac{3.65}{1.54} = 2.37$
CLASS VI.			
Clay from Mönchsberg, near Cassel	$4.41(Al_2O_3 \cdot 2.37SiO_2) + RO$	20	$\frac{4.41}{2.37} = 1.86$
CLASS VII.			
Clay from Niederpleis, on the Sieg	$3.89(Al_2O_3 \cdot 2.37SiO_2) + RO$	10	$\frac{3.89}{2.37} = 1.64$

A comparison of these numbers leads to the following results:—1. The quotients in the fourth column decrease in the same order as the numbers in the third, which express the fire-resisting powers directly determined; and in the most refractory clays the differences of the quotients are large for small differences in the fire-resisting powers.

2. The crude Kaolin of Saarau, in Class III., forms a striking exception to this rule. Direct experiments showed, however, that this Saarau clay, when ground to an impalpable powder, is more fusible than the Mühlheim clay in Class IV., and appears more refractory in its crude state merely because it contains coarse grains of quartz.

3. It is remarkable, also, that the average sample of Saarau clay (Class I.) and the clay from Zettlitz (Class II.) give quotients so nearly equal, although they differ considerably in their fire-resisting power. But in this case, also, the peculiarity is due to the state of aggregation, the Zettlitz kaolin being in the state of an extremely soft powder, which yields to the softening influences of a high temperature more readily than the compact stony clay of Saarau.

In the preceding considerations no account has been taken of the proportions between the silica and the fluxes; and, indeed, Bischof shows that this proportion does not afford a satisfactory criterion of the pyrometric value of a clay. In the coal-formation of Saarbrück there are found, in the Wellesweiler and Duttweiler pits, two clays, belonging unmistakably to the same species, and having the character of slate-clays, but differing considerably in their degree of purity: the Wellesweiler clay being comparatively pure, whereas that from Duttweiler is more contaminated with sand, and especially with iron-oxide and magnesia. Their composition is given in the following table, I. denoting the clay from Wellesweiler, II. that from Duttweiler:—

	SiO ² and Sand	Al ² O ³	FeO	CaO	MgO	K ² O	Loss on ignition	
I. {	38.05	35.19	.28	.45	.31	1.13	13.70	= 100.61
	11.50							
II. {	29.35	25.13	1.95	.50	1.49	1.70	10.90	= 100.27
	29.25							

From which may be calculated the formulæ—

representing the following proportions:—

	I.	II.
Alumina to fluxes . . .	10.78 : 1	2.67 : 1
Alumina to silica . . .	1 : 1.61	1 : 2.67
Quotient	$\frac{10.78}{1.61} = 6.70$	$\frac{2.67}{2.67} = 1$
Silica to fluxes	17.36 : 1	7.13 : 1

Here, then, we see that although the ratio of silica to fluxes is much greater in I. than in II., the quotient $\frac{A}{B}$ is also greater: hence the greater fire-resisting power of the first variety.

In the two clays from Saarau (Class I.) the ratio of fluxes to silica is, in the refractory, as 1 : 27.70; in the more refractory, as 1 : 26.57. Lastly, in two clays from Namur, having respectively the formula $12.28(\text{Al}^2\text{O}^3.2.25\text{SiO}^2) + \text{RO}$ and $7.18(\text{Al}^2\text{O}^3.2.51\text{SiO}^2) + \text{RO}$, and giving for the first the quotient $\frac{A}{B} = 5.46$, for the second 2.86, the ratio of fluxes to silica is, in the first, which is the more refractory, 1 : 27.63, in the second, or more fusible, 1 : 18.02.

Whereas, then, in the clays from Saarbrück and from Namur, the ratio of silica to fluxes increases with the fire-resisting power, the contrary holds good in the clay from Saarau, the more refractory clay from this locality containing less silica in proportion to the fluxes than the less refractory.

These considerations show that though the determination of the quantities of silica

and fluxes contained in a clay is of this great importance for the determination of its fire-resisting power, the ratio of the silica to the fluxes does not of itself afford any safe criterion for that determination. Fire-clays, in fact, are double compounds, which cannot be correctly compared by a one-sided consideration of the ratio of silica to fluxes without regard to the alumina. This, indeed, Bischof has clearly shown by experiments on the fusibility of mixtures containing 100 parts of silica to 1, 2, and 4 parts of alumina, and 100 parts silica to 1, 2, and 4 parts of magnesia. The most fusible of these mixtures is that which contains 4 parts alumina to 100 silica. In presence of so large a proportion of silica, alumina is a better flux than magnesia. Independently, also, of the uncertainty attending the valuation of a fire-clay solely by reference to the ratio of silica to fluxes, the consideration of this ratio is, in fact, superfluous, the ratio of the aluminium silicate to the fluxes and of the alumina to the silica being quite sufficient to afford a trustworthy estimate of the pyrometric value of a clay. It is, of course, understood, that the analytical determinations must be made with all attainable exactness.

The following analyses of fire-clays are also by Bischof (*Diagl. polyt. J. cxxxiii. 29; cxxxv. 39; Jahresb. 1867, 920*): a. From Ebernheim near Vallendar, on the Rhine. b. From Mühlheim on the Rhine. c. From Grünstadt in the Bavarian Palatinate. The clays were analysed after drying at 100°.

COAL. *Estimation of Sulphur in Coal and Coke.*—The method usually adopted for the estimation of sulphur in coal and coke, consists in treating a known weight of the finely powdered material with nitromuriatic acid, and after digesting it at a moderate temperature until the whole of the sulphur is supposed to be converted into sulphuric acid, determining the latter as barium sulphate.

In operating in this manner there are several sources of error. In the first place, the figures obtained include the sulphur or sulphuric acid combined with calcium, as well as that existing as pyrites in the coal; and it is obviously most important, with regard to the use of coal in iron-smelting, that those figures should be returned separately, since the sulphur, combined with the calcium as sulphate or sulphide, is perfectly harmless, while the pyrites seriously affect the quality of the iron, by combining with it as ferrous sulphide during the process of smelting.

Again, in carrying out the above-mentioned process, unless the nitric acid be carefully and entirely removed by evaporation, grave errors in the weight of barium sulphate will ensue, and if the evaporation of the nitromuriatic acid be carried too far, a basic iron sulphate is sometimes formed, which even long boiling with water fails to remove from the carbonaceous mass, so that a deficiency of sulphur is entailed.

To remedy these defects, Calvert (*Chem. News*, xxiv. 76) operates in the following manner:—A weighed portion of the finely powdered coal is boiled in water with an equal weight of sodium carbonate for twenty hours, by which means the calcium sulphate is decomposed, while the iron sulphide remains unattacked. The residue is then filtered, and rapidly washed with boiling water. In the case of coke, nitric acid in slight excess must be added to the filtrate, to convert the sodium sulphide into sulphate, and the sulphuric acid therein determined in the usual manner. The sulphur found in the residue will then correctly represent the amount of pyrites present in the coal.

In estimating this latter, Calvert objects to the dry oxidising process, since it invariably entails a slight loss of sulphur. A more exact method is to oxidise with nitromuriatic acid, then concentrate the liquid, add sodium carbonate in excess, and heat the whole to near the fusing point, by which means the iron, silica, and alumina, are rendered insoluble. The mass is then treated with water, well washed, and the filtrate acidified with acetic acid; barium chloride will now precipitate the whole of the sulphuric acid from this solution.

The figures in the subjoined table contrast the results obtained from three distinct samples, when analysed by the old and by the improved method:

	Old process		New process		In washings		Difference
	Sulphur p.c.	Mean	Sulphur p.c.	Mean	Sulphur p.c.	Mean	
1.	{ 1.36 1.40	1.38	{ 0.60 0.58	0.59	{ 0.79 0.78	0.79	0.79
2.	{ 1.59 1.55	1.57	{ 0.63 0.67	0.65	{ 0.97 0.95	0.96	0.92
3.	{ 1.78 1.73	1.75	{ 0.89 0.85	0.87	{ 0.85 0.88	0.87	0.88

The relative proportions of iron and sulphur in the pyrites of Iowa coal have been determined by R. Emery (*Sill. Am. J.* [3] iii. 34). The coal was first treated with very dilute hydrochloric acid, so as to remove everything which was soluble in that menstruum. The residue was then oxidised with hydrochloric acid and potassium chlorate, and the percentage of iron and sulphur calculated in the usual manner.

Ten samples were examined. In four samples the relative proportions of iron and sulphur corresponded very closely with that existing in FeS_2 , viz., 53.3 p.c. of sulphur. In four samples there was a decided excess of sulphur, the percentage rising in two instances to 63.0 p.c., while in two samples there was a marked deficiency of sulphur, 45.0 and 50.0 p.c. only being found.

The results of the analyses of the coals of Ohio, by Prof. Wormley, show that in every instance the amount of sulphur present is too large for combination with the iron as bisulphide.

Gases enclosed in Coal. E. v. Meyer has examined the gases enclosed in coal from several coal-fields in Germany (*J. pr. Chem.* [2] v. 144, 418; vi. 389), and in English coal from the Newcastle and Durham districts (*ibid.* v. 407).

The gases were obtained by introducing two to four hundred grams of the coal into a flask, which was immediately filled up with hot de-aerated water, and the water was boiled so as to expel the gases from the coal, and drive them through a short straight tube fitted by a caoutchouc plug to the mouth of the flask into a number of tubes inserted in a basin of water supported on the end of the tube proceeding from the flask. The gases so collected were analysed by Bunsen's method.

	CO	O	N
7	48.7	1.8	49.5
8	38.2	1.2	60.6
9	54.9	1.2	43.9

Further experiments were made to determine whether exposure of a coal to a continued temperature of 50° caused an alteration resulting in further production of gas, or if the gases contained in it underwent any change of composition. The Zwickau coal, 1 (a), after the last of the analyses above quoted, was left between three and four months in a cool dry place, when it was found to give off gas of the composition—

CO² = 12.91, O = 2.57, N = 57.8, C²H⁴ = 22.62, CH⁴ = 4.06 per cent.

At the time that this examination was made, another portion of the coal was kept for two days at 45°, and then immediately treated in the usual manner, when it evolved gas as rapidly as the unwarmed portion. It was found to be free from marsh-gas. The composition of the gas was:—

CO² = 10.65, O = 3.2, N = 74.72, C²H⁴ = 9.8, and gas absorbed by sulphuric acid, 1.63 per cent.

By calculation it is shown that the heavy hydrocarbon is probably butylene.

It thus appears that on warming, the whole of the marsh-gas escapes first, by reason of its greater diffusibility.

The gases from another coal from Zwickau were also examined both before and after heating the coal to 50° for twenty-four hours. The hydrocarbons present were methane, ethane, and butylene. In the gas from the heated coal, some higher term of the paraffin series, probably propane, appeared to be present. The analytical numbers agree well with those required by:—

CO² = 15.6, O = 3.10, N = 73.33, C²H⁴ = 4.39, C²H² = 2.06, C²H⁶ = 1.75.

Coal from the Saar district yielded gases containing, besides methane, some of its homologues, which were calculated as C²H⁶. Ethene, which G. Bischof found, Meyer was unable to detect. The coal from the Gerhard pit is as hard and dense as Durham coal, and the gases contained in it resemble in quality and quantity those enclosed in the latter. The following table contains the results:—

Locality and time when the coal was examined	CO ²	CH ⁴	C ² H ⁴	O	N	100 grams gave a.c. gas

Max seam	2.90	89.93	—	—	7.27	15.0

Gases enclosed in English Coal.—The following are the results of the examination of the gases obtained from eight samples of coal from the Newcastle and Durham districts:—

- No. 1. Low Main seam, from Bewicke Main Colliery (Newcastle district).
 No. 2. Maudlin seam, from Bewicke Main Colliery (Newcastle district).
 No. 3. Main coal seam, Urpeth Colliery, Newcastle (Durham district).
 No. 4. 5-seam, Urpeth Colliery, 30 fathoms from surface.
 No. 5. 5-seam, Wingate Grange Colliery, Durham district, 74 fathoms from surface.
 No. 6. Low main seam, Wingate Grange Colliery, 108 fathoms from surface.
 No. 7. Hurvey seam, Wingate Grange Colliery, 148 fathoms from surface.
 No. 8. Hurvey seam, Emily Vil., Woodhouse Close Colliery, 25 fathoms from surface; district not given.

From the following table it will be seen that no other hydrocarbon than marsh-gas was found in any case:—

No. of Analysis	District	CO ²	CH ⁴	O	N	100 grm. gave — c. c. gas
1	Newcastle	5.55	6.52	2.2	85.65	25.2
2	"	8.54	26.54	2.95	61.97	30.7
3	Newcastle—Durham.	20.86	—	4.83	74.31	27.4
4	"	16.51	trace	5.65	77.84	24.4
5	Durham	0.34	85.8	trace	13.86	91.2
6	"	1.15	84.04	0.19	14.62	238.0
7	"	0.23	89.61	0.55	9.61	211.2
8	Unknown	5.31	50.01	0.63	44.05	84.0

Taking the specific gravity of coal as 1.3, it will be seen that Nos. 6 and 7 contain nearly three times their volumes of gases measured at ordinary pressures, and that therefore, as the coal is very hard and dense, the condensation of that gas must be very great.

Gases enclosed in certain Lignites.—(Kolbe u. Zitowitsch, *J. pr. Chem.* [2] vi. 79). The gas which accumulates in lignite mines has long been recognised and dreaded as consisting mainly of carbon dioxide, whereas marsh-gas has never been detected in it. The great oxidability of lignite has been demonstrated by the experiments of Varrentrapp (*Chem. Centr.*, 1865, p. 953).

The gases enclosed in Bohemian patent lignite, and in an earthy lignite of inferior quality, have been examined by Zitowitsch. The mode of collection was the same as that adopted by v. Meyer with pit-coal. The quantity obtained from both varieties was small, and was not determined. The gases were found to consist of carbonic anhydride, carbon monoxide, nitrogen and oxygen, in the following proportions:—

Gas from	CO ²	CO	N	O
I. } Bohemian lignite	80.60	1.80	8.03	0.51
II. }	82.40	3.00	14.15	0.45
III. } Earthy lignite	83.99	1.04	14.91	0.65

Coal Tar and Pitch. The composition of coal-tar varies considerably with the temperature at which coal is distilled; the higher the temperature the larger is the yield of solid bodies. Tar produced in gas-retorts contains more benzene and toluene, but also more naphthalene and other solid hydrocarbons than that obtained by distilling coal in coke-furnaces in which the distillation takes place at a lower temperature; the latter tar contains chiefly liquid hydrocarbons and a considerable quantity of compounds soluble in alkalis, but only a very small quantity of carbonic acid. When heavy coal-tar oil is allowed to run into a furnace heated to a bright-red heat, it yields, besides naphthalene, 2 per cent. of benzene and toluene and a little xylene, but only traces of higher homologues. At a lower temperature the decomposition of the oil is less complete, and at a higher temperature, the benzene is converted into naphthalene. In the furnaces there remains a kind of graphite, which is a very valuable fuel for producing high temperatures.

The pitch which is left behind in the distillation of tar is partially soluble in benzene and carbon sulphide; the residue consists of a black powder having the composition of Welsh anthracite. When pitch is passed through a red-hot tube, it yields about 250 vol. of a gas consisting almost entirely of hydrogen; but on distilling it from a retort, it yields about 25-30 per cent. of an oil containing pyrene, chrysene, and anthracene. The other products consist of 0.2 per cent. of light oils and gases containing ammonia and hydrogen, and 48-52 per cent. of coke is left behind. In some works the pitch is distilled with over-heated steam in order to obtain anthracene; in this case the residue is a very brittle pitch, which is mixed with naphthalene, and then used like the undistilled pitch, as asphalt, or as fuel, by mixing it with coal-dust and forming the mass into bricks, and for other purposes (Behrens, *J. pr. Chem.* [2] vi. 277).

COBALT. Co.—*Atomic Weight.*—R. II. Lee (*Sill. Amer. J.* [3] ii. 44) has determined the atomic weight of this metal by the analysis of crystalline cobaltcyanides of alkaloids having high atomic weight.

Commercial cobaltic oxide was first converted into an impure sulphate, and the solution of the salt treated with a current of hydrogen sulphide to remove all metals precipitable by that gas. The iron in the filtrate was peroxidised with chlorine, and afterwards removed, together with manganese, by the addition of barium carbonate. The solution was then treated with a large excess of barium carbonate, and gaseous hydrogen cyanide passed into the liquid, until the whole of the cobalt was converted into cobalticyanide of barium. The nickel, as well as traces of iron and manganese, still present in the solution, were removed by boiling with mercuric oxide, and the mercury having been removed from the filtrate by hydrogen sulphide, the solution of barium cobalticyanide was regarded as chemically pure.

The brucine and strychnine salts were prepared by decomposing the sulphates of these bases with the above solution of cobalticyanide, and repeatedly crystallising the salts formed. The crystals of the two alkaloids closely resemble each other; they are but slightly soluble in water, crystallising almost completely from their solutions on cooling. The water of crystallisation having been directly determined, the quantity of cobalt was found by carefully burning the salt in a platinum crucible, first in air, then in oxygen, and finally reducing the oxide to the metallic state by a current of pure hydrogen.

The atomic weight of the metal, calculated from the mean results of six analyses of the strychnine salt, was fixed at 59.05, and from a similar number of analyses of the brucine salt, at 59.15. As a check upon the foregoing numbers, another series of experiments was made by igniting the chloride of purplecobalt in a current of hydrogen. The atomic weight calculated from the per-centage of metal obtained was found to be 59.09.

The mean of all these determinations, eighteen in number, is 59.10: a result higher than those obtained by all other experimenters, except Schneider (60) and Sommaruga (59.93); almost identical with that of Dumas (59.08); differing somewhat more from that of Rothoff, and from the higher number given by Marignac (59.02), still more from Marignac's lower number (58.64), and from those of Winkler (58.92) and Russell (58.74).

Physical Properties.—According to Valenciennes (*Compt. rend.* lxx. 607) cobalt, after fusion and rolling, has the aspect of polished iron: it is harder, but may be rolled into spiral bands like good iron.

Respecting alloys of cobalt and copper, see COPPER.

On the coating of metals with Cobalt and Nickel, see Stolba (*Dingl. pol. J.* ccl. 145).

Detection, and Distinction from Nickel, Manganese, and Zinc.
a. By Sodium Sulphocyanate.—On adding a drop of a concentrated solution of cobalt to strong solution of sodium sulphocyanate, a blue coloration is produced, owing to the formation of a compound which crystallises, either at once or after spontaneous evaporation, in long blue needles insoluble in carbon bisulphide. When the cobalt solution is dilute, the colour appears only on warming. It is advisable to evaporate the cobalt solution nearly to dryness, add the sulphocyanate, and warm. In this way cobalt may be detected in one drop of a solution containing 0.0005 grm. in 1 c.c. Iron, nickel, zinc, and manganese do not interfere with the reaction, provided the solutions are neutral (Schönn, *Zeitschr. anal. Chem.* 1870, 209).

b. By Potassium Ferricyanide.—When a solution of a cobalt salt is mixed with ammoniac, ammonia, and excess of potassium ferricyanide, the liquid immediately assumes a deep blood-red coloration, similar in appearance to the reaction between potassium sulphocyanate and a ferric salt: the solution remains perfectly clear even on heating, and no precipitation whatever of the cobalt takes place.

When a salt of nickel is similarly treated, and the solution gently boiled, the liquid first becomes turbid, and in a short time deposits the whole of the nickel as a copper-red precipitate, which has a great tendency to adhere to the sides of the vessel. The presence of cobalt in no way interferes with the precipitation of the nickel, neither does this latter metal obscure the coloration produced by the cobalt: the foregoing test affords therefore a ready means of detecting these two metals when they occur together in the same solution.

When a solution of manganous sulphate is treated with ammonium chloride and ammonia, and potassium ferrieyanide gradually added, a whitish precipitate is formed, which changes, with the addition of more ferrieyanide, to a dark brown colour. As this reaction takes place immediately in the cold, it may serve to distinguish manganese from cobalt and nickel; the manganese, however, interferes with the subsequent tests for cobalt and nickel, when all three metals are present in the same solution.

An ammoniacal solution of zinc sulphate, in presence of ammonium chloride, is not precipitated, either in the cold or on boiling, by the addition of potassium ferrieyanide; but potassium ferrocyanide instantly throws down the zinc as a white precipitate.

Since the four metals, nickel, cobalt, manganese, and zinc, frequently occur in analysis in presence of ammoniacal salts, the above method may be useful as an additional mode of distinguishing between them. The characteristic reactions are:

1. A brown precipitate indicates manganese.
2. A deep red solution indicates cobalt.
3. No change in the cold, but a copper-red precipitate on boiling indicates nickel.
4. No change in either hot or cold liquid; a white precipitate on addition of potassium ferrocyanide indicates zinc (Allen, *Chem. News*, xxiii. 290).

Bromide, CoBr^2 . When metallic cobalt is left for about a week in contact with bromine and a little water, and the filtered purple solution is then evaporated, it assumes a splendid blue colour, and on evaporation over sulphuric acid, deposits purple-red prismatic crystals of the hexhydrate $\text{CoBr}^2 + 6\text{H}_2\text{O}$. This hydrate is both deliquescent and efflorescent; when heated to 100° it melts and gives off two-thirds of its water, leaving the dihydrate $\text{CoBr}^2 + 2\text{H}_2\text{O}$, which, on cooling, forms a mass of purplish-blue crystals covered with a blue opaque crust. This hydrate, which is deliquescent, gives off the whole of its water at 130° , leaving the anhydrous bromide in the form of a vivid green, deliquescent, amorphous mass (W. N. Hartley, *Paper read before the Chemical Society*, April 2, 1874).

Iodide, CoI^2 . Cobalt, treated with iodine and water, yields a red liquid which, when evaporated down till it turns green, and then placed over sulphuric acid, assumes a brown colour on cooling down to 16° , and after a day or two deposits the hexhydrate $\text{CoI}^2 + 6\text{H}_2\text{O}$ in large deliquescent hexagonal prisms having the colour of dark smoky quartz. When the red solution is evaporated down till a steam forms on the surface, and then left over sulphuric acid, it yields a compact mass of green deliquescent crystals consisting of the dihydrate $\text{CoI}^2 + 2\text{H}_2\text{O}$. This hydrate, on exposure to the air, deliquesces first to a green, then to a brown, and finally to a red solution. By heating either of these hydrates to 130° , the anhydrous iodide is obtained as a black mass, having a graphitic lustre (Hartley).

COBALT-BASES, AMMONIACAL (i. 1051; 1st Suppl. 477).

Dinitro-octammoniocobaltic or Croceocobaltic salts, $8\text{NH}_4^+\text{Co}^2(\text{NO}_2)^2\text{X}^2$ (Gibbs, *Sill. Am. J.* [3] vi. 116).—These salts are formed, like the xanthocobaltic salts, by the action of alkaline nitrites on ammoniacal solutions of cobalt, the production of a salt of one or the other series depending upon the conditions of the experiment.

The croceocobaltic salts resemble those of xanthocobalt; they have a fine sherry-wine colour, and are but sparingly soluble even in boiling water. They nevertheless crystallise well. The solutions are decomposed by boiling, with evolution of ammonia, but the addition of a small quantity of acetic acid prevents or retards the decomposition.

The nitrate $8\text{NH}_4^+\text{Co}^2(\text{NO}_2)^2(\text{NO}_3)^1$ is prepared by mixing a solution of cobaltous chloride with ammonium nitrate, and then with ammonium nitrate containing much free ammonia; the solution absorbs oxygen, acquires a deep orange colour, and after some time deposits the nitrate abundantly in orange-brown crystals. The reaction is:—

If potassium nitrite and cobaltous nitrate are used in this reaction instead of ammonium nitrite and cobaltous chloride, a similar orange-yellow crystallisation is obtained, which, however, on recrystallisation, separates into prismatic crystals of croceocobaltic nitrate and octahedral crystals of xanthocobaltic nitrate.

Croceocobaltic nitrate is most easily obtained in the pure state by boiling the sulphate with barium chloride and a little acetic acid. It crystallises in orange-yellow needles or prisms, slightly soluble in cold water, more soluble in boiling water and in dilute acid. It explodes when heated, though not violently. It is distinguished from xanthocobaltic nitrate by its crystalline form, and by yielding a splendid cinnabar-red precipitate with a solution of iodine in potassium iodide, and a precipitate of orange-yellow needles with potassium dichromate.

The sulphate $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{SO}^4$ is obtained by treating a solution of cobaltous sulphate with ammonia and potassium nitrite. The solution, on exposure to the air, gradually deposits orange-yellow crystals and a green flaky substance. On filtering, a bright green mass of cobaltic hydrate, mixed with orange-yellow crystals, remains in the filter, and the solution of this mass in boiling in very dilute sulphuric acid deposits the sulphate in crystals on cooling. From hot concentrated solutions the sulphate is deposited in small very brilliant yellow scales which, under the microscope, appear to belong to the quadratic system. In larger crystals it has a dark wine-red colour like that of xanthocobaltic salts. It is but slightly soluble in water, even at the boiling heat, more soluble in hot dilute sulphuric acid.

The chloride $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{Cl}^2$ is best prepared by boiling the crude sulphate with barium chloride, and a little hydrochloric acid. It forms beautiful iridescent crystals of the characteristic sherry-wine colour, which are rather more soluble than those of the sulphate. It combines with various metallic chlorides, forming double salts. The *aurchloride*, $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{Cl}^2\cdot 2\text{AuCl}^3$, forms an indistinctly crystalline precipitate of a fine canary-yellow colour. The *platino-chloride*, $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{Cl}^2\cdot \text{PtCl}^4$, separates in fine orange-brown prismatic crystals on adding a solution of sodium-platinic chloride to croceocobaltic nitrate.

The *chromate*, $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{CrO}^4$, and *dichromate*, $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{Cr}_2\text{O}^7$, are obtained by precipitating a solution of the nitrate with potassium monochromate or dichromate; the first forms brilliant lemon-yellow scales, the second orange-yellow needles.

The *periodide*, $8\text{NH}^+\cdot\text{Co}^2(\text{NO}^2)_2\cdot\text{I}^2$, is obtained as a crystalline precipitate of a magnificent cinnabar-red colour on adding a solution of iodine in potassium iodide to a solution of the nitrate. Heated with a solution of sodium sulphite it is immediately converted into the yellow di-iodide.

The chloride sulphate and periodide of this series may be represented by the following constitutional formulæ, 4 of the iodine-atoms in the last being regarded as trivalent:—

Erdmann's salt.—When potassium nitrite is added to a solution of cobaltous chloride-containing excess of ammonium chloride, oblique rhombic crystals are deposited, to which Erdmann assigned the formula $\text{Co}^2(\text{NH}^+)(\text{NO}^2)_2\cdot\text{K}^2$ (*1st Suppl.* 870). This salt exhibits a curious relation to the croceocobaltic salts, the number of atoms of NO^2 in either of the two being the same as that of the atoms of NH^2 in the other. Further, on adding a solution of Erdmann's salt to a solution of croceocobaltic nitrate, potassium nitrate is formed, and a double nitrite, $\text{Co}^2(\text{NH}^+)(\text{NO}^2)_2\cdot\text{Co}^2(\text{NH}^+)(\text{NO}^2)_2$, is precipitated, which gives the reactions of the croceocobaltic salts.

A few other octammoniated cobaltic salts have been described by various chemists. Gibbs and Gent, in 1856, obtained, in more than one reaction, small quantities of a leak-green crystalline precipitate, the base of which they termed provisionally *præcobalt*. This body was afterwards described by F. Ross, according to whose analyses its composition is $\text{Co}^2(\text{NH}^+)_4\cdot\text{Cl}^4$. Künzel (*J. pr. Chem.* lxxii. 218) obtained a hypsulphate which appeared to have the composition $\text{Co}^2(\text{NH}^+)_4\cdot\text{S}^2\text{O}^8$.

Flavocobaltic salts (Gibbs, *Deut. Chem. Ges. Ber.* iii. 42).—These octammoniated compounds are closely related to the xanthocobaltic salts; e.g.:

Flavocobaltic chloride is obtained by adding a hot solution of *purpureocobaltic chloride* to a solution of sodium nitrite mixed with a few drops of acetic acid; the liquid then acquires a deep orange colour, and, on cooling, deposits crystals of *flavocobaltic chloride*:

Flavocobaltic chloride is very much like *xanthocobaltic chloride*, and forms well-crystallised double salts with the chlorides of gold, platinum, tin, mercury, and other metals. Treated with an acid solution of silver nitrate, it yields *xanthocobaltic nitrate*, together with silver chloride and nitrite, according to the equation:

With ammonium oxalate it yields *xanthocobaltic oxalate*, together with ammonium chloride and nitrite. With potassium ferrocyanide, it yields *xanthocobaltic ferrocyanide*:

Flavocobaltic sulphate has the composition $10\text{NH}_3\cdot\text{Co}^2(\text{NO}_2)^2\cdot\text{SO}_4^4$; the *nitrate* is anhydrous and contains $10\text{NH}_3\cdot\text{Co}^2(\text{NO}_2)^4(\text{NO}_2)^2$. The chloride, sulphate and nitrate, are crystalline, have a deep orange-red colour, and are easily soluble in hot water; they give flocculent precipitates with cyanides of alkali-metal, and with the nitrates of platinum, cobalt, nickel and cadmium; *xanthocobaltic nitrate* does not form a precipitate with either of these reagents.

Purpureocobaltic chloride forms, with silver nitrate, a brown-orange-coloured solution which, after evaporation, deposits octahedral crystals of the salt $10\text{NH}_3\cdot\text{Co}^2(\text{NO}_2)^4$. We have, then, the following series of salts:—

Some *roseocobaltic* and *purpureocobaltic salts* are capable of taking up bromine and iodine by direct addition, forming crystalline, but very unstable, compounds. *Lutecobaltic salts* also unite with halogens (Gibbs).

Lutecobaltic chloride, $12\text{NH}_3\cdot\text{Co}^2\text{Cl}^2$.—Dana described the crystals of this salt as trimetric (i. 1055); but, according to recent measurements by C. Klein (*Ann. Ch. Pharm.* elxvi. 188) they are monoclinic, having the axes $a : b : c = 1.7115941 : 1 : 1.1128766$. Angle of inclined axes: $b, c = 57^\circ 31' 9''$. Principal angles: $0\text{P} : +\text{P}\infty = 113^\circ 12'$; $+ \text{P} : +\text{P}\infty = 151^\circ 45'$; $\infty \text{P} : \infty \text{P} = 127^\circ 30'$.

Observed forms (fig. 8):

more rarely: $+\frac{1}{2}\text{P}, \infty \text{P}\infty$, and as twin-face $+\frac{1}{2}\text{P}\infty$.

The crystals are sometimes tabular according to 0P , sometimes prismatic according to ∞P , in the latter case with felspathic development. They seldom occur as simple individuals, but frequently as aggregates, some of

FIG. 8.

which may be referred to regular twin-combinations, in which either: (1) the twin-axis is the principal axis, and the combination face is $\infty \text{P}\infty$; or (2) the twin-axis is the normal to $+\frac{1}{2}\text{P}\infty$; twin and combination face $+\frac{1}{2}\text{P}\infty$. The combinations formed according to the first law are contact-twins, always implanted by the end which exhibits the re-entering dome-angles; those formed according to the second law are either contact or intersecting twins. Besides these regular combinations, others frequently occur which are formed with a certain regularity, but cannot, perhaps, be called twin-crystals in the ordinary sense of the word. Their structure may be understood by regarding them as formed according to

the following law:—Twin-axis normal to the base; combination- and twin-plane, the base; angle of rotation 180° .

The plane of the optic axes is perpendicular to the plane of symmetry, and the first positive median line is nearly at right angles to OP, while the second coincides with the orthodiagonal.

Double salts of Luteocobaltic sulphate.—When a solution of this salt is mixed with a very acid solution of cerous sulphate, a very beautiful light yellow crystalline precipitate is formed, having the composition $12\text{NH}_4\text{Co}^2(\text{SO}_4)^2 + \text{Co}^2(\text{SO}_4)^2 + \text{H}_2\text{O}$, and capable of bearing a heat of 150° without decomposition. When a neutral solution of cerous sulphate is mixed with luteocobaltic sulphate, a cerous double sulphate is formed, having the composition $12\text{NH}_4\text{Co}^2(\text{SO}_4)^2 + 3\text{CeSO}_4 + \text{H}_2\text{O}$. This salt forms small crystals undistinguishable under the microscope from those of the ceric double salt, and apparently isomorphous with them. Exactly similar cerous and ceric salts are formed with rosecobaltic sulphate. These, likewise, appear to be isomorphous, but they do not form measurable crystals (C. H. Wing, *Deut. Chem. Ges. Ber.* vi, 508).

COBALT-YELLOW. The yellow precipitate formed by the action of potassium nitrite on cobaltous salts was regarded by Stromeyer as a basic potassio-cobaltic nitrite, $3\text{K}^2\text{O} \cdot \text{Co}^2\text{O}_3 \cdot 5\text{N}^2\text{O}^3$ or $\text{K}^6(\text{Co}^2)^{10} \left\{ \begin{smallmatrix} (\text{NO}_2)^{10} \\ \text{O}'' \end{smallmatrix} \right\}$ (i. 1058). Erdmann, however, afterwards showed (*J. pr. Chem.* xvii. 385; *Jahresb.* 1866, 248) that the composition of the precipitate thus formed varies accordingly as the solution is acid or neutral: a neutral solution of cobaltous chloride yielding with excess of potassium nitrite a yellow crystalline precipitate of *potassio-cobaltous nitrite* $3\text{CoK}^2(\text{NO}_2)^4 + \text{H}_2\text{O}$, or $3(\text{CoO} \cdot \text{N}^2\text{O}^3 + \text{K}^2\text{O} \cdot \text{N}^2\text{O}^3) + \text{H}_2\text{O}$, its composition being the same whether the precipitation takes place in contact with the air or in an atmosphere of carbonic anhydride, whereas a solution mixed with excess of acetic acid yields salts of more complex and somewhat uncertain composition, containing, according to circumstances, either cobaltous or cobaltic oxide. These observations have been confirmed by Sadtler (*Sill. Am. J.* [2] xlix. 189), who finds that when a solution of cobaltous chloride strongly acidulated with acetic acid is mixed with a concentrated solution of potassium nitrite, a salt is formed which, after washing, first with potassium acetate and then with alcohol, has the composition of *tripotassio-cobaltic nitrite* $\text{Co}^2\text{O}_3 \cdot 3\text{N}^2\text{O}^3 + 3(\text{K}^2\text{O} \cdot \text{N}^2\text{O}^3)$ or $\text{Co}^2\text{K}^6(\text{NO}_2)^{12}$. According to the concentration of the solution employed, it separates in combination with 4, 3, 2, 1 mol. water, or in the anhydrous state, the colour varying accordingly from light yellow to dark greenish-yellow. It is easy to see, therefore, that mixtures of these several hydrates will frequently separate out, and it is difficult to give an exact process for obtaining either of them in a definite state.

A solution of cobaltous chloride kept constantly acidulated with acetic acid yields, on addition of sodium nitrite, first a brown precipitate of *tetranodio-cobaltic nitrite* $\text{Co}^2(\text{NO}_2)^6 + 4\text{NaNO}_2 + \text{H}_2\text{O}$, and, on further addition of sodium nitrite, *triodio-cobaltic nitrite* $\text{Co}^2(\text{NO}_2)^4 + 6\text{NaNO}_2 + \text{H}_2\text{O}$. The solution of the latter salt mixed with luteocobaltic chloride yields a yellow crystalline salt insoluble in water, in which the sodium is replaced by luteo-cobalt, its formula being $\text{Co}^2(\text{NO}_2)^4 + \text{Co}^2(\text{NH}_2)^{12}(\text{NO}_2)^6 + \text{H}_2\text{O}$. In like manner are obtained the corresponding *rosecobaltic salt* $\text{Co}^2(\text{NO}_2)^4 + \text{Co}^2(\text{NH}_2)^{10}(\text{NO}_2)^8$, and a *xanthocobaltic salt* which, however, has not been analysed. The corresponding ammonium salts, viz., *tetrammonio-cobaltic nitrite* $\text{Co}^2(\text{NO}_2)^6 + 4(\text{NH}_4)\text{NO}_2 + 2\text{H}_2\text{O}$, and *hexammonio-cobaltic nitrite* $\text{Co}^2(\text{NO}_2)^4 + 6(\text{NH}_4)\text{NO}_2 + 2\text{H}_2\text{O}$, have also been obtained; but the conditions of their formation have not been ascertained further than that the hexammonio-compound is formed when strong solutions of ammonium nitrite and cobaltous chloride are employed. No substituted compounds have been obtained from these ammonio-salts.

A warm neutral solution of cobaltous chloride yields, on addition of a dilute solution of potassium nitrite, first a black or green crystalline precipitate of *potassio-dicobaltous nitrite* $2\text{Co}(\text{NO}_2)^2 + 2\text{KNO}_2 + \text{H}_2\text{O}$, afterwards a yellow, slightly crystalline or amorphous precipitate of *potassio-monocobaltous nitrite* $\text{Co}(\text{NO}_2)^2 + 2\text{KNO}_2 + \text{H}_2\text{O}$, the latter agreeing in composition with the salt which Erdmann obtained under similar circumstances, except in the amount of water (Sadtler).

COBALTCYANIDES. See CYANIDES.

COCCOGNIN, $\text{C}^{20}\text{H}^{22}\text{O}^8$. A colourless crystalline substance contained in the seeds of *Daphne Mezereum*. It is sparingly soluble in water, easily in alcohol and ether, sublimes when heated, emitting an odour like that of coumarin; it differs from daphnin by not yielding sugar when boiled with dilute sulphuric acid (Caselmann, *Zeitschr. f. Chem.* [2] vi. 681). See DAPHNE.

COCHINEAL. The following determinations of the composition of cochineal

and carmine, from various sources, have been made by C. Mène (*Compt. rend.* lxxiii 666):—

	Cochineal				Carmine			
	Guatemala	Canaries	So-called dead	Java	So-called Chère Vert	From Provence	From Spain	From Poland
Water and loss	4.700	6.060	4.135	8.033	7.214	6.435	6.855	6.217
Stearin . . .	8.155	10.131	3.090	4.255	3.108	2.925	2.935	3.120
Margarin . . .	8.451	8.293	3.007	3.108	1.435	1.409	1.517	2.006
Insol. matter	6.172	6.004	12.712	14.159	12.735	11.728	11.892	14.415
Nitrogenous matter	7.115	7.152	15.115	12.152	15.355	14.915	14.925	13.277
Substances soluble in water . . .	13.208	10.031	30.674	17.617	25.965	30.248	33.841	37.755
Colouring matter . . .	48.823	49.007	26.172	33.795	26.955	24.190	20.975	15.100
Ash . . .	3.376	3.322	5.065	6.210	6.233	8.150	7.060	8.080

• **Colouring matter of Cochineal: Carmine or Carminic Acid.**—The salts of carminic acid are generally violet. Pure calcium carminate, however, is a black precipitate which appears greenish when in thin layers. It is formed by treating carminic acid or a decoction of cochineal with calcium bicarbonate. The precipitate produced is insoluble in water and in alcohol, but dissolves in concentrated acetic acid. In contact with an excess of lime-water the black carminate becomes deep violet, the solution also assuming the same colour. The lime employed in these experiments contained no traces of iron (Guignet, *Bull. Soc. Chim.* [2] xviii. 162).

Testing.—J. M. Merrick (*Pharm. J. Trans.* [3] i. 906; *Chem. Soc. J.* [2] ix. 501) compares the colouring power of different samples of cochineal by boiling equal weights of the samples with water for the same time (2 grams with 750 c.c. water for half an hour), and adding a weak solution of potassium permanganate to equal volumes of these decoctions till the original deep red colour changes to a very pale pink, almost yellow. The quantities of colouring matter in the samples thus treated are directly proportional to the quantity of permanganate required to produce this change of colour.

Spectroscopic characters.—An ammoniacal solution of carmine, examined by the spectroscope, exhibits two dark absorption-bands between the Fraunhofer lines D and E, like those of blood, one situated at 8°, the other at 9°–10° of a spectroscope having a scale of 20°, in which the sodium line falls at 7.7°. With such a spectroscope, therefore, it would be impossible to distinguish an ammoniacal solution of carmine from that of blood.

The aqueous solution of cochineal does not exhibit any dark bands, but on adding ammonia in quantity sufficient to give the solution a red colour inclining to violet, the two dark bands of the ammoniacal carmine solution make their appearance (Campani, *Gazzetta chimica italiana*, i. 471).

Nitrococcus acid, $C^6H^3(NO^3)_3O^2$.—This acid, which De La Rue obtained by the action of nitric acid on carminic acid (i. 804), may also be prepared by gradually adding finely powdered carmine to boiling nitric acid (sp. gr. 1.37) as long as the violent evolution of red vapours lasts. On cooling, the liquid solidifies to a mass of crystals of oxalic acid and nitrococcus acid, which are separated by recrystallisation from very dilute nitric acid. The nitrococcus acid is thus obtained in large silvery plates. On heating it with water in closed tubes to 180°, it splits up into carbon dioxide and trinitrocresol, $C^6H^3(NO^3)_3OH$, identical with that which Ducloux obtained from coal-tar cresol. This reaction shows that nitrococcus acid is one of the isomeric trinitrocresotic acids, and that the colouring matter of cochineal contains methylated benzene-residues (Liebermann & van Dorp, *Dent. Chem. Ges. Ber.* iv. 655).

Rufococcin, $C^6H^3O^2$.—On heating a solution of carmine in concentrated sulphuric acid, the yellowish-red colour of the solution changes at 120° into violet, carbon

dioxide and sulphur dioxide being evolved at the same time; and if, after the temperature has been kept for some time at 140°-150°, the liquid be poured into cold water, rufiococin is obtained as a brown precipitate, which may be purified by washing, drying, exhausting with boiling alcohol, and evaporating the solution.

It is very sparingly soluble in cold water; dissolves in alcohol with a fine yellow fluorescence. When heated it gives off red vapours which condense to yellowish-red needles. It yields a calcium-compound having the composition $C^{14}H^{14}CaO^4$.

By heating rufiococin with zinc-dust, a solid crystalline hydrocarbon, $C^{16}H^{12}$, is obtained, which sublimes in white plates, melting between 183° and 188°. It yields by oxidation a quinone resembling anthraquinone, but melting at 250° (anthraquinone melts at 275°).

Another body formed at the same time as rufiococin, by the action of sulphuric acid on carmine, appears to have the formula $C^{22}H^{22}O^{12}$; and inasmuch as it yields, after heating with baryta-water, the same hydrocarbon as rufiococin, it appears to contain the same carbon-nucleus (Liebmann a. van Dorp, *ibid.* iv. 656; *Ann. Ch. Pharm.* clxiii. 97).

Rufiocarmine, $C^{14}H^{12}O^4$, another condensation-product of carmine-red, is formed by heating carmine with water. A dark resinous body is then deposited, from which rufiocarmine may be extracted by ether. It is a carmine-coloured powder, differing from carmine-red by its total insolubility in water, and from rufiococin by its extreme solubility in alcohol.

Rufiococin and rufiocarmine are intimately related to coccinin, the substance which Hlasiwetz a. Grabowski obtained by fusing carmine-red with potash (1st *Suppl.* 414). These chemists assigned to it the formula $C^{24}H^{12}O^3$, but their analytical numbers agree equally well with the formula $C^{24}H^{16}O^4$; in fact, coccinin gives by analysis very nearly the same per-centage of carbon as rufiococin, and a larger proportion of hydrogen, as appears from the following comparison:—

	Rufiococin, according to Liebmann a. van Dorp					Coccinin, according to Hlasiwetz a. Grabowski			
C	61.10	63.58	63.78	63.93	61.47	61.8	61.3	61.5	65.0
H	4.51	4.05	3.66	3.76	3.67	4.8	4.3	4.3	4.7

It has not, however, been found possible to obtain coccinin from rufiococin or rufiocarmine by the action of sodium-amalgam or by fusion with alkali (Liebmann a. van Dorp).

COCKCHAFER. *Melolontha vulgaris*.—These insects contain, together with leucine and other substances, a colourless crystalline substance called melolonthine (*q. v.*).

COCOA-NUTS. The fatty matter extracted from these nuts is used almost exclusively for the manufacture of toilet soap. The cake left after the extraction of the fat is used in England as fodder for cattle, in Italy as manure.

The oil-cake of the cocoa-nut was examined some years ago by Grouven (*Wochenblatt der Annalen der Landwirtschaft*, 1866, p. 453), who found:—

In 100 parts of the air-dried oil-cake—

Proteids	Oil	Cellulose	Water
21.20	8.60	7.70	9.36;

and in 100 parts of the ash (CO^2 deducted)—

K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ²	SiO ²	Cl
40.67	2.30	4.71	2.95	3.54	26.08	3.78	3.38	13.42

As, however, the cocoa-nuts now sent to Europe are of selected quality, and more carefully freed from the other parts of the fruit than formerly, and as, moreover, many improvements have been made in the extraction of the fat, it has been thought worth while to make a fresh examination of the cocoa-nut and of the oil-cake, such as is obtained for the soap-works of Cav. Mazzuchetti, in Turin, and sent in large quantities to England as fodder for cattle:

	Cocoa-nuts in the natural state	Oil-cake from Mazzuchetti's Soap-works
Water	5.80	11.60
Fat (extracted by CS^2)	67.85	12.34
Cellulose	21.80	69.46
Mineral substances	1.55	6.11
	100.00	100.00

100 parts of the fresh oil-cake contain 2.75 p.c. nitrogen, and 100 parts of the cake contain 24.35 p.c. phosphoric anhydride (Nallino, *Gazzetta chimica italiana*, 11. 20).

CODANINE. Hesse, in his latest communication on the opium-bases (*Ann. Ch. Pharm., Suppl.* viii. 261), assigns to this compound the formula $C^{20}H^{23}NO$ instead of the former one $C^{21}H^{23}NO$ (*1st Suppl.* 480). He finds that it melts at 126° when crystallised from benzene, and at 121° when crystallised from alcohol or ether; with ferric chloride it forms a dark green liquid, with separation of ferric oxide. It appears to form compounds with caustic alkalis.

CODEINE. $\text{C}^{18}\text{H}^{21}\text{NO}^3$, or $\text{C}^{18}\text{H}^{19}\text{NO}^4$. *Action of Hydrobromic acid* (Wright, *Proc. Roy. Soc.* xix. 371, 504).—It has been shown by Matthiessen and Wright (*1st Suppl.* 480) that when codeine is heated with a large excess of strong hydrochloric acid, the following reactions successively take place:—

Coupling

Chlorococaine

Chlorocodide

Amorphous

When codeine is gently heated with hydrobromic acid, the first stage of the reaction appears to be similar to that of hydrochloric acid, yielding bromocodide, $C^{36}H^{42}Br^2N^2O^4$, analogous to chlorocodide; but this base appears to be further acted on with great ease, giving rise to two others, viz., dioxycodine, $C^{36}H^{42}N^2O^4$, soluble in ether, and bromo-tetracodine, $C^{44}H^{66}Br^2N^2O^4$, insoluble in ether. These reactions may be represented as follows:—

Bronze's solid

Codeine

Deoxycodine

Bromo-tetracodeine

Moreover, the formation of bromocodido is preceded by that of a brominated base having the composition $C^{16}H^{13}BrN^2O^4$, the action in this respect also being analogous to that of hydrochloric acid.

Bromocodide is not easily obtained pure on account of the facility with which it is altered; but by digesting 1 part of codeine at 100° for an hour or two with 3 parts of acid solution (containing 48 p.c. HBr); precipitating with excess of sodium carbonate; filtering to remove excess of codeine, which remains dissolved; exhausting the precipitate with ether; and agitating the ethereal solution with hydrobromic acid, crude hydrobromide of bromocodide is produced; and by repeating the process and precipitating fractionally to remove colouring matters, the purified hydrobromide is obtained, yielding by analysis numbers agreeing nearly with the formula $C^{10}H^{15}BrN^3O_2 \cdot 2HBr$.

Crude hydrobromide of bromocedonic, obtained by digesting cedonic for five or six hours with from three to five times its weight of acid containing 48 p.c. HBr, deposits, on standing for some days, crystals not readily soluble in cold water; these recrystallised several times from boiling water, produce minute snow-white crystals which slightly darken in colour on drying over oil of vitriol, and on analysis give numbers agreeing with the formula of deoxycedonic hydrobromide, $C^{10}H^{15}N_2O \cdot 2HBr$.

Bromotetracodecine is conveniently obtained as hydrobromide by treating codeine with three times its weight of hydrobromic acid containing 48 p.c. HBr for two hours on the water-bath, precipitating the product (diluted with water) with excess of sodium carbonate, exhausting the well-drained precipitate with ether, dissolving the residue in the smallest possible quantity of weak hydrobromic acid, and fractionally precipitating by cautious addition of stronger acid. The second precipitate is dissolved in water, in which it is readily soluble, and a few drops of solution of sodium carbonate are added. The filtrate from this yields, with strong hydrobromic acid, nearly white flakes, which are wholly devoid of crystalline character under the microscope. These remain solid at 100°, if previously completely dried over oil of vitriol, but, if warmed while moist, are converted into a more or less coloured tar. Dried at 100°, they give numbers agreeing with the formula, $C_{27}H_{45}BrN^{(O)}_{12} \cdot 4HBr$.

Sodium carbonate throws down from the hydrobromide a nearly white precipitate, which rapidly darkens, and finally becomes deep green or nearly black, owing to rapid absorption of oxygen; an analysis of the altered product gave the formula for bromotetradecine plus 9 atoms of oxygen; the salts, however, when dry, may be kept without alteration, and slowly darken by exposure to air only when moist.

The qualitative reactions of bromotetradecine appear to be identical with those of bromo- and chloro-codide. The base itself, when freshly precipitated, is slowly soluble in water, being thrown down again by the addition of strong brine; in ether and benzene it is almost insoluble, and in alcohol but sparingly soluble.

When crude bromotetracadeine is dissolved in weak hydrochloric acid, and precipitated twice or thrice by excess of stronger acid, nearly white flakes are ultimately obtained, which, when dried over oil of vitriol and finally at 100°, have the composition of the hydrochloride of chlorotetracadeine. $C_{14}H_{19}ClNO_2 \cdot 8HCl$.

2nd Sup. Chlorotetracodeine, in all its physical and chemical properties, closely resembles

bromotetracodeine^{*}; the qualitative reactions of the two bases are identical, they have an intensely bitter taste, and apparently but slight physiological action, at any rate in small doses.

When hydrobromide of bromotetracodeine is heated with hydrobromic acid, the homologous base bromotetramorphine is produced, with elimination of hydrogen bromide:—

By the action of hydrochloric acid in the cold on bromotetramorphine, the corresponding chlorinated base, chlorotetramorphine, is formed; and by interrupting the action of hydrobromic acid on codeine at a certain point, a base intermediate between bromotetramorphine and bromotetracodeine appears to be formed; and this, by the action of hydrochloric acid, is converted into the corresponding chlorinated base chloro-dicodeno-dimorphine, $\text{C}^{10}\text{H}^{106}\text{Cl}^2\text{N}^2\text{O}^2$.

By the action of hydrobromic acid on bromocodide, methyl bromide is formed, and simultaneously bromotetramorphine, and apparently a base, deoxymorphine, $\text{C}^8\text{H}^{52}\text{N}^2\text{O}^2$, homologous with deoxycodeine; this latter, like its homologue, much resembles apomorphine in chemical characters, but produces no vomiting; it is doubtful whether deoxymorphine has been obtained perfectly free from deoxycodeine. From these results, taken in conjunction with former ones, the following formulæ are ascribed to the corresponding bases:—

Deoxymorphine does not seem to be produced by the action of hydrobromic acid on deoxycodeine, the only product being a black substance unfit for analysis, along with a little methyl bromide.

Dr. Michael Foster has examined the physiological action of the foregoing derivatives, and finds that the chloro- and bromotetracodeine and tetramorphine salts produce in adult cats a condition of great excitement, almost amounting to delirium in younger animals; a want of co-ordination of muscular movements follows, terminating in sleepiness, stupor, and death. Paralysis of the inhibitory fibres of the pneumogastric appears to be produced in cats and dogs; with rabbits all these salts appear to be almost inert.

Deoxycodeine and deoxymorphine salts are absolutely destitute of emetic properties; in adult cats they produce convulsions of an epileptic character, followed by the symptoms observed in the case of the tetra-bases. No marked difference could be detected between the hydrobromides and hydrochlorides of either base; whereas with the tetra-bases, the morphine-compounds appeared to be rather more potent than their higher homologues.

Action of Hydrochloric Acid.—By acting for 2½ hours on codeine with 6 to 8 parts of strong hydrochloric acid a viscid uncrystallisable product is obtained, which is inferred from its analysis to be a mixture of the hydro-chlorides of two chlorinated bases, viz.:

From these mixed hydrochlorides sodium carbonate throws down a mixture of the bases $\text{C} + \text{HCl}$ and $\text{C} + 2\text{HCl} - 2\text{H}^2\text{O}$, both of which are soluble in ether, and form non-crystalline salts; the second is identical with chlorocodide derived from codeine by substitution of Cl^2 for 2HO .

It thus appears that the formation of chlorocodide is preceded by that of a base containing only 1 atom of chlorine to 36 atoms of carbon, and consequently chlorocodide must be represented by a formula containing C^{36} at least; but as ordinary codeine is formed from chlorocodide by the action of water (1st Suppl. 480), chlorocodide must be a derivative of ordinary codeine, and not of any of its higher polymers, and consequently the molecule of codeine must also contain 36 atoms carbon.

By the long-continued action of hydrochloric acid on the mixture of bases produced

as above, different results are obtained according to the circumstances of the experiment. Matthiessen & Wright showed (1st Suppl. 839), that by acting on codeine in sealed tubes at 140°-150° with strong hydrochloric acid, methyl chloride is formed, and apomorphine results, *identical with that obtained from morphine*. When, however, the action is allowed to take place at 100°, different bodies result; methyl chloride is eliminated, but the elements of water are not removed to such an extent as to produce apomorphine, two isomeric bases being then formed, intermediate in composition between morphine and apomorphine. One of these bases yields crystalline salts, and is readily soluble in ether; the other is insoluble in that liquid, and gives amorphous salts, and evidently belongs to the 'tetra' series. The two bodies are, therefore, considered to have respectively the formulæ:

and are respectively termed *diapo-dimorphine* and *tetrapo-tetramorphine*. In physiological effects, diapo-dimorphine does not resemble tetrapo-dimorphine (apomorphine), the experiments of Dr. J. G. Blackley indicating that doses of 0.1 gram given subcutaneously to cats do not produce vomiting but only profuse salivation. The removal of the elements of water from (hypothetical) dimorphine and from tetramorphine gives rise to a different kind of alteration in the physiological effect (on cats) of the resulting product, the emetic action being *less* in the first case the more of the elements of water are removed, and *more* so in the second case.

Action of Hydriodic Acid on Codeine in presence of Phosphorus (Wright, *Proc. Roy. Soc.* xx, 8). The first action appears to be in accordance with the equation:

the quantity of methyl iodide evolved being close upon that required by theory; this evolution of methyl iodide does not take place however in the absence of phosphorus, much iodine being set free in that case.

According to the action of hydriodic acid (3 to 5 parts of 50 per cent. acid) and phosphorus ($\frac{1}{15}$ part) upon codeine (1 part) takes place at 100° or at higher temperatures, different products are obtained, all of which may be considered as derived from morphine hydriodide by quadruplication of the molecule, addition of hydrogen and hydriodic acid to the product, and further alteration of the resulting compound by successive subtraction of the elements of water and of oxygen. Thus, if the reaction takes place at 100°, the product may be viewed as formed by the equation:

If the mixture be gently boiled so that the boiling point rises to 110°-115° by the time that methyl iodide ceases to be evolved, the product obtained contains 4H²O less than this formula; whilst, if the boiling be performed rapidly, so that the boiling point rises to 130°-135°, the end-product contains O⁸ less than this latter body: thus—

These three substances much resemble each other; they form colourless tarry masses, which rapidly become yellow by exposure to air; when quite dry they do not soften at 100°; water dissolves them with decomposition; from the solution bases derived from the original compounds by subtraction of the elements of HI may be obtained. Their qualitative reactions are identical with those of their derivatives, but utterly different from those of the codeine derivatives previously examined.

Denoting a hypothetical base, C³⁴H⁴⁰N²O⁴, by the symbol X, and another, C³⁶H⁴²N²O⁶, by the symbol Y, these three bodies and their derivatives may be all included in one or other of the two general formulæ:

By dissolving the product obtained at 100° (4X + 12HI) in boiling water and boiling for some time, flakes of a peculiar microscopical structure are obtained on cooling the liquid; the same product is also formed from the substance obtained at 110°-115° by similar treatment, and is produced by the reactions:

On similarly treating the substance thus obtained, a further reaction takes place, indicated by the equation :

If the original product formed at 130°-135° be treated in like manner, it finally yields an analogous substance formed by the reaction :

the elements of 8 molecules of water being thus taken up.

On treating the original codeine-products with alkalis, the same reactions appear to ensue : yielding the free bases $(4X + 2HI - 4H^2O)$, $(4X + 4HI)$ and $(4X - 4H^2O)$. Of these the one containing no iodine is least soluble in ether, and the one containing most iodine is the most soluble ; they readily absorb oxygen from the air.

On again subjecting these derivatives formed by water or alkalis to the action of hydriodic acid, bodies are produced, not identical with those first obtained from codeine, but still belonging to the same family, and denoted by the same general formulæ. The reactions represented by the following equations have been verified quantitatively :

Polymerisation of Codeine by the action of Phosphoric Acid.—When codeine is polymerised by the action of hydrobromic or hydriodic acid, as in the reactions previously described, part of the hydrogen in the polymeride is always replaced by bromine or iodine, forming such products as bromotetracodeine, di-iodotetracodeine, &c. By the action of phosphoric acid, however, polymerides are formed without the occurrence of these substitutions. When 1 part of codeine, 3 of glacial phosphoric acid, and 5 of water, are very gently boiled in an open vessel until the temperature rises to nearly 200°, a considerable quantity of the codeine becomes polymerised, forming simultaneously *dicodeine* $C^{12}H^{18}N^2O^{12}$, and *tetracodeine* $C^{14}H^{22}N^2O^{14}$, which are sharply distinguished from codeine and from each other by their physical properties and chemical reactions. The first of these bases forms a crystalline hydrochloride, whose water of crystallisation is lost at 100°, the base itself being amorphous and immediately precipitated from its salts by sodium carbonate; whereas codeine is crystalline, and not immediately precipitated by sodium carbonate, and its hydrochloride, as shown by Matthiessen and Wright (*Proc. Roy. Soc.* xviii. 87), loses none of its water of crystallisation on drying over the water-bath at a temperature probably a little below 100°. Tetracodeine is amorphous, forms amorphous salts, and differs from codeine and dicodeine by being insoluble in ether.

These polymerides, obtained by the action of phosphoric acid, appear to be identical with the products formed by treating codeine with dilute sulphuric acid, viz., dicodeine with the amorphous isomeride of codeine which Armstrong obtained by heating codeine with dilute sulphuric acid for a short time only (*Chem. Soc. J.* [2] ix. 56), and tetracodeine with the amorphous codeine which Andersen obtained by the prolonged action of the same reagent (*Ed. Phil. Trans.* xx. [1] 57). On repeating the processes of these chemists, Wright obtained products apparently identical with those of the action of phosphoric acid, with this difference only, that Armstrong's process appears to give rise to a small quantity of another polymeride (in addition to dicodeine), which is non-crystalline and soluble in ether. Its hydrochloride utterly refuses to crystallise, and its reactions are different from those of either of the other polymerides. The dicodeine is separable from this by repeated crystallisation of its hydrochloride until the salt ceases to give a blood-red coloration on addition of nitric acid, the tint produced by pure dicodeine being a yellow orange, not intense. From the circumstance that in many instances this polymeride exhibits similarity to dicodeine, but in others to tetracodeine, Wright regards it as probably intermediate, i.e. as *tricodeine*, $C^{10}H^{12}N^2O^{11}$.

Hydrochloric acid acts on these polymerides very differently. On tetracodeine it has no action whatever after six hours' ebullition ; with tricodeine at 100° for 1½ hours it produces the following reaction :—

and with dicodeine the following :—

With codeino, as already observed, the first action appears to be to form an addition-product, thus:—

from which water is subsequently eliminated.

The composition of these chlorinated derivatives affords further proof that the lowest admissible formula of codeine is $C^{20}H^{12}N^2O^6$, and that of diocodeine $C^{22}H^{14}N^2O^{12}$. The reactions of tetracodeine, as shown below, lead to $C^{24}H^{16}N^2O^{24}$ as its lowest formula. The product $C^{20}H^{14}N^2O^{12}$ from tricodeine much resembles in its properties the apocodeine of Matthiessen and Burnside (*1st Suppl.* 481), produced by the action of zinc chloride on codeine; probably, therefore, this action gives rise to a mixture of 'apo' derivatives of the general formula $(C^{18}H^{10}NO^2)_n.HCl$, in which the derivative $n = 6$ predominates.

Hydriodic acid, in conjunction with phosphorus, acts differently on diocodeine and tetracodeine. Tetracodeine hydriodide boiled with hydriodic acid till the boiling point rises to 130° is decomposed as shown by the equation:

the product being the hydriodide of a tetra-base insoluble (or nearly so) in ether.

Diocodeine becomes polymerised to a tetra-base nearly insoluble in ether, but in addition to methyl-elimination, hydrogen-addition takes place:—

the formula of the product proving that the minimum formula of tetracodeine must contain C^{14} and not C^{12} only. The hydrogen-addition, however, does not go so far as it does when ordinary codeine is employed; thus:—

Codeine at 100°	produces . . .	$8(C^{17}H^{10}NO^3 + H^2)$	+ 12HI
" " 110° – 115°	" . . .	$8(C^{17}H^{10}NO^3 + H^2)$	+ 12HI – $4H_2O$
" " up to 130°	" . . .	$8(C^{17}H^{10}NO^3 + H^2 - O)$	+ 12HI – $4H_2O$
Diocodeine " 120°	" . . .	$8(C^{17}H^{10}NO^3 + H)$	+ 9HI – $4H_2O$
Tetracodeine " 130°	" . . .	$8(C^{17}H^{10}NO^3)$	+ 10HI – $2H_2O$.

Hence diocodeine is in this respect strictly intermediate between codeine and tetracodeine.

The following table exhibits the principal differences between codeine and its polymers, above described:—

Reagent, &c.	Codeine	Diocodeine	Tricodeine	Tetracodeine
Alcohol.	Soluble.	Soluble.	Soluble.	Soluble.
Ether.	Soluble.	Soluble.	Soluble.	Insoluble.
Character of base.	Crystalline; stable in the air.	Amorphous; stable in the air.	Amorphous; very slowly oxidises while moist.	Amorphous; very slowly oxidises while moist.
Character of hydrochloride.	Crystallises with $2H_2O$ for C^{18} ; not lost at 100° .	Crystallises with $3H_2O$ for C^{18} ; lost at 100° , and partially at lower temperatures.	Non-crystalline; extremely deliquescent.	Non-crystalline; deliquescent.
Ferric chloride.	Nil.	Nil, when pure.	No colour at first; reddish-purple on standing.	Reddish-purple colour immediately.
Nitric acid.	Light orange.	Light orange.	Blood-red.	Blood-red.
Potassium dichromate and sulphuric acid.	Nil.	Nil.	Evanescent red.	Evanescent red.
Sodium carbonate and solution of hydrochloride.	No immediate precipitate; crystals on standing.	Instantaneous amorphous precipitate, but little soluble in excess.	Same as diocodeine.	Same as diocodeine.

Reagent, &c.	Codeine	Dicodeine	Tricocodeine	Tetracocodeine
Caustic potash and solution of hydrochloride.	Oily precipitate if concentrated, becoming crystalline on standing; not markedly soluble in excess.	Oily precipitate if concentrated, not becoming crystalline, more dilute solutions give a white amorphous precipitate, soluble in large excess.	Same as dicodeine.	Same as dicodeine.
Action of hydrochloric acid not pushed to extreme.	Product contains Cl for C ³⁶ ; after further action it contains Cl ² for C ³⁶ .	Product contains Cl for C ³² .	H ² O removed for C ¹⁸ ; product contains no basic Cl.	Nil.
Action of hydrochloric acid in conjunction with phosphorus.	Polymerises to tetra series, forming bases derived from (C ¹⁷ H ²¹ NO ³) ₄ , or (C ¹⁷ H ²¹ NO ²) ₄ , H ¹ being added on for C ¹⁷ in product, and ClH ² evolved for C ¹⁸ in original.	Polymerises to tetra series, forming bases derived from (C ¹⁷ H ²¹ NO ³) ₄ , H ¹ being added on for C ¹⁷ in product, and ClH ² evolved for C ¹⁸ in original.	---	H ² O removed, and H ¹ added on (or I substituted for OH), no H ¹ added on; ClH ² removed for C ¹⁸ in original.
Action of sulphuric acid not pushed to extreme.	Polymerises, forming successively di-, tri-, and tetracodeine.	Polymerises, forming tetracodeine.	—	Nil; further action probably dehydrates and oxidises.
Formula inferred from above properties and reactions.	C ³⁶ H ⁴² N ² O ⁴ .	C ³² H ³⁸ N ² O ¹² .	C ¹⁰⁸ H ¹²⁰ N ⁶ O ¹⁸ .	C ¹⁴⁴ H ¹⁴⁸ N ⁶ O ²⁴ .
Physiological action of 0.1 gram of anhydrous hydrochloride, subcutaneously injected into adult cats.	Extreme hypersensitiveness and cerebral congestion; dilation of pupils; no diarrhoea; no vomiting in any instance.	No hypersensitiveness or cerebral congestion; dilation of pupils; vomiting in every instance. With a dog, profuse diarrhoea, without vomiting.	Hypersensitiveness scarcely marked; vomiting in some instances, in others salivation and defecation.	No hypersensitiveness; vomiting, salivation, or diarrhoea in every case; great depression. With a dog, profuse salivation and depression.

The following table, in which \bar{C} stands for codeine, and \bar{M} for morphine, exhibits the composition of the derivatives and polymerides of codeine above described, together with their origin and their relations to codeine:—

DERIVATIVES CONTAINING πC^{36} (CODEINE SERIES).

COERULIGNONE, $C^{136}H^{160}O^6$ or $C^{22}H^{91}O^{12}$ (Liebermann, *Deut. Chem. Ges. Ber.* v. 746; vi. 381). A blue substance obtained as a bye-product in the manufacture of wood-vinegar.

The crude calcium acetate obtained by neutralising with lime the acid liquor produced by the distillation of wood, is in practice decomposed by distillation with the requisite quantity of hydrochloric acid, the crude acetic acid thus obtained being purified by the addition of potassium bichromate. Under these circumstances the crude acetic acid deposits blue films, which sink to the bottom as a violet sediment. The substance thus deposited is purified first by elutriation, and afterwards by dissolution in cold phenol, from which it is precipitated by alcohol or ether. The precipitate thus obtained consists of pure coerulignone.

Coerulignone crystallises in small dark steel-blue needles. It is insoluble in all the ordinary solvents, and neither distils nor sublimes without change. It dissolves with blue colour in concentrated sulphuric acid, but has not been separated from the solution in its original state. It neither dyes with nor without a mordant. With acetic anhydride it yields a crystalline product, and when treated with nitric acid it is oxidised to oxalic acid. Heated with potash-solution it gives a green liquid, which quickly becomes yellow. If the solution be concentrated till the potash begins to fuse, a point is reached at which the mass dissolves in water with an intense but fugitive violet colour. The action of hydriodic acid and phosphorus at 160° gives rise to the same colouring substance as that which is produced by the action of potash. This product, when dissolved in ether, yields an almost colourless solution, and is deposited in the amorphous state when the solution is evaporated in a vacuum: to an alkaline solution it communicates an intense but evanescent violet coloration.

The formation of coerulignone was observed on the addition of potassium bichromate to a variety of samples of crude acetic acid, but it has not yet been ascertained whether the acetic acid obtained from all kinds of wood yields this substance; it has, however, been obtained from the acid resulting from the distillation of both birch and beech wood.

Hydrocoerulignone, $C^{136}H^{160}O^6$, is obtained by the action of tin and hydrochloric acid, potassium hydrate, ammonium sulphide, sulphurous acid, or sodium-amalgam on coerulignone. It crystallises well, is soluble in alcohol and acetic acid, and less so in water. It melts at 190°, and may be distilled almost without change if carefully heated. The distillate solidifies to long colourless crystals. It is also volatile to a certain extent with the vapour of acetic acid. It is converted into coerulignone by oxidising agents, and forms compounds with acetic anhydride and benzoyl chloride. Concentrated sulphuric acid dissolves it, producing an orange colour, which is changed by heating into fuchsine red.

Hydrocoerulignone contains two replaceable hydrogen-atoms. The addition of potassium ethylate to its alcoholic solution producing an egg-yellow precipitate

$C^{12}H^{10}K^{2}O^6$, and sodium ethylate forms a similar precipitate $C^{12}H^{10}Na^{2}O^6$. *Benzoyl-hydrocoerulignone* $C^{16}H^{14}(C^6H^5O)^2O^6$, obtained either by the action of benzoic chloride on hydrocoerulignone, or by heating that compound with benzoic anhydride to 150° – 160° in an open flask by means of an oil-bath, crystallises in prisms resembling sublimed benzoic acid, sparingly soluble in alcohol, melting at 244° . The *acetyl-derivative* $C^{16}H^{14}(C^2H^3O)^2O^6$ forms white crystals slightly soluble in alcohol, melting at 216° .

When hydrocoerulignone is heated with hydrochloric acid in sealed tubes, methyl chloride is formed, together with hexoxydiphenyl, $C^{12}H^{10}O^6$.

Hexoxydiphenyl forms magnificent, glistening, colourless crystals, grouped in rosettes. It is soluble in most solvents. Its solutions in alkalis have a splendid purple colour, which however appears to be the result of oxidation. With metallic acetates it yields violet to blue unstable precipitates, that produced by cadmium acetate being the most finely coloured.

A crystalline *hexacetyl-derivative* $C^{12}H^{10}(C^2H^3O)^6O^6$, and the corresponding *propionyl-derivative* are obtained by treating the compound with the chlorides of acetyl and propionyl. The *benzoyl* and *isobutyryl* derivatives have not been obtained pure. Hexoxydiphenyl is decomposed when passed over heated zinc-dust, yielding diphenyl.

Liebermann regards hexoxydiphenyl as a dipyrrogallol, and hydrocoerulignone as its tetramethyl-derivative:

Whether coerulignone is the quinone $C^{16}H^{10}O^6$, or the quinhydrone $C^{32}H^{20}O^{12}$, of hydrocoerulignone is not yet determined.

Coerulignone or hydrocoerulignone treated with strong sulphuric acid, yields two compounds, $C^{12}H^{10}O^6$ and $C^{14}H^{12}O^6$, intermediate between coerulignone and hexoxydiphenyl. The first forms yellow needles; the second, which results from prolonged action of the acid, is an amorphous orange-coloured powder. These compounds may be regarded as coerulignone in which one and two atoms of methyl are replaced by hydrogen.

To ascertain from which constituent of wood coerulignone is produced, pure cellulose (Swedish filter-paper or unbleached calico), oak-bark and beech-wood were severally subjected to dry distillation. Pure cellulose yielded no coerulignone; 2 lbs. of oak-bark yielded only doubtful traces; but from 2 lbs. of beech-wood no less than half a gram of pure coerulignone was isolated, thus showing that it is derived from some peculiar constituent of beech-wood.

COFFEE. The ash of the undermentioned parts of the coffee-tree grown in Brazil has been analysed by H. Ludwig (*Arch. Pharm.* [3] i. 482), with the following results:—

I. Root of a young tree in bearing. II. Root of an old tree. III. Leaves. IV. Pulp of the pericarp. V. Parchment-like coating of coffee-beans. VI. Coffee-beans grown on gneiss soil. VII. Coffee-beans grown on limestone soil.

The amount of phosphoric acid in young trees increases from the root to the fruit and its separate parts. The increased proportion of this acid in the roots of old trees is remarkable.

From analyses of the ash of coffee-beans of various growths made by Graham, Stenhouse, and Campbell (i. 1071) these chemists inferred that sodium-compounds and silica are entirely wanting in that part of the tree. The inference is not borne out by the present analyses, which show the presence of considerable quantities of sodium. The silica found by Ludwig in the ash of the beans may, he thinks, be derived from small quantities of adhering earth; but that silica is an essential constituent of other parts of the tree is clearly shown by the fact that it increases in amount from the root to the leaves and pulp, decreases in the parchment-like coating of the beans, and suddenly disappears in the beans themselves.

The influence of the soil upon the ash-constituents is shown in a marked manner in the amount of potash, iron, &c., in columns VI. and VII.

COLLIDINE, $C^8H^{11}N$, is formed by the action of chlorethylidene on ammonia. When chlorethylidene, prepared either from aldehyde and pentachloride of phosphorus or from ethyl chloride and chlorine, is heated to 160° in a sealed tube with alcoholic ammonia, the tube becomes filled in the course of twelve hours with crystals of sal-ammoniac; and the alcohol holds in solution an oily base which, if aqueous instead of alcoholic ammonia be used, separates at once as a layer above the sal-ammoniac. When dried over potash and rectified, it boils at 180 – 182° , and in odour and in the characters of its beautifully crystallised platinum salt, it exhibits entirely the characters of collidine. This base and sal-ammoniac appear to be only products of the reaction (Krämer, *Zeitschr. f. Chem.* [2] vi. 568).

Collidine is also found among the products of the decomposition of aldehyde-ammonia by acids (Krämer & Pinner, *ibid.* 470).

COLLODION. A very tenacious collodion may be prepared by dissolving collodion-pyroxilin in a mixture of ether and absolute alcohol, and adding a small quantity of copaiba balsam (Böttger, *Chem. Centr.* 1872, 745). On the preparation of collodion for photography, see also *Chem. Soc. J.* [2] x. 272, 533.—On the preparation of collodion-paper, *ibid.* 337.

E. Vettchow (*Chem. Centr.* 1872, 361) has made a number of experiments on the sensibility of collodion as affected by the varying proportions of pyroxilin and iodising salts, from which it appears that, with the same amount of pyroxilin, a certain addition of iodising salts increases the sensibility of the collodion, but beyond this it rather diminishes this sensibility. The limit is $1\frac{1}{2}$ per cent. of a solution containing 20 per cent. iodine and bromine, in the proportion of 3 parts iodine to 1 part bromine, added to collodion containing $\frac{1}{4}$, $\frac{1}{2}$, or $\frac{3}{4}$ per cent. pyroxilin.

The collodion should not contain less than about $\frac{1}{2}$ per cent. of pyroxilin, nor should less than 1 – $1\frac{1}{2}$ per cent. iodine-solution, nor more than about 2 per cent. be added. The raw collodion should be made as thick as possible, and iodised so that the product may contain from 1.5 to 1.75 per cent. of iodine and bromine.

COLOPHENE. See OILS, VOLATILE.

COLOPHONY. This resin, usually regarded as a mixture of pinic, sylvic, and colopholic or pimic acid, consists, according to Maly (*Ann. Ch. Pharm.* cxxix. 94; cxxxii. 249; and *Gmelin's Handbook*, xviii. 2), chiefly of abietic anhydride $C^{19}H^{32}O^4$, together with a volatile oil. When the resin collected from pines or larches is freed from volatile oil by heating over the water-bath, there remains an amorphous yellow mass, which softens between 90° and 100° , is of a syrupy consistence at 100° , and dissolves easily in alcohol, ether, and chloroform; this body has the composition of abietic anhydride.

Abietic acid, $C^{19}H^{30}O^3$, is formed by the combination of the anhydride with water, and may be prepared by digesting powdered colophony for a week with alcohol of 70 p. c. whereby it is converted into a granular mass. By redissolving this mass in alcohol of 90 to 92 p. c., precipitating with hot water, and leaving the resinous precipitate to itself for one to three weeks, a crystalline mass is obtained mixed with a soft brown resin which may be removed by cold alcohol; and by pressing the remaining crystalline mass and recrystallising from hot alcohol, abietic acid is obtained in irregular, transparent, pointed crystals belonging to the triclinic system. It has an acid reaction, begins to melt at 129° , melts completely at 144° , dissolves in carbon bisulphide, wood-spirit, chloroform, alcohol, ether, and benzene. It is bibasic, forming mostly neutral salts; those of the alkali-metals are soluble in water and alcohol, and uncrystallisable. The neutral barium, calcium, and magnesium salts $C^{19}H^{28}M^2O^4$ are amorphous precipitates, slightly soluble in water, easily in alcohol. An acid magnesium salt $(C^{19}H^{28}O^3)_2Mg$ is obtained as a light white mass resembling magnesite, by boiling abietic acid with magnesium carbonate and pouring the filtered liquid into a large quantity of water. The silver salt, $C^{19}H^{28}Ag^2O^4$, is a white pulverulent mass, slightly soluble in alcohol, easily in aqueous ammonia and in ether. *Abietic acid*

$C^{14}H^{10}(C^2H^2)^2O^2$, obtained by decomposing the silver salt with ethyl iodide, is a clear yellowish rather soft mass, becoming syrupy at 100° , decomposed by distillation, with elimination of water, insoluble in water, slightly soluble in alcohol, easily in ether and ether-alcohol. A mixture of concentrated alcoholic abietic acid and glycerin deposits, after standing for a fortnight, small white crystals of abietin, melting at 125° , and having, according to Maly, the composition $C^{31}H^{70}O^3 = 3C^2H^2O^2 + C^{14}H^{10}O^2 - 6H^2O$.

Abietic acid in alcoholic solution is decomposed by hydrochloric acid gas, producing sylvic and sylvinoic acids:

Sylvic acid is also produced when a hot alcoholic solution of abietic acid is mixed with sulphuric acid. Abietic acid triturated with phosphorus pentachloride yields on distillation, a volatile oil $C^{14}H^{10}$ called by Maly, abietone, besides hydrochloric acid and phosphorus oxychloride. Fused with potash it yields propionic, but no pyrotechnic acid. Sodium-amalgam added to a warm alcoholic solution of abietic acid converts it into the sodium salt of hydrabietic acid $C^{14}H^{10}O^2$. This acid forms white fatty laminae, melting completely at 160° : it is bibasic, forming neutral salts $C^{14}H^{10}M^2O^2$ (Maly).

Strecker (*Ann. Ch. Pharm.* cl. 131; *Zeitschr. f. Chem.* [2] vi. 381) denies the existence of Maly's abietic acid, and regards the formula $C^{14}H^{10}O^2$ as founded on incorrect analyses. He points out that the so-called abietic acid is prepared from the same material, and in the same manner, as the sylvic acid of Unvordorben, Trommsdorff, Siewert, and others (v. 611), Trommsdorff, and Siewert in particular, not having used sulphuric acid in the preparation, by which, according to Maly, abietic acid undergoes transformation; moreover, that the properties of abietic acid, as described by Maly, exhibit a general agreement with those of sylvic acid, excepting in the melting point, which has been stated by various authors at temperatures ranging between 129° and 162° . Duvernoy found 139° ; Maly's own statements, made at different times, vary between 129° and 165° . For these reasons, Strecker regards abietic acid as identical with sylvic acid, and as having the composition $C^{20}H^{30}O^2$. The same view is held by Duvernoy (*Ann. Ch. Pharm.* cxlviii. 143; *Zeitschr. f. Chem.* [2] v. 503). See, on the contrary, Maly (*Ann. Ch. Pharm.* cxlix. 244; *Zeitschr. f. Chem.* [2] v. 304; further *Ann. Ch. Pharm.* cxli. 1151).

In the last of these papers, Maly points out that Strecker's view of the identity of abietic and sylvic acids is founded chiefly on the experiments of Duvernoy, who obtained an acid having the composition $C^{20}H^{30}O^2$, not from ordinary colophony, but from French galipot, which is a very different material.

To throw further light on the question, Maly has repeated the preparation of the resin-acid from colophony in the following manner:—Coarsely pounded colophony is digested for two days with weak spirit, the liquid then poured off from the crystalline and nearly white pulp, and the latter squeezed in a press: if the residuo is not quite white, it may be rendered so by renewed stirring with alcohol, and pressure. A considerable quantity of the press-cake is dissolved in hot stronger alcohol, and the solution is left to itself either at ordinary temperatures, or in a cellar, whereby a white crystalline crust (1) is obtained, which slowly increases, and the mother-liquor when cooled by ice, usually solidifies to a pulp of loose white laminae (2) which constitutes the greater portion of the product. The former, especially when its quantity is small, gives by analysis numbers approximating to the formula of sylvic acid $C^{20}H^{30}O^2$, but the latter is found, both by combustion and by the analysis of its salts, to have the composition of abietic acid $C^{14}H^{10}O^2$. Great care is required in the analyses on account of the tendency both of the crystallised acids and of their salts to absorb oxygen from the air.

The abietates of the alkali-metals were found, as in the former investigation, to be uncrystallisable. The most definite is the sodium salt, which is obtained as a snow-white flocculent precipitate floating on the liquid, either by decomposing the potassium-salt with sodium nitrate, or by dissolving the acid in caustic soda and salting out with sodium nitrate. From this sodium salt the following salts were obtained, by double decomposition. The silver salt gave, as the mean of eleven determinations, 24.42 p.c. silver, the formula of the abietate, $C^{14}H^{10}AgO^2$, requiring 24.37, whereas that of the sylvate, $C^{20}H^{30}AgO^2$, requires 26.40. The barium salt gave somewhat variable results, ranging in fifteen determinations from 16.05 to 17.66 p.c. Ba; the abietate requires 16.98, the sylvate 18.54 p.c.* The zinc salt gave 11.02 p.c. zinc oxide, which agrees exactly with the formula $C^{14}H^{10}ZnO^2$, whereas $(C^{20}H^{30}O^2)_2Zn$ requires 12.14 p.c.

* It is somewhat remarkable that some of the silver and barium salts analysed were prepared with acid of the first crystallisation, others with acid of the second crystallisation, and that nevertheless, all appear to have given analytical numbers agreeing most nearly with the formula $C^{14}H^{10}O^2$.

These results are regarded by Muly as confirming his former conclusion that the principal constituent of colophony is a resin-acid having the composition $C^{14}H^{13}O_3$; it appears, however, to be mixed with a small quantity of another acid of different constitution, probably $C^{20}H^{19}O_2$.

Colophony oxidised with nitric acid yields chiefly isophthalic acid, together with trimellitic acid and a resinous acid (J. Schredor, *Deut. Chem. Ges. Ber.* vi. 413).

COLUMBITE. Syn. with NIOBITE; see TANTALATES.

CONGLUTIN. This name is applied by Ritthausen to the legumin of almonds and of lupines. (See LEGUMIN).

CONINE. $C^8H^{15}N$. *Artificial Formation* (Hugo Schiff, *Ann. Ch. Pharm.* clvii. 352. *Deut. Chem. Ges. Ber.* v. 42). When butyric aldehyde is acted upon by alcoholic ammonia at temperatures not above 100° , two bases, dibutyraldine, $C^8H^{17}NO$, and tetra-butyraldine, $C^{12}H^{25}NO$, are produced; the former by condensation of two, the latter by condensation of four molecules of butyraldehyde, with assumption of the elements of ammonia and elimination of water:

The former of these bases, when subjected to dry distillation, yields, among other products, a volatile, oily base, having the composition and many of the properties of conine from hemlock:

Preparation. 1. Butyric aldehyde heated for two months with alcoholic ammonia at about 30° , then for one day at 100° , afterwards neutralised with hydrochloric acid, and fractionally precipitated with platinic chloride, yielded a yellow flocculent precipitate of *tetra-butyraldine platinochloride* $2(C^8H^{17}NO.HCl).PtCl^4$ forming the greater part of the product; and the mother-liquor gave by further treatment a small quantity of a yellow crystalline powder consisting of *dibutyraldine platinochloride*, $2(C^8H^{17}NO.HCl).PtCl^4$.

This last compound, decomposed with hydrogen sulphide and treated with concentrated potash-ley, yielded free dibutyraldine. On distilling this base with sand in an oil-bath, water and oily products passed over; and the distillate, freed from ammonia by gentle heating, neutralised with hydrochloric acid to separate tarry substances, concentrated, and mixed with platinic chloride, yielded a precipitate which by recrystallisation from alcohol, was obtained as an orange-coloured crystalline powder, having the composition of conine platinochloride $2(C^8H^{15}N.HCl).PtCl^4$. From this salt the base $C^8H^{15}N$ was separated by means of potash and ether.

2. About half a kilogram of butyric aldehyde was mixed with an alcoholic solution of ammonia and placed in sunshine during the summer months; but, instead of neutralising with hydrochloric acid, and treating the solution with platinic chloride as above, the alcohol, ammonia, and unaltered butyric aldehyde were separated by distillation, the brown syrupy residue was heated for a day to 130° – 150° , and the volatile portion distilled off in a current of steam. The tarry residue was then heated in sealed tubes to 200° , and again distilled with steam. On removing the basic portion of the oily distillate with hydrochloric acid, decomposing the resulting hydrochloride with potash, and repeatedly distilling the basic oil thereby separated in a stream of hydrogen, a portion boiling at 166° – 170° was gradually obtained, then a second portion between 175° and 195° , and a third between 205° and 215° . The greater portion of the first fraction boiled at 168° and had the composition of conine.

The base $C^8H^{15}N$ obtained by either of these processes exhibits in the highest degree the odour of natural conine, and exerts a similar and equally violent poisonous action on the animal organism. It is very slightly soluble in water, the solution becoming milky when heated and clear again on cooling. Its solution, containing free hydrochloric acid, becomes light red when evaporated, afterwards violet, or, in presence of a strong hydrochloric acid, blue-green. When it is left to evaporate under a bell-jar over strong sulphuric acid, the acid acquires a deep red colour. Chlorine-water produces in the aqueous solution a white precipitate soluble in hydrochloric acid. Iodated potassium iodide produces a brown precipitate soluble in excess of potassium iodide. The base precipitates cupric hydrate from cupric sulphate, and silver oxide from the nitrate of silver. With mercuric chloride a thick yellow precipitate is formed, which unites into a viscid mass. A small quantity of the base introduced into a drop of auric chloride forms a viscid yellow precipitate which, in a few hours, becomes deep violet, yielding reduced gold.

All these reactions are exactly like those of natural conine; in the following reactions, however, differences are observed. Natural conine, evaporated with strong hydrochloric acid, acquires a deep indigo-blue colour; whereas the artificial base becomes only greenish-blue. The precipitation of silver oxide by natural conine at ordinary temperatures takes place immediately; artificial conino produces the same effect after some time only: immediately, however, at slightly higher temperatures (about 40°). The above-mentioned violet reaction with auric chloride takes place much more quickly with natural than with artificial conine. The platinumchloride of the artificial base is less soluble in water than that of natural conine. The artificial base differs also from natural conine in having a greater coefficient of expansion, in being less soluble in water, and in having no action on polarised light. The artificial variety is distinguished as *paraconine*.

To determine the constitution of conine and *paraconine*, the following considerations are adduced:—Dibutyraldine, $C^8H^{12}NO$, is susceptible of two isomeric modifications, according as the two aldehyde-residues which it contains are linked together by a nitrogen-atom or by carbon-atoms, viz.:

and these, by elimination of H^2O , give three isomeric conines, the first derived from butyraldine I., the second and third from butyraldine II.

Natural conine, which contains one atom of replaceable hydrogen (ii. 5), and in which the group C^4H^4 (conylene) is bivalent (ii. 964) is represented by the third formula. Artificial conine contains no replaceable hydrogen, inasmuch as no separation of water occurs on heating it with *anantliol*; and when treated with ethyl iodide, it yields the iodide of an ammonium base, the oxide of which is a bitter, alkaline, easily decomposable syrupy liquid; its constitution may therefore be represented by the formula I.

Other isomerides of conino may perhaps be formed from isobutyric aldehyde, or from a mixture of this with normal butyric aldehyde.

The portion of the oily distillate obtained in the second mode of preparing *paraconine* (p. 380) which boils above 200°, contains the base $C^{10}H^{12}N$, derived from *tetra-butyraldine*. This base is formed also in small quantity by the distillation of *paraconine*: thus—

It boils at 210°, and has a specific gravity of 0.915 at 15°.

The base $C^{10}H^{12}N$ obtained by *Ljubavon* from *valeraldehyde* is doubtless the 10-carbon *paraconine*. Its constitutional formula is—

Optically active *valeraldehyde* would probably yield the corresponding homologue of natural conine (*Schiff*).

CONNECTIVE TISSUE. It is not yet definitely ascertained in how far the connective tissue of the invertebrata agrees with that of the vertebrata, or in how far it is to be considered as true embryonal tissue. Microscopical investigation has shown that the connective tissue of invertebrata mostly corresponds in appearance with the connective tissue of the vertebrates. Only in some groups is mucous tissue found (*Calenthrata*, *Vermes*, *Heteropoda*), while the fibrillar tissue is found only in the *Cephalopoda*, cartilage only in the *Cephalopoda* and in the lingual cartilage of the *Gasteropoda*, while bone does not exist in the invertebrata at all. The question to determine was whether all these tissues really agree with their homologues in the vertebrata in chemical composition, and whether gelatin might be obtained from them.

A number of vineyard snails were boiled for some time. The decoction did not gelatinise. It was completely precipitated by acetic acid, and hence must be regarded

as chondrin, or some similar substance. It could be converted into chondro-glucose by boiling with hydrochloric acid. A similar result was obtained with fresh specimens of *Anodonta* and *Unio*.

The *Gastropoda* and *Lamellibranchiata* therefore possess a connective tissue nearly allied to the connective tissue of vertebrates. They differ, however, from the *Cephalopoda*, for Hoppe-Seyler obtained from these, specimens of pure gelatin free from chondrin.

To determine whether the pen of the *Sepiæ* and *Loligide* contained a substratum of connective tissue, the salts were dissolved out by hydrochloric acid, and the framework boiled in closed tubes for twenty hours. The decoction did not gelatinise, but became turbid when cold. This substance was insoluble in alcohol, but soluble in acetic acid and sodium acetate. Ferro-cyanide of potassium caused no precipitate. The other characters show that the stroma of the sepiæ-pen is not conchiolin, as might have been supposed from its homology with the shells of molluscs. It would appear that in the cephalopods the chitin of the arthropods and the connective tissue of the vertebrates are combined. No gelatin or similar substance could be obtained from cockchafer, which were under analysis for chitin (Frerich, *Iflinger's Archiv. f. Physiologie*, 1872, 320).

COPPER. A specimen of supposed native copper found in a cargo of copper pyrites from the Tharsis mines in Spain is described by H. Bowman (*Chem. News*, xxiii. 19). It weighs 2½ lbs., has a specific gravity of 8·4, and varies in colour in different parts from copper-red to almost white, with a hackly fracture. The interior is full of cavities above shot size. Its composition is:

Cu	Fe	Zn	Ni	Co	Sb.	As.	S.	O.
84·80	5·54	trace	0·78	0·14	0·50	7·10	0·73	0·41 = 99·50

On the occurrence of copper in Cajuput oil, see page 231.

Selenium in Copper. According to Violette (*Compt. rend.* lxx. 729), commercial copper sometimes contains selenium. To separate this element, the metal is first oxidised in a muffle-furnace, and the oxide thus formed is heated to redness for several hours in a stream of pure dry air. If the copper contains selenium, there is found after some time at the end of the tube, a white volatile crystalline ring which exhibits all the reactions of selenious acid. In this manner the selenium may be not only detected, but estimated.

Alloys of Copper with Cobalt and Manganese. With cobalt, copper forms ductile and malleable alloys which fuse at about the melting point of copper. Manganese has a great affinity for copper. Alloys containing 3, 5, 8, 12, 15, and 20 p.c. manganese have been prepared; they all greatly resemble the alloys of copper and tin, are very hard and sonorous, and fuse readily. The alloy containing 15 p.c. manganese is grey, very hard and brittle, melts like bronze, may be readily cast, and does not appear to alter by keeping. The 12 p.c. alloy is still brittle; it is grey after rolling, but soon acquires a brass-yellow colour. The alloys containing less manganese are ductile, and may be hammered out into plates as thin as brass-foil (Valenciennes, *Compt. rend.* lxx. 319).

Electrodeposition of Copper and Brass. A solution containing one pound of cupric sulphate and one pound of sulphuric acid to the gallon of water, deposits the metal in a solid compact mass, with a somewhat botryoidal surface. The addition of one ounce of zinc sulphate (as recommended by Napier) annuls this botryoidal form, and renders the deposit tough, compact, and even. From a solution containing a greater proportion of zinc sulphate the metal is deposited in tufts of needles standing at right angles to the surface of the metal. Ordinary electro-brassing solutions show the same peculiarity in even a more marked degree, and this makes it impossible to produce a good deposit of more than 0·01 to 0·03 inch in thickness. This form of deposit is owing chiefly to a copious evolution of hydrogen taking place during its formation. But, by employing a solution containing both the oxides and the cyanides of the constituent metals, together with some neutral ammonium tartrate, this evolution of hydrogen may usually be avoided, or, should it, nevertheless, take place to a slight extent, it may be entirely stopped by the addition of cupric ammonide. Such a solution yields brass of a uniform character, and the deposit, which may be obtained of any desired thickness, is tough, and has a compact even texture. As there is no evolution of hydrogen, no electric force is wasted, and perfect results may be obtained with a single Wollaston's or Smee's cell (W. H. Waller, *Phil. Mag.* [4] xli. 41).

Absorption of Gases by Electro-deposited Copper (R. Lenz, *J. pr. Chem.* cviii. 438).—Copper precipitated by electrolysis from a solution of cupric sulphate contains a certain quantity of gases which escape on ignition. Taking the volume of the copper = 1, the composition of the gaseous mixture in volumes per cent. is found to be 77.3 hydrogen, 8.4 carbon oxide, 11.1 carbon dioxide, and 3.2 water-vapour.

Reactions of Copper-compounds. Cuprous oxide dissolves in a strong solution of magnesium chloride even in the cold, more easily, however, at the boiling heat, with separation of magnesium hydrate and formation of cuprous chloride. Cuprous and ferrous oxide and chloride in the manner as shown by the equations:

The final result of the action of cuprous oxide on ferrous chloride may be represented by the equation:

The reaction between cupric chloride and ferrous oxide is represented by the equations:

Cupric oxide is decomposed by ferrous chloride in the following manner:

The insolubility of the cuprous chloride renders the action very slow; but if common salt be added, and the liquid heated so as to increase the solubility of the cuprous chloride, the transformation is rapid and complete (T. Sterry-Hunt, *Compt. rend.* lxxix. 1357).

Aluminium immersed in a solution of cupric sulphate or nitrate does not act upon it at first, but after two days, the foil becomes covered with crystals consisting partly of dendrites, but for the most part of well-defined octahedrons. A solution of the nitrate yields, together with metallic copper, a green insoluble powder consisting of a basic salt. Copper is immediately precipitated by aluminium from a solution of cupric chloride, and likewise, though more slowly, from the acetate. The reduction also takes place immediately when to the solution of the sulphate or nitrate there is added a small quantity of a very dilute solution of an alkaline chloride, the precipitation being complete if a sufficient quantity of aluminium is present (Cossa, *Il nuovo Cimento* [2] iii. 75).

Detection of Copper. According to F. Bellamy (*Zeitschr. anal. Chem.* ix. 382), a five-millionth part of copper or iron may be detected in water by the blue colour produced by addition of an alcoholic extract of logwood, whereas the bicarbonates of the alkalis or alkaline earths merely change the yellow colour of the tincture to a light reddish violet. An excess of hæmatoxylin gives rise to the formation of blue flocks, which may be further examined for copper or iron.

Schönbein observed (*ibid.* viii. 67), that nearly all copper salts, in presence of hydrocyanic acid, impart to solutions of guaiacum, and to starch-paste containing potassium iodide, a deep blue colour. Brown cupric cyanide and green cuproso-cupric cyanide produce this reaction even in very dilute solutions. Further, it is found by E. Schar (*ibid.* ix. 93 and 109), that cupric cyanate, sulphocyanate, and ferricyanide also possess this property, whereas cupric ferrocyanide acts only on guaiacum, not on potassium iodide. All soluble cyanides, ferrocyanides, ferricyanides, sulphocyanates, and nitroprussides are capable of indicating the presence of traces of cupric salts by the blueing of guaiacum. A solution containing only $\frac{1}{1000}$ p.c. of cupric sulphate is still coloured very distinctly blue by the addition of a little prussic acid and tincture of guaiacum. In carrying out this mode of detection, A. Aë (*ibid.* ix. 901) recommends the addition of a few drops of chloroform to the mixture, which is to be gently agitated and left to stand. The chloroform then acquires a deep blue colour, even if the dilution is so great that no change of colour is perceptible in the aqueous liquid.

Quantitative Estimation. At the Mansfeld copper works, the quantity of copper in poor ores and schists was formerly estimated by Rose's method, as cuprous sulphide (1st *Suppl.* 492), and in the richer reguli (*Rohsteine* and *Spursteine*), by the Swedish method of precipitation with metallic iron. Both these methods, however, require too much time to be available for the metallurgic assaying. The Directors, therefore, in 1807, offered a prize for the discovery of a process which could be completed in five or six hours, and should yield results lying between fixed limits of error. Out of sixteen essays, the prize was adjudged to only one, namely that of

Steinbeck, as fulfilling all the required conditions; but honourable mention was also made of a second, by C. Luckow, for its simplicity, cheapness and elegance.

1. Steinbeck digests 5 grams of the finely pulverised schist with 40 to 50 c. c. of common hydrochloric acid of sp. gr. 1.16; allows the carbonic anhydride to escape; and adds to all bituminous ores, 6 c. c. of a mixture of equal volumes of water and pure nitric acid of sp. gr. 1.2, to non-bituminous or previously roasted ores, only 1 c. c. After half an hour's digestion, the liquid is boiled briskly for ten to fifteen minutes, whereby the whole of the copper is dissolved, together with the other metals present (the residue being found to contain not more than 0.03 p.c. copper), and all the nitric acid together with lower oxides of nitrogen is driven off. The solution is filtered into a beaker-glass, in which is placed, upon a strip of platinum foil, a bar of zinc as free as possible from lead, weighing about 8 grams. In half or three-quarters of an hour the whole of the copper is precipitated; the excess of zinc is then removed, and the spongy metallic precipitate is washed by decantation with spring water. This precipitate is treated with 8 to 16 c. c., according to its quantity, of the above-mentioned nitric acid mixture, and dissolved at a gentle heat; the solution, after cooling, is mixed with 10 c. c. of a mixture of 2 vols. water and 1 vol. ammonia of sp. gr. 0.93 (if 16 c. c. of nitric acid have been used, the liquid must be previously diluted to 100 c. c., and halved with a pipette). The next step is the titration of the copper with solution of potassium cyanide (il. 58), 1 c. c. of which indicates 0.005 gram of copper, so that as 5 grams of substance were taken for the assay, 1 c. c. indicates 0.1 p.c. copper. The termination of the experiment is indicated by the complete disappearance of the blue colour. With constant use the change in the strength of the standard solution is inconsiderable; indeed, it need not be redetermined more than once a week, as the alteration is barely perceptible even in a fortnight. By the preceding process six samples of ore may easily be assayed in four hours.

When the directions above given are closely observed, the variations in the amount of ammonium nitrate, free ammonia, lead, and zinc in the liquid to be assayed, do not affect the final result by more than 0.05 p.c. Greater variations may arise from performing the titration at a higher temperature, on which account the ammoniacal copper solution must be previously cooled.

2. Luckow precipitates the copper electrolytically. He finds that even proportionately weak voltaic currents are capable of precipitating copper in beautiful reguline form from solutions not containing more than 0.1 gram nitric acid in the cubic centimeter (nitric acid of sp. gr. 1.2 contains 0.32 gram in the cubic centimeter). From the acid solution the following metals are not precipitated by the current: zinc, iron, nickel, cobalt, chromium, the earth-metals, alkaline earth-metals and alkali-metals. On the other hand, lead and manganese are completely precipitated at the positive pole as peroxides, silver only partially; easily oxidisable substances, organic or inorganic, ferrous oxide, for example, retard the precipitation at the negative pole, mercury, silver, copper and bismuth are deposited in reguline form, the mercury first, which afterwards forms an amalgam with the copper. From arsenic and antimonie acids, arsenic and antimony are separated some time after the precipitation of the copper.

In the application of this method for assaying purposes, the copper schist (2 grams) is first roasted, with stirring, for six or seven minutes on an iron crucible cover or in small porcelain crucibles. The roasted product is introduced by means of a bent card into a small beaker glass, washed off the sides of the glass with 2 or 3 c. c. of nitric acid, sp. gr. 1.2, and mixed with 10 to 15 drops of strong sulphuric acid. The whole is then gradually heated on a sand-bath, and at last strongly enough to drive off all the sulphuric acid. To prevent spitting, the liquid is covered with a perforated watch-glass (or a wide-necked funnel). The evaporation may be accelerated by addition of 10 to 20 drops of hydrochloric acid, but even then it takes from an hour to an hour and a half. When the liquid has cooled, the watch-glass (or funnel) is rinsed with nitric acid of sp. gr. 1.2 diluted with 6 vol. water, the beaker is filled to one-half with the same liquid, and a few drops of tartaric acid are added. For the precipitation of the copper, a platinum wire half a line thick, $7\frac{1}{2}$ inches long and rolled up for $\frac{2}{3}$ of its length into a flat spiral like a watch-spring is used as the positive pole. If the liquid above the evaporation-residue is very turbid, 1 or 2 c. c. of a strong solution of barium nitrate is added, and mixed with the liquid by moving the spiral up and down. The acid liquid, after standing for a while, remains only slightly turbid. The negative pole is formed of a cylinder of platinum foil $2\frac{1}{2}$ inches long, $1\frac{1}{2}$ inch broad, and immersed in the liquid to three-fourths of its length, so that it remains separated from the spiral by about $1\frac{1}{2}$ line. The circuit being once closed, the termination of the copper precipitation is easily ascertained by immersing the platinum cylinder deeper in the liquid, after addition of dilute sulphuric

and observing whether any further deposition of copper takes place on the clean part; if the battery is sufficiently strong, the precipitation is usually completed in about eight hours. The increase of weight of the platinum foil, after washing with water, rinsing with alcohol and drying, gives the quantity of copper present. For the assaying of poor ores, the current should be capable of evolving from 16 to 25 c. c. of detonating gas in half an hour; for richer ores and reguli (containing more than 60 p.c. copper) a current is required capable of evolving from 50 to 75 c. c. of detonating gas in the same time. Silver must be removed with very dilute hydrochloric acid, the liquid made up to 200 c. c., and the washing of the copper in the beaker effected by displacing the mother-liquor with a stream of water.

Further details of this method, especially with reference to the assaying of rich ores and reguli, and such as contain considerable quantities of iron are given in the *Zeitschrift für Analytische Chemie* xi. Jahrgang, 1-16. In ores containing from 17 to 21 p.c. iron difficulties arise from the action of nitrogen dioxide or ferrous oxide, which takes place simultaneously with the reduction of the copper at the negative pole, the metallic solution acquiring a brown-black colour, which increases as the precipitation of the copper goes on, especially outside the platinum cylinder, where the action of oxygen is but slight, whereas within the cylinder, where oxygen is evolved in excess, no such coloration takes place. This coloration is avoided by using for the negative electrode, instead of the cylinder, a hollow cone of platinum having several slits in its side. A negative electrode of this form, not only prevents loss by the spitting of the oxygen-bubbles, but likewise allows the oxygen evolved at the inner surface of the cone to escape through the slits to the outer side, whereby the partial reduction of the ferric to ferrous oxide, and of the free nitric acid to nitrogen dioxide, and consequently the black-brown coloration of the liquid, is prevented. For highly ferruginous samples, the current must be strong enough to yield from 100 to 120 c. c. of detonating gas in half an hour.

The copper precipitated as above described is often covered with a brown or black film of some foreign substance, which, when the quantity of copper is small, may render the result of the analysis inexact. The quantity of this black deposit is too small to allow of the determination of its nature by analysis; but synthetical experiments have shown that arsenic and selenium are separated by the electric current, but later than the copper, which therefore becomes coated with those substances. Antimony and bismuth have not been detected in the schists and furnace-products of Mausfeld. It has lately been found that selenium may be completely precipitated by the electric current from nitric acid solutions. In many cases, however, the grey-black colorations of the copper appear to owe their origin to traces of hydrochloric acid in the solution: indeed they are produced by the addition of extremely small quantities of this acid.

The whole of the lead contained in the solution mostly separates as peroxide on the spiral which forms the positive pole, and must be estimated gravimetrically, if its quantity is not great. When larger quantities are present, part attaches itself to the platinum wire and the rest separates in the form of loose thin laminae. Experiments are still in progress, for the purpose of discovering an exact method of estimating the lead.

To render the electrolytic determination of copper generally applicable, it is very desirable to get rid of the black deposits above mentioned. As they make their appearance only after the precipitation of the copper, this end might perhaps be attained by stopping the process as soon as the black deposits begin to show themselves; but it would be difficult to ensure that the whole of the copper had been precipitated. By the following method, however, the desired certainty may be attained. As soon as the precipitation is completed, the hollow platinum cone, together with the black copper deposit, is removed in the ordinary way from the glass, then rinsed, dried, and gently ignited for a short time in a gas or spirit flame or in a red-hot muffle. The dark substance then volatilises, and the metallic copper is converted into cuprous or cupric oxide without perceptible loss. The cylinder or cone thus treated is placed in a small beaker glass, and connected with the conducting wire proceeding from the positive pole of a small battery; and a somewhat larger, previously weighed platinum cylinder attached to the wire proceeding from the negative pole of the battery, is suspended over it. On pouring into the glass a sufficient quantity of dilute nitric acid (1 acid to 6 water) or an equivalent quantity of 1:8 dilute sulphuric acid, the electrolytic action begins. The oxidised copper attached to the cylinder which serves as positive pole, dissolves, and is deposited with bright metallic lustre on the cylinder which serves as negative pole. The entire manipulation takes a few hours longer than the preceding process, but it yields good results.

This process is applicable, however, only when the quantity of antimony, arsenic or selenium present is very small; in that case the platinum is not attacked, because the black deposit is formed on the copper alone. But when larger quantities of these

substances are present, the only thing to be done is to watch for the moment when the precipitation of the copper is completed, and it begins to blacken. The current must then be interrupted, and the platinum cone taken out of the solution and treated as above.

In the assay of highly ferruginous copper ores, &c., the addition of oxalic acid to the liquid is recommended instead of tartaric acid.

As already observed, the strength of the current must be varied according to the quantity of copper present in the assay, large or small batteries being used accordingly. The paper above cited in the eleventh volume of the *Analytische Zeitschrift* gives a full description of the forms of battery which have been found best adapted for the purpose. With the apparatus there described, it is said that two persons can make 10,800 copper determinations in a year.

On the electrolytic precipitation of copper see also Merrick (*Chemical News*, xvi, 155, and Lecoq de Boisbaudran, *Bull. Soc. Chim.* [2] vii, 468; xi, 35; *Jahresb.*, 1867, 850; 1869, 901).

Estimation by Precipitation as Sulphide, Iodide, and Sulphocyanate (1st Suppl. 492). According to Ulrici (*J. pr. Chem.* cvii, 110) the weight of copper sulphide precipitated by hydrogen sulphide and ignited, bears a constant ratio to that of the copper contained in it. The residue left on ignition is always a mixture of cuprous sulphide and cupric oxide, though its weight corresponds almost exactly with the formula Cu_2S . By ignition in an open crucible more oxide is formed and less sulphide, whereas in a covered crucible, which, however, must be removed from the flame from time to time and opened for a few seconds, a residue is obtained, represented in composition by the formula $\text{Cu}_2\text{S} \cdot \text{CuO}$. As, however, the percentage of copper in the sulphide Cu_2S is the same as that in the oxide CuO , it matters not, so far as the calculation of the amount of copper is concerned, in what proportion these two compounds are mixed. An excess of sulphur precipitated together with the copper sulphide, has of course no influence on the result. By a series of seventeen experiments in which copper was dissolved in nitric acid, and precipitated, after dilution, with hydrogen sulphide, it was found that, on igniting the strongly dried precipitate in an open crucible, residues were obtained which gave by calculation from 100.9 to 102.6 p.c. copper, whereas experiments in a covered crucible gave from 99.8 to 100.8 p.c. As the differences are perhaps attributable to the ashes of the filters, and the results of half the experiments did not differ from the calculated quantity by more than 0.2 p.c., this simplified process appears to be capable of yielding good results.

According to E. Fleischer (*Chem. News*, xix, 206) the precipitation of copper as sulphide by heating a solution of cupric chloride with sodium thiosulphate is well adapted for the separation of copper from metals whose sulphides are soluble in dilute hydrochloric acid. The precipitate contains excess of sulphur, and cannot, therefore, be directly dried and weighed. It might, however, be treated by Ulrici's method just described.

According to Duclaux (*Bull. Soc. Chim.* [2] xviii; *Chem. News*, xxv, 156), very small quantities of copper may be estimated by precipitation with hydrogen sulphide, redissolving the sulphide in a platinum crucible, reducing the copper with zinc in contact with the platinum, then washing out the crucible with alcohol, drying, and igniting it together with the copper deposit. In this manner, Duclaux states that he has found in 1000 parts of the ash of cæno-beans, from 0.009 to 0.040 part of copper; in 1000 parts of the outer shell, from 0.035 to 0.225 of copper, and in chocolate from various makers from 0.005 to 0.125 part.

For the transformation of cupric salts into cuprous iodide, the only advantageous reducing agent is according to Fleischer, *stannous chloride*, since both sulphurous acid and ferrous chloride dissolve considerable quantities of cuprous iodide. Addition of sal-ammoniac facilitates the precipitation, which, if the liquid be kept cool, is so complete that no copper can be detected in the filtrate by potassium ferrocyanide, or by introducing a platinum wire wetted with it into a colourless flame. The cuprous iodide after washing with solution of sal-ammoniac (if washed with pure water it passes through the filter) is warmed with a solution of ferric sulphate, whereupon the following reaction takes place:

The separated iodine may be completely expelled by boiling for ten minutes, and the ferrous oxide estimated by permanganate, every 2 molecules of it corresponding to 3 atoms of copper. This method may also be used for the estimation of iodine in presence of chlorine and bromine.

The precipitation of copper as cuprous sulphocyanate, $\text{Cu}_2(\text{ONS})^2$, recommended by Rivot is performed by Fleischer as follows: The cupric chloride or sulphate

addition of potassium or sodium chloride, is reduced, if free from iron, with sodium sulphite, in the contrary case, with stannous chloride, after which potassium sulphocyanate and sal-ammoniac are added. The washed precipitate is boiled with caustic potash or soda, and the cuprous oxide thereby produced is quickly separated by filtration and titrated as above with ferric sulphate.

By Titration with Potassium Ferrocyanide.—Galetti (*Bull. Soc. Chim.* [2] ii. 83; *Zeitschr. anal. Chem.* viii. 135; *Jahresh.* 1864, 710; 1869, 901), uses for this purpose a solution containing 32.485 grams of ferrocyanide in the litre, so that 100 c. c. correspond with 1 gram of copper, according to the equation $K^+FeCy^{4-} + 2CuCl^+ = 4KCl + Cu^2FeCy^4$. To apply this method to the analysis of copper pyrites, the mineral is first oxidised with strong nitric acid, hydrochloric acid is then added, the solution evaporated to half its bulk, then diluted and mixed with ammonia in quantity rather more than sufficient to precipitate the whole of the iron. It is then boiled with a quantity of acetic acid sufficient to give it an emerald-green colour; ammonia is again added in excess, and the liquid is acidulated with very dilute acetic acid. As soon as the basic ferric acetate has settled down, the copper is precipitated by potassium ferrocyanide. The liquid may also be filtered after the second addition of ammonia, and the precipitate washed with a boiling dilute solution of acid ammonium acetate (20 grams of acetic acid saturated with ammonia and then mixed with 15 grams of acetic acid and 585 of water). If zinc, nickel, or cobalt is present, the copper must first be precipitated as sulphide or in the metallic state, then redissolved and treated as above.

By Titration with Potassium Cyanide.—In applying this method, described in vol. ii. p. 58, to the estimation of copper in compounds containing zinc, some modification is required to counteract the disturbing influence of the zinc. Yvon (*Compt. rend.* lxxiv. 1252) proceeds as follows: Solutions of zinc and copper nitrates, with excess of ammonia, containing 1 gram of metal per litre, are first prepared. The amount of cyanide required to decolorise 50 c. c. of pure copper solution is noted, and then the amounts after addition of 5, 10, 15, 20, &c., c. c. of zinc solution. From these results the amounts corresponding with 1 c. c. of cyanide are deduced.

The alloy to be analysed, such as brass, is dissolved in nitric acid, ammonia added, and the whole made up to a litre. After titrating 50 c. c. with cyanide, another 50 c. c. is acidified strongly, boiled with sodium thiosulphate, and the cupric sulphide dissolved in nitric acid and ammonia, and again titrated. The difference represents the zinc.

On the determination of copper in brass by titration, see also Kirpitschon (*Zeitschr. f. Chem.* [2] vii. 207; *Chem. Soc. J.* [2] ix. 755).

By Titration with Stannous Chloride.—F. Weil (*Ann. Ch. Phys.* [4] xxv. 109) describes this method as based on the two facts, (1.) That in a hot solution containing excess of hydrochloric acid, the least trace of cupric chloride gives a greenish colour, the tint being deeper as the quantity of acid is larger. (2.) Stannous chloride instantly reduces green cupric chloride to colourless cuprous chloride.

A solution of stannous chloride containing 6 grams of tin per litre is titrated with a solution of cupric sulphate containing 4 grams of copper per litre; 25 c. c. of this solution are treated with 10 c. c. of concentrated hydrochloric acid, and heated to boiling, and the tin solution is rapidly added till the liquid becomes colourless; 10 c. c. more acid are now added, and if the liquid acquires thereby a greenish tint, tin-solution is slowly dropped in till no colour remains. To make quite sure that the tin-solution is in slight excess, 1 c. c. of the cooled liquor is treated with a drop of saturated solution of mercuric chloride; 0.05 c. c. of the tin-solution in 30 c. c. of liquid causes a distinct turbidity of calomel when thus treated. This volume is therefore deducted from the total volume of tin-solution used, and the strength calculated from the remainder.

Estimation of the Copper.—1. *When Iron and Nickel are absent.*—The substance is heated with strong nitric acid; the nitric acid is expelled by sulphuric, or in the case of silver, by hydrochloric acid; the volume of the solution is brought to 250 c. c. or 500 c. c.; 25 c. c. are then treated with the tin-solution exactly as above described in the case of the standard copper-solution, and the quantity of copper present is calculated from the volume of liquid employed.

2. *When Iron is present.*—*Process A.* 25 c. c. of the solution to be tested are reduced as just described. A fresh quantity of the same volume is then heated with water, metallic zinc, and platinum-foil till all the iron is reduced. The copper, together with any lead, tin, or arsenic that may be present is thus precipitated as metal. The iron is then estimated in the decanted liquid with permanganate. The strength of the tin-solution having been calculated for iron from the number for copper, the proper deduction is made from the total quantity used. *Process B.* The metallic copper precipitated as described under *A* may be dissolved and directly

estimated with tin-solution without estimating the iron. *Process C.* The solution containing ferrous salt, described in A, may be treated with permanganate till the latter is in distinct excess, then boiled till no red colour remains but that due to iron. Tin-solution is now added till the iron is reduced, and the quantity thus used is subtracted from the total quantity employed for copper and iron together.

3. *When Nickel or Cobalt is present.*—*Process A.* The solution of the substance in nitric acid or aqua regia is nearly neutralised with sodium carbonate and then agitated with barium carbonate till all the copper and iron are precipitated. The precipitate is dissolved in acid, and the copper in it is estimated by tin-solution. *Process B.* See above, 2nd Application, B.

Arsenic does not interfere with this method, since arsenic acid is not reduced by stannous or cuprous chloride. The results obtained vary only a few tenths of a per cent. from those obtained in the gravimetric way.

Separation of Copper from Bismuth.—The separation of these metals when they are alloyed together may be effected by treating the alloy at a low red heat with potassium sulphocyanate. One part of a mixture of 8 parts potassium cyanide and 3 parts of sulphur is thrown upon 16 parts of the alloy melted at a low temperature. As soon as the reaction takes place, the crucible is covered, and when all deflagration has ceased, the metal is well stirred with a clay rod, the flux allowed to set, and the fluid metal poured out. The bismuth thus obtained is quite free from copper (H. Tamm. *Chem. News*, xxv. 85).

Separation from Silver.—A quick method of separating these metals is based on the fact that silver nitrate is insoluble in strong nitric acid, whereas cupric nitrate is soluble. The nitric acid solution of the metals is evaporated to the consistence of a thick oil, and then mixed with strong nitric acid free from hydrochloric acid, whereby all the silver salt is precipitated in the crystalline state, the copper salt remaining in solution. The precipitate, which is coloured blue from adhering copper salt, is obtained quite white and free from copper by two or three washings with strong nitric acid. The adhering acid evaporates on drying the precipitate. Care must be taken not to evaporate the mixed nitrate solution to dryness, as it is then very difficult to wash out the copper from the precipitated silver nitrate. The more concentrated the nitric acid, the more fully is the silver salt thrown down. An acid of sp. gr. 1.25 gives good results. For every part of concentrated metallic solution, three to four parts of acid are requisite for separation. R. Palm (*Dingl. polyt. J.* cciv. 75).

According to Hahn (*Chem. Centr.* 1870, 240; *Zeitschr. f. Chem.* vi. 352) the separation of copper from silver cannot be effected by dissolving the two metals in excess of potassium cyanide and treating the solution with hydrogen sulphide or the sulphide of an alkali-metal—whereby, according to Rose and Frosenius, the silver is precipitated as sulphide, while the copper remains dissolved—inasmuch as the sulphides of both these metals are soluble in potassium cyanide, and only mercury, if present, is thrown down as sulphide.

Compounds of Copper.

Arsenide.—Frenzel (*Jahrbuch f. Mineralogie*, 1873, 26), has examined three varieties of this compound, regarded by mineral dealers as distinct species, and named accordingly. I. Domeykite from the San Antonio mine near Copiapo, Chile. II. Algodonite from Lake Superior. III. Whitneyite from Cerro las Paracutas, Ciguazuala, Mexico. Analysis showed that all three are varieties of one species, Domeykite, viz. :—

Sp. gr. (at 22°)	I.	II.	III.
	6.700	7.207	7.547
Copper	70.16	72.02	72.09
Arsenic	25.89	28.29	27.10
Iron	3.50	—	—
Manganese		—	—
Sulphur	0.49	—	—
Residue	0.45	—	—
	100.49	100.31	100.09

The formula of Domeykite, Cu_2As , requires 71.72 p.c. copper and 28.28 arsenic. The 25.88 p.c. of arsenic found in I. would require, according to this formula, 55.94 p.c. copper. The copper arsenide in it is probably mixed with native copper, iron arsenide, and a sulphur compound. The third variety also probably contains native copper.

All three varieties exhibit, on newly fractured surfaces, a tin-white to bluish

colour. The bright metallic lustrous powder of II. (the purest variety) is light grey; that of III. dark grey; of I. greyish black. In the course of 24 hours they all acquire a yellow tarnish.

Accompanying these minerals were found native copper, red copper ore, malachite, quartz, and small quantities of a radio-fibrous mineral, probably wavelite.

Weisbach (*ibid.* 64) describes a variety of Domeykite found imbedded in the argillaceous porphyry (*Thonsteinsporphyr*) on the right bank of the Mulde, near Zwickau. It occurs in masses having a dense or very fine-grained fracture, with a decided tendency to cleavage, and therefore to crystalline structure. Colour and streak blackish grey. Lustrous metallic, brighter on the streak. Hardness 5 (equal to that of apatite). Sp. gr., 6.84. Brittle, with decided inclination to softness. It differs from the Chilian mineral chiefly in colour and hardness, the latter being tin-white, and intermediate in hardness between calcspar and fluor-spar. This Zwickau mineral affords the first instance of the occurrence of Domeykite on the continent of Europe.

Chlorides.—According to Maumond (*Chem. News*, xxv. 156), when cuprous chloride is formed by the gradual combination of copper with chlorine, an external layer of cupric chloride is produced at the same time, and these two chlorides unite together forming the compound $\text{Cu}^+\text{Cl}^{10} = 3\text{CuCl}^2 + 2\text{Cu}^2\text{Cl}^2$.

Iodides.—*Cuprous iodide*, Cu^+I^2 , is formed by the action of copper on hydriodic acid. When strips of copper or pieces of copper-wire are immersed in this acid, no formation of iodide takes place as long as the liquid remains colourless; but as soon as iodine begins to separate, pulverulent cuprous iodide is also precipitated, and the reaction once commenced goes on quickly. By retarding the separation of iodide, which may be effected by the introduction of traces of hydrogen sulphide, the cuprous iodide may be obtained in tetrahedral crystals. Larger and better developed tetrahedrons, sometimes with combination-faces, are produced by the action of hydriodic acid on cuprous sulphides, as, for example, on the slightly oxidised copper-glance of Sangerhausen. The crystals have a greenish yellow colour, becoming darker on exposure to light (E. Miesel, *Dent. Chem. Ges. Ber.* iii. 502).

Cuprous iodide is also formed, together with allyl bromide, by the action of allyl iodide on an alcoholic solution by cupric bromide (Oppenheim, *ibid.* 412).

Cuproso-mercuric Iodide.— Cu^+HgI^4 . When cupric sulphate is added to a boiling solution of potassio-mercuric iodide, a large quantity of iodine is set free, and cuproso-mercuric iodide is precipitated as a dark brown powder changing on cooling to a fine red. When heated either alone or with water, it becomes dark-coloured, but recovers its red colour on cooling. According to Miesel (*Berliner Monatsberichte*, 1870, 123), this precipitate is a mixture of cuprous and mercuric iodides; but Wilm and Caventou (*Bull. Soc. Chim.* [2] xlii, 220) regard it as a definite compound, because when cold it has a deeper red colour than mercuric iodide, and it is but very slowly decomposed in the cold by potassium iodide, whereas mercuric iodide, as is well known, is quickly dissolved by that reagent. On heating the precipitate with potassium iodide, mercuric iodide is dissolved and cuprous iodide remains. With ammonia, the double iodide yields two kinds of crystals, both containing mercury and copper. Boiled with ammonia, it yields a blue solution, and a very heavy brown liquid which solidifies at a slightly lower temperature. The filtered blue solution deposits on cooling blue needles consisting of an ammoniacal iodide of copper and mercury containing the copper in the form of cupric iodide CuI^2 . The formation of this compound is due to the mercury which is set free and remains mixed with the precipitate. When the fused mass is redissolved in boiling slightly ammoniacal water, green crystals are formed which likewise contain mercury and copper, the latter, however, in the form of cuprous iodide CuI^2 ; they appear to be formed by simple addition of ammonia to the original compound, into which, indeed, they are reconverted on exposure to the air, or treatment with an acid. The blue crystals, on the other hand, which, when dried by heat, are likewise converted into a double iodide, give up iodine at the same time, even before they have parted with all their ammonia.

Cuprous oxide.—This oxide has been found in crystals (cuprite) in an ancient Russian tomb, at Dimitrow, in the Telsch district of the Kowno Dominion. At a depth of 120 c.m. below the surface, in a bed of loose yellow sand overlying compact red boulder-clay, were found a number of objects, many of them of metal. Sand being a material in which the corrosion of metallic bodies goes on more rapidly than in peat, or marsh, or water, the bronze was covered with a thick crust of malachite. On opening the grave, a lump of red ferruginous sand was found containing a necklace of wire

thread covered over with fragments of skull. In some little cavities in the crust of iron rust that covered the wire, small ruby-red crystals of cuprite ($\infty O \infty . O . O \infty$) were seen. The cuprite evidently arose from the reduction by water containing ferrous carbonate, of the ammoniacal solution of copper oxide produced by the reaction of the decomposing human remains on the bronze (Growthig, *Jahrbuch f. Mineralogie*, 1871, 76).

Oxychloride.—Crystals of atacamite from Walleroo in Australia, carefully selected and free from foreign admixtures, were found by H. Ludwig (*Deut. Chem. Ges. Ber.* vi. 553) to have the composition $Cu^2ClH^2O^2$ or $CuCl^2.3CuH^2O^2$, agreeing with the older analyses by Klaproth, J. Davy and others (i. 428).

Atacamite is decomposed by heat; when it is gradually heated, water-vapour escapes and there remains a mixture of cupric oxide and cupric chloride from which the latter may be extracted by water. This decomposition, however, begins only at 220° and goes on but slowly at 250° , not being completed for several days. When the temperature rises above 250° , hydrochloric acid escapes with the water-vapour, and the residue, when treated with water, no longer yields the original compound. Water does not act perceptibly on atacamite, even when heated with it to 200° for several hours in sealed tubes.

From these results Ludwig infers that atacamite is not, as generally supposed, a molecular compound of cupric chloride with cupric hydroxide (*vid. sup.*) or of cupric oxychloride with water, $Cu^2Cl^2O^2 + 3H^2O$, but an atomic compound, $Cu^2Cl^2O^2H^2$ or $Cu^2Cl^2O^2H^2$, containing quadrivalent copper, and represented by the structural formula

In like manner brochantite, $Cu^2SO^4H^2$, which is decomposed only at temperatures above 300° , giving off water and leaving a mixture of cupric oxide and cupric sulphate, may be regarded, not as a molecular compound, $Cu^2SO^4.3Cu^2H^2O^2$, containing bivalent copper, but as an atomic compound of quadrivalent copper, represented by the formula

The constitution of malachite, azurite and the so-called basic copper salts prepared artificially, may also, according to Ludwig, be more appropriately represented by atomic formulae containing quadrivalent copper, than by the usual molecular formulae.

Sulphides.—Native copper-glance (Cu^2S) from Catamarca, of sp. gr. 4.7 and having distinct crystals of iron pyrites and quartz imbedded in it, gave by analysis:

Cu	S	Fe	As	Zn	SiO ² (matrix)	Bi, Sb
48.82	26.71	6.64	9.16	0.74	7.52	traces = 99.59

L. Schinnerer (*Jahrbuch f. Mineralogie*, 1872, 977).

Cuprous sulphide is formed in crystals, with evolution of hydrogen, when copper turnings are digested in colourless solution of ammonium sulphide free from sulphhydrate. The crystals consist of very slender needles having a grey colour and metallic lustre: they change by oxidation on exposure to the air. On adding water or hydrochloric acid to the liquid from which they have separated, a precipitate containing copper is thrown down. Now, as the solution is colourless, the copper contained in it could not have been in the form of the red copper-ammonium sulphide described below, though perhaps a similar compound may exist containing a smaller proportion of sulphur (K. Heumann, *Deut. Chem. Ges. Ber.* vi. 748).

Cupric oxide treated with ammonium monosulphide yields a black precipitate consisting chiefly of Cu^2S , but containing a considerable quantity of CuS . The supernatant liquid treated with hydrochloric acid yields a precipitate of sulphur (Heumann).

A copper-ammonium-sulphide having the composition $(NH^4)^2S.2CuS^2$, is deposited in cinnabar-red needles from a hot solution of cupric sulphide in ammonium sulphide left to cool in a closed vessel (Bloxam, *Chem. Soc. J.* [2] iii. 94). It is also formed when an ammoniacal solution of the complex thiosulphate $(Cu^2)^2Cu^2Na^2S^2O^2.3NH^4$, described by Peltzer (v. 633), or of the yellow salt obtained from it, or a dilute ammoniacal solution of cupric sulphate, is added by drops to a solution of ammonium polysulphide till a permanent precipitate is formed, and the solution is filtered into a flask which must be quite filled with it and closed air-tight. After a day or two the double sulphide separates in small garnet-red concentrically grouped needles, or as an amorphous powder if the liquid is shaken.

This sulphur salt dissolves with yellow colour in water and ammonia, and

in alkaline carbonates. According to Bloxam, it is not decomposed by cold hydrochloric or nitric acid; according to Peltzer, on the other hand, it is decomposed by dilute acids, with evolution of hydrogen sulphide and separation of red-brown or black-brown copper sulphide, but without separation of sulphur. When heated with potash it appears to be at first converted, with evolution of ammonia, into the corresponding potassium-compound, but afterwards black copper sulphide is precipitated. Heated in a glass tube it gives off sulphur and ammonium sulphide (Peltzer).

CORALLIN. The names *Red Corallin* and *Peonin* (iv. 324), have been given to the red colouring matter which Kolbe a. Schmitt obtained by treating phenol with sulphuric and oxalic acids. This body has been further examined by H. Fresenius (*J. pr. Chem.* [2] v. 184; *Chem. Soc. J.* [2] x. 705), who purifies it by combining it with magnesia, and afterwards decomposing the compound with sal-ammoniac. Crystallised from alcohol it forms filamentous, interlacing, scarlet, lustrous crystals; crystallised from glacial acetic acid, it forms magnificent rhombic crystals which are combinations of the prism ∞P with a second prism not determined, the brachy-pinaeoid, ∞P_{∞} , and sometimes the brachydome \bar{P}_{∞} . Ratio of axes $a : b : c = 0.541 : 1 : 0.354$; angle $\infty P : \infty P = 123^{\circ} 3'$; $\infty P : \infty P_{\infty} = 118^{\circ} 25'$; $\bar{P}_{\infty} : \bar{P}_{\infty} = 141^{\circ} 5'$; $\bar{P}_{\infty} : \infty P_{\infty} = 109^{\circ} 29'$. Cleavage distinct parallel to OP .

The crystals are red by transmitted, dark green by reflected light, moderately soluble in phenol, slightly in boiling chloroform and boiling benzene, insoluble in carbon bisulphide; become strongly electric when rubbed. They melt at 156° . Kolbe a. Schmitt found the melting point to be 80° , probably because their product still retained considerable quantities of phenol.

Corallin gives by analysis (mean) 69.07 p.c. carbon, and 5.38 hydrogen, agreeing with the formula $C^{10}H^{10}O^{11}$ which requires 69.18 carbon and 5.47 hydrogen. Regarding again as $C^{10}H^{10}O^{11}$ (p. 118), the relation between these two compounds may be expressed by the equation $2C^{10}H^{10}O^{11} + 5H^{10}O = C^{10}H^{10}O^{11}$.

The mode of formation of corallin, however, suggests a simpler formula: for the gas which escapes during its preparation by oxalic acid is chiefly carbon dioxide: hence it is inferred that the substance which is most active in its formation is carbon monoxide derived from the oxalic acid: and this conclusion is corroborated by the fact that formic acid may be used in preparing corallin, in place of oxalic acid. Hence Kolbe, in a note to Fresenius' paper, suggests that corallin is formylated phenol $C^8H^8O^2 = C^8H^8(COH)OH$, its formation being represented by the equation

The formula $C^8H^8O^2$ requires 68.85 p.c. carbon and 4.90 hydrogen.

Corallin is likewise obtained when phenetol or anisol is substituted for phenol in its preparation; also when meta- or para-phenylsulphonic acid is acted upon by oxalic acid.

Caro a. Wanklyn's rosolic acid, obtained by the action of nitrous acid on rosaniline is different from corallin; its composition being, according to analyses by Fresenius, $C^{12}H^{12}O^{10}$ (Caro a. Wanklyn gave the formula $C^{12}H^{12}O^8$), it melts at about 158° , and its alcoholic solution is not decolorised, like that of corallin, by concentrated solution of acid sodium sulphite. Fresenius proposes to call this body *pseudocorallin*.

Printing with Corallin.—Corallin is much used for dyeing on wool, and may also be employed for printing on wool, provided some means be adopted for neutralising the acids with which it is sure to come in contact in the course of treatment to which it is subjected. The effect of the acids, which is to cause the red colour to fade into yellow, may be prevented by the use of calcined magnesia, the corallin being dissolved in water or in alcohol. The resulting colour is a rich Turkey-red, which maintains its intensity and brilliancy for years. This red is about 30 p.c. cheaper than cochineal red, and has this advantage over the latter, that it is not turned blue by washing in water containing calcium carbonate, the only disadvantage being that of its fading in contact with strongly acid colours, if the acid be more than sufficient to neutralise the magnesia. The following mixture is recommended for printing:—80 grams corallin, $\frac{1}{2}$ litre glycerin, $\frac{1}{2}$ litre water, 140 grams magnesia, well stirred up with $\frac{1}{2}$ litre of water. The whole is thickened with $\frac{1}{2}$ litre of gum-water (500 grams to the litre), and printed, steamed, and washed in the usual way.

Corallin may also be printed on cotton, the colour being thickened with starch and egg-albumin in addition to magnesia. This mixture must be used fresh, as in time an insoluble compound is formed between the magnesia and the albumin (*Diag. polyt. J. civ. 338*).

CORIARIA. The poisonous principle of the Tutu plant (*Coriaria ruscifolia*) of New Zealand does not appear to be of the nature of an alkaloid. The ground seeds repeatedly treated with alcohol yield a greenish-red substance, which, when

CREATINE, $C_4H_7N^+O_2$. A compound isomeric with creatine, called isocreatine or alacreatine, is formed by direct combination of alanine with cyanamide: $C_2H_5NO_2 + CH_3N^+ = C_4H_7N^+O_2$. When a concentrated aqueous solution of the two substances mixed with a little ammonia is left to stand for some time, dicyanamide crystallises out first, and then alacreatine, the yield of which may be increased by employing an excess of alanine, but never reaches the theoretical limit.

Alacreatine forms anhydrous prismatic crystals resembling creatine. It is almost insoluble in cold alcohol, and very sparingly soluble in hot alcohol, but dissolves freely in water, namely, in 12 parts at 15° , whereas creatine, according to Liebig, requires 71 parts at 18° . When heated to 170° – 180° , or treated with dilute sulphuric acid, it loses water and is converted into alacreatinine, $C_4H_7N^+O$, which dissolves in water and in alcohol more freely than alacreatine, crystallises from water in long needles resembling urea, and from alcohol in small rhombohedral anhydrous crystals (E. Baumann, *Ann. Ch. Pharm.* clix. 77).

CREATININE. C_4H_7NO .—*Preparation from Urine*.—A few litres of human urine are evaporated to about one-third of the original volume, and the liquid, after being decanted from the salts which crystallise out, is precipitated with lead acetate. The filtrate is freed from lead by sodium carbonate or sulphuretted hydrogen, neutralised either with acetic acid or with sodium carbonate, and precipitated with mercuric chloride. The precipitate, a combination of creatinine with the mercuric salt, is decomposed under water with sulphuretted hydrogen, and the liquid, after treatment with animal charcoal, is evaporated. On recrystallising the crystalline residue once or twice from alcohol, pure creatinine hydrochloride is obtained in white crusts or hard shining prisms. The same results were obtained with horses' urine (Maly, *Ann. Ch. Pharm.* clix. 279).

Alacreatinine, obtained, as above described, by dehydration of alacreatine, dissolves in alcohol and water more freely than the latter, crystallises from water in long needles resembling urea, and from alcohol in small anhydrous rhombohedral crystals, which, on exposure to the air, absorb water and change into needles. Alacreatinine is a base resembling creatinine, and forming double salts with zinc chloride and other chlorides. It also reduces mercuric oxide, yielding, together with other products, an alkaline base, but no oxalic acid (Baumann, *loc. cit.*)

CRENIC ACID. According to Bontigny (*Compt. rend.* lviii. 247), the medicinal waters of Forges-les-Baux contain ferrous salts of crenic and apocrenic acids. On exposure to air the waters deposit an insoluble ferric compound, from which crenic acid can be extracted by boiling with caustic potash and precipitating the solution with hydrochloric acid. The purified crenic acid is capable of dissolving ferrous carbonate. The source of the waters is a peaty stratum, overlying a vein of iron pyrites.

CRESOL. $C^6H^5O = C^6H^4 \begin{Bmatrix} CH^3 \\ OH \end{Bmatrix}$. H. L. Buff (*Deut. Chem. Ges. Ber.* iv. 378) has obtained a solid and a liquid cresol by subjecting coal-tar creasote to fractional solution in soda-ley, and fractional precipitation with hydrochloric acid; treating the fraction boiling at 204° – 205° with benzoyl chloride, whereby a solid and a liquid cresyl benzoate were produced; and decomposing these ethers with alcoholic potash. The solid body was obtained in large, white, hard crystals, which melted at 70° – 70.5° , and solidified at 52.6° . Its properties agree with those of paracresyl benzoate, which melts at 70° . The cresol obtained from it is a colourless body, having a sharp urinous smell. It solidifies in a mixture of ammonium sulphocyanate and water, melts at 34° , and boils at 205° . Its properties are those of paracresol (*1st Suppl.* 608).

The liquid ether boils above 360° , and does not solidify in a mixture of ammonium sulphocyanate and water. The cresol separated from it by alcoholic potash cannot be made to solidify; after fusion with potash, it gives, with ferric chloride, the reaction of salicylic acid.

Chlorocresol, $C^6H^4Cl \begin{Bmatrix} CH^3 \\ OH \end{Bmatrix}$, may be prepared by heating cresol-vapour with chlorine, removing the resulting hydrochloric acid by a stream of carbonic anhydride, subjecting the product to fractional distillation, and separating the portion which distils between 235° and 245° . This liquid, when cooled by a freezing mixture, deposits crystals of chloro-cresol, easily soluble in alcohol, ether, benzene, and petroleum oil, melting at 56° , boiling at about 240° . This compound does not yield any definite products with ammonia, aniline, potassium cyanide or silver cyanide; neither can orcin be produced from it by heating with alcoholic potash or fusion with potassium hydrate. Hence it may be inferred that the chlorine-atom is contained, not in the lateral chain CH^3 —as might perhaps have been expected from the formation of the compound at a

high temperature—but in the benzene nucleus, as indicated by the formula above given (R. Biedermann, *Deut. Chem. Ber.* vi. 325).

Cresol-sulphonic acid, $C^6H^5SO^4 = C^6H^5 \begin{Bmatrix} CH^3 \\ SO^3H \\ OH \end{Bmatrix}$, was prepared by heating

sulphuric acid and the above-mentioned cresol to 60°. The barium salt and calcium salt are very soluble, crystallise badly, and have a tendency to form basic salts. The potassium salt forms star-shaped groups containing two molecules of water. The salts of this acid appear to correspond with those of the γ -cresol-sulphuric acid of Engelhardt and Latschinoff (*1st Suppl.* 507). On fusing the potassium salt with potash and treating the product in the usual way, pyrocatechin was obtained, but no orcin (Biedermann).

With the view of obtaining orcin, cresol was treated with an alkaline solution of iodic acid and iodine, according to the method of Körner, whereby an iodised cresol was obtained in the form of an oil which decomposed below its boiling point, and this oil heated to 250°–300° with alcoholic potash, was decomposed, yielding a brown amorphous mass. This substance was several times dissolved in an alkali and precipitated by an acid, and was afterwards purified by various solvents. It becomes red on treatment with ammonia, dissolves in alkalis with a dark red colour, softens at 50°, melts at 100°, and is free from iodine. By analysis it gave numbers agreeing with the formula $C^6H^{11}O^3$ or $\begin{Bmatrix} CH^3 \\ HO \end{Bmatrix} C^6H^5-O-C^6H^5 \begin{Bmatrix} CH^3 \\ OH \end{Bmatrix}$ (Biedermann).

CRESOTIC ACID, $C^6H^5O^3 = C^6H^5 \begin{Bmatrix} CH^3 \\ OH \\ CO^2H \end{Bmatrix}$. Biedermann a. Pike (*Deut. Chem.*

Ges. Ber. vi. 323) have prepared this acid from coal-tar cresol obtained from Calvert's manufactory. This liquid did not yield to fractional distillation any product of constant boiling point, but the portion boiling at 203° was regarded as pure cresol.

Cresotic acid was prepared, according to Kolbe's method (*1st Suppl.* 508), by dissolving sodium in the cresol, and passing carbonic anhydride into the solution; the sodium cresotate was then precipitated from the liquid by a concentrated solution of ammonium carbonate, and pure cresotic acid was separated from the aqueous solution of the precipitate by hydrochloric acid. It was found, however, that only a small portion of the cresol is converted by this treatment into cresotic acid, probably because one of the modifications of cresol in the mixture is more easily acted on than the other two.

Cresotic acid thus prepared melts at 174°. According to Kolbe, the melting point is 153°. Engelhardt a. Latschinoff, on the other hand, found that the cresotic acid which they prepared from γ -cresol or meta-cresol by the action of phosphoric anhydride on thymol (*1st Suppl.* 507), melted at 168°–173°, whereas the melting points of their α and β cresotic acids (prepared by fusing α - and β -toluenesulphonate of potassium with potash) were much lower, viz., 114° and 147°–150° respectively. It would appear, then, that the cresotic acid prepared as above is γ -cresotic or meta-cresotic acid.

This cresotic acid crystallises from water in beautiful shining needles resembling salicylic acid, and strikes a deep violet colour with ferric chloride. The calcium salt and barium salt are very soluble in water, crystallise badly, and retain no water of crystallisation. The silver salt forms a white powder soluble in hot water, and yields methyl cresotate when it is heated with methyl iodide. This ether boils at 236°–237°, and smells like gaultheria oil. Alkalis act on it, forming an alkaline methyl-cresotate, which by further treatment with alkali splits up into methylic alcohol and cresotic acid. Ammonia converts it into methyl alcohol and cresotamide, a solid slightly soluble mass, which has not yet been investigated.

An attempt to prepare the aldehyde of cresotic acid by the distillation of calcium cresotate and calcium formate was unsuccessful, cresol and other products not yet investigated being formed. Nothing giving a crystalline product with sodium bisulphite was obtained.

CRONSTEDTITE. This mineral, found only at Příbram in Bohemia, and in Cornwall, was first analysed by von Kobell, who assigned to it the formula $3(FeO \cdot SiO_2) \cdot 4(Fe_2O_3 \cdot 3H_2O)$, or $3Fe^{2+}SiO_3 \cdot 4(Fe^{3+})_2H_2O^6$ (ii. 112). This formula has recently been confirmed by Maskelyne a. Flight (*Chem. Soc. J.* [2] ix. 9), who found in a well selected Cornish specimen, 41.27 p.c. ferrous oxide, the formula requiring 41.54. Many specimens, however, exhibit a smaller percentage of ferrous oxide, and an excess of ferric oxide, probably from association with a ferric silicate, like hisingerite, with which, indeed, cronstedtite has been shown to be associated.

The crystals of cronstedtite belong to the hexagonal system and are hemimorphous. The specimens formerly examined from Příbram and from Wheal Maudlin in Cornwall

did not yield measurable crystals; but amongst those from other Cornish localities examined by Maskelyne and Flight, were a few on which the diverging groups of the crystals of cronstedtite presented here and there a crystal, or more generally a small group of crystals, with more definite features. In some cases the crystals were mutually interpenetrating, the brilliant cleavage-planes of the different crystals projecting through one another, and presenting re-entering angles which indicated the probability of their being twinned. In most cases, again, a careful scrutiny of the bright summit plane showed that it was tessellated, and that the crystal was in fact composite, the different individuals comprising it being generally in parallel juxtaposition (fig. 9), but sometimes (fig. 10) twinned round the normal to that plane (the morphological axis of the crystal); but never so as to mask the truly hemimorphous character of the crystal. The symmetry round the axis of each crystal is trigonal, the form of the crystal being that resulting from the combination of two rhombohedrons, of which only the planes on one side of the unique plane of symmetry (that parallel to the summit plane) are extant. The crystal thus presents the aspect of a combination of two trigonal pyramids, of which one is more acute than the other (fig. 11). For angular measurements see the original paper.

FIG. 9.

FIG. 10.

FIG. 11.

CROTON OIL, ACIDS OBTAINED FROM.

It has hitherto been admitted, on the authority of Schlippe, that croton oil yields by saponification crotonic acid $C_7H_{12}O_2$ and angelic acid $C_5H_8O_2$ (ii. 112). But from recent experiments by Geuther and Fröhlich (*Zeitschr. f. Chem.* [2] vi. 26, 549), it appears that this oil does not yield any liquid acid having the composition $C_7H_{12}O_2$, and that the solid acid, $C_5H_8O_2$, which it yields, is not angelic acid.

Croton oil (2 kilo.) is saponified with strong soda-ley; the brown soap removed; the black under-liquor supersaturated with sulphuric acid and distilled; the distillate (on which oil-drops float) is neutralised with sodium carbonate, then evaporated to a small bulk and supersaturated with sulphuric acid; the acids which separate in oily form are removed from the watery liquid; the latter is several times exhausted with ether free from alcohol; the ether added to the oily acids; the ethereal liquid dehydrated with calcium chloride; and the ether distilled off. By this process, a brown oil is obtained as residue (44 grams) which by repeated fractional distillation may be separated into four portions, the first boiling at 115° – 160° , the second at 160° – 190° , the third at 190° – 205° , and the fourth at 205° – 270° .

The first fraction contains butyric and acetic acids (no propionic acid was observed); the second, butyric and valeric acids. The third contains a crystallised acid, constituting nearly the whole, which has the constitution of angelic acid, but is not identical therewith. When freed from adhering oily acid by repeated crystallisation from water, this acid forms transparent, colourless, rhombic plates and prisms, which at 61° begin to melt at the edges, and at 64° melt completely to a limpid oil, gradually solidifying again between 60° and 58° . It boils without decomposition at 201.1° (corr.), tastes very sour, and when pure has a pleasant aromatic odour. Geuther and Fröhlich designate this acid provisionally as tiglic acid, and point out that it is, perhaps, identical with Frankland and Duppa's methyl-crotonic acid (1st Suppl. 828). Its ethylic ether $C_5H_9O_2.C_2H_5$ boils at 160° (corr.), has a specific gravity of 0.926, is colourless, transparent, and insoluble in water, and has a peculiar aromatic odour, not at all like the disagreeable odour ascribed by Frankland and Duppa to methyl-crotonic ether.

Barium tiglate, $(C_5H_9O_2)_2Ba + 10H_2O$, separates from its aqueous solution on evaporation, as a dense crystalline mass made up of small needles; it is very soluble in water, but by no means difficult to crystallise, as the methyl-crotonate is said to be. It gives up its water of crystallisation over oil of vitriol. Silver tiglate $C_5H_7AgO_2$ is a white crystalline powder, nearly insoluble in water, and but little altered by light. The fourth fraction (205° – 270°) of the original mixture of acids appears to contain caproic, or cennanthic, or pyroterebic acid, together with higher members of the

acrylic series or of the next lower isologous series $C^aH^{a-1}O^2$: the quantity of this fraction is, however, very small.

CROTONIC ACID. $CH^2H^2O^2$ (Kekulé, *Deut. Chem. Ges. Ber.* iii. 604; *Zeitschr. f. Chem.* [2] vi. 705). Solid crotonic acid (hitherto distinguished as α -crotonic acid) is produced by the action of oxygen or atmospheric air on crotonic aldehyde (formed by condensation of acetic aldehyde),—also as a silver salt by oxidising crotonic aldehyde with silver oxide. The acid thus produced melts at 71° – 72° . In a small distilling flask it boils at 180° – 181° ; when distilled according to Kopp's directions, at 182° (corr. 181°); with the mercury-column entirely in the vapour, at 189° . In vessels exposed to the sun, it sublimes in large rhombic plates. It dissolves in 12.47 parts of water at 19° and is obtained by evaporation of this solution in well-defined monoclinic crystals exhibiting the combination ∞P , $\infty P \infty$, OP , $+ P \infty$. Angle ∞P : $OP = 112^\circ 50'$; ∞P : $\infty P = 107^\circ 30'$ (laterally); OP : $+ P \infty = 125^\circ 30'$. Axes a : b : $c = 1$: 1.8065 : 1.5125 . Angle $bc = 131^\circ$. Cleavage parallel to OP and $\infty P \infty$ (vom Rath). When fused with potash, it yields nothing but acetic acid.

The same characters are exhibited by crotonic acid prepared from the allyl cyanide obtained from mustard oil (1st *Suppl.* 510). According to Will a. Körner, this acid melts at 72° ; according to Bulk, it melts at 72° , boils at 183.8° (corr. 187°), and dissolves in 12.07 parts water at 15° . With regard to the crystalline form, Bulk gives measurements by Knop, from which, it appears that the crystals of the acid are monoclinic. Knop's measurements (*Ann. Ch. Pharm.* cxxxix. 62) are indeed affected with certain obvious errors, but four out of the six angles measured by him agree nearly with those determined by von Rath. The identity of the crotonic acid from allyl cyanide prepared from mustard oil with that obtained by oxidation of crotonic aldehyde, is therefore established; and the same may be said of the acid which Wislicenus obtained by the distillation of β -oxybutyric acid, which melts at 71° – 72° and boils at 181° – 182° (corr.) The crotonic acid obtained from allyl cyanide synthetically prepared (by the action of potassium or silver cyanide on allyl iodide) likewise exhibits the same physical properties, but according to Claus (*Deut. Chem. Ges. Ber.* iii. 93), when fused with potash, it yields, not acetic, but propionic and carbonic acids. Kekulé, however, finds that this statement is erroneous. He prepared crotonic acid in the manner described by Claus, viz., by converting allyl iodide into the cyanide, and distilling the latter with potash, and purified the portion distilling between 180° and 195° by converting it into the sparingly soluble silver salt and separating the acid therefrom. The crotonic acid thus obtained melted at 72° , boiled at 182° , and gave by fusion with potash, nothing but acetic acid.

Constitution of Solid Crotonic acid.—The identity of the crotonic acid from crotonic aldehyde and from allyl cyanide being thus established, it would seem to follow that this crotonic acid must have the formula $CH^2=CH-CH^2-COOH$, inasmuch as the constitution of allyl alcohol is constantly represented by the formula $CH^2=CH-CH^2OH$, and, therefore, that of allyl cyanide by $CH^2=CH-CH^2-CN$; and, in fact, Kekulé formerly represented crotonic acid by the formula just mentioned, assigning, also, a similar constitution to crotonic aldehyde, and supposing it to be formed from acetic aldehyde in the manner shown by the following equation, in which the bracketted symbols indicate the eliminated atoms of hydrogen and oxygen:

(See 1st *Suppl.* p. 513). Now, however, he considers it more probable that the two hydrogen-atoms are taken, not one from each of the methyl groups present, as above, but both from the same methyl group, giving for the resulting crotonic aldehyde a formula in which the two middle carbon-atoms are doubly linked, thus:

That such is the true representation of the change may be inferred with great probability from the analogous synthesis of cinnamyl chloride from benzoic aldehyde and acetyl chloride, discovered by Bortagnini:

In this case it can scarcely be supposed that the carbon-atom already attached to the aromatic nucleus by one unit of affinity could become more intimately united with it, so as to form the group $C^aH^2=CH-$.

Admitting, then, for crotonic aldehyde the formula $CH^2-CH=CH-COH$, it follows that the crotonic acid formed from it, and therefore also, the acid formed from

allyl alcohol, must have the constitution $\text{CH}^2=\text{CH}=\text{CH}-\text{COOH}$. In the latter case it must be supposed that, at some stage in the passage from the alcohol to the acid, a change occurs in the arrangement of the hydrogen-atoms, either that the iodide prepared from the alcohol has no longer the formula—

or that the cyanide is not—

or that the cyanide constituted according to the first formula yields an acid corresponding to the second cyanide.

The formula thus assigned to crotonic acid is confirmed by the fact that when fused with alkalis it is resolved into two molecules of acetic acid. For all the acids of the acrylic series when thus treated, split up at the point where the carbon-atoms are doubly united (1st *Suppl.* 42), so that when the molecule $\text{CH}^2=\text{CH}=\text{CH}-\text{CO}^2\text{H}$ is acted upon by $2\text{H}^2\text{O}$ (or 2KHO), the group CH^2-CH takes up 2 atoms of oxygen, and the right-hand group $\text{CH}-\text{CO}^2\text{H}$ takes up 2 atoms of hydrogen, forming 2 mols. acetic acid $\text{CH}^3-\text{CO}^2\text{H}$, while the remaining 2 atoms of hydrogen are eliminated. An acid having the constitution $\text{CH}^2=\text{CH}-\text{CH}^2-\text{CO}^2\text{H}$ would split up, under similar circumstances, into formic and propionic acids.

The formula $\text{CH}^2=\text{CH}=\text{CH}-\text{COOH}$ was formerly assigned to the liquid crotonic acid said to be obtained, 1. by saponification of croton oil (Schlieper); 2. by the action of chloroethylidene and metallic silver on chloroacetic acid (Stacewitz); 3. by the action of nascent hydrogen on the modification of chlorocrotonic acid which melts at 59.5 (Geuther; see 1st *Suppl.* 509). With regard to the first of these products, it appears, from the experiments of Geuther & Fröhlich, that the saponification of croton oil does not yield any acid having the composition $\text{C}^4\text{H}^6\text{O}^2$ (p. 395). With regard to the second, it has been shown by Kekulé & Zincke (*Ann. Chem. Pharm.* cxlii. 125) that the supposed isomeride of chloroethylene or vinyl chloride, called *chloracetylene* or *chloroethylidene*, said by Harnitzky to be formed by the action of phosgene on aldehyde, has no existence; hence it is probable that the liquid product obtained in the second of the above-mentioned reactions was nothing but crotonic aldehyde (formed by the action of hydrochloric acid on the acetic aldehyde) mixed with hydrochloric acid.

The liquid crotonic acid obtained by the third reaction, called *quartenylic* acid by Geuther, is said by him to yield nothing but acetic acid when fused with potash; but this, according to Kekulé, is the reaction exhibited by solid crotonic acid: hence Kekulé considers the existence of this liquid crotonic acid as somewhat doubtful, and suggests that it should have been confirmed by converting the acid in question into a silver salt and separating it therefrom. The chlorocrotonic acid of higher melting point is converted by nascent hydrogen into solid crotonic acid.

On the whole, then, Kekulé considers that only two modifications of the acid $\text{C}^4\text{H}^6\text{O}^2$ have as yet been satisfactorily made out, viz:

Crotonic acid (solid). $\text{CH}^2=\text{CH}=\text{CH}-\text{COOH}$.

Methacrylic acid.

$$\begin{array}{c} \text{H}^2\text{C} \\ \diagdown \\ \text{C}-\text{COOH} \\ \diagup \\ \text{H}^2\text{C} \end{array}$$

The third modification, $\text{CH}^2=\text{CH}-\text{CH}^2-\text{COOH}$, remains to be discovered.

On the constitution of crotonic acid see also Paternò (*Zeitschr. f. Chem.* [2] vi. 88); Lwow (*ibid.* 245).

Chlorocrotonic acids.—Trichlorocrotonic acid, $\text{C}^4\text{H}^2\text{Cl}^3\text{O}^2$, is produced by oxidation of crotonic chloral with fuming nitric acid. The action is very violent and must be moderated by cooling; with impure crotonic chloral it takes place immediately, but with the pure substance, after some time only. The trichlorocrotonic acid obtained from somewhat impure crotonic chloral often remains liquid for several days, and crystallises only in contact with crystals of the pure acid.

Trichlorocrotonic acid crystallises in colourless radiate needles, melting at 44° and boiling at $236^\circ-238^\circ$; it is very caustic, and destroys the skin. It takes up 33 p.c. of water, and, on the other hand, 25 parts of water dissolve one part of the acid. By acting upon it with zinc and hydrochloric acid the chlorine is replaced by hydrogen. All the products thus obtained crystallise well; best of all, *monochlorocrotonic acid*, which melts at 95° (Judson, *Zeitschr. f. Chem.* [2], vii. 40).

Potassium trichlorocrotonate, $\text{C}^4\text{H}^2\text{KCl}^3\text{O}^2$, is obtained by adding potassium carbonate slowly and in small quantities to the moderately concentrated acid; it crystallises in prisms and is very hygroscopic. *Ammonium trichlorocrotonate*, $\text{C}^4\text{H}^2(\text{NH}^4)\text{Cl}^3\text{O}^2$,

crystallises from alcohol in colourless scales. *Lead trichlorocrotonate*, $(C^4H^3Cl^3O)_2Pb + 2H^2O$, is prepared by shaking an ethereal solution of the acid with lead carbonate. On evaporating the solution, the salt crystallises in needles arranged in tuft-like groups; it is insoluble in cold water and sparingly soluble in boiling water. *Silver trichlorocrotonate*, $C^4H^3AgCl^3O^2$, is obtained by mixing moist silver oxide with a dilute solution of the acid, and adding silver nitrate and ammonia to the filtrate until it shows a slight alkaline reaction; the salt is thus obtained as a crystalline precipitate, which may be dried in vacuo. The *ethylic ether*, $C^4H^3C^2H^5O^2.C^2H^5$, is formed by heating equal numbers of molecules of the acid and ethyl alcohol in sealed tubes for some hours to 100° . It is a colourless, heavy liquid, which boils at 212° and has an aromatic odour (Judson).

Trichlorocrotonyl chloride, $C^4H^3Cl^3OCl$, a heavy liquid, boiling at 162° – 166° , is prepared by heating the acid with phosphoric chloride to 120° . Water acts on it slowly, but by alcohol it is instantaneously decomposed, ethylic trichlorocrotonate being formed (Judson).

Trichlorocrotonamide, $C^4H^3Cl^3ONH^2$, is easily formed by pouring aqueous ammonia over the chloride. It is sparingly soluble in cold, more readily in boiling water, and crystallises from alcohol and ether in silvery scales, which melt at 96° (Judson).

When silver trichlorocrotonate is heated with water in a flask connected with a reversed condenser, a brisk evolution of carbonic acid takes place, and silver chloride and *dichlorallylene*, $C^2H^2Cl^2$, are formed. The latter is a heavy oil which has a penetrating odour: it boils at 78° and combines readily with bromine. The same compound is obtained by acting on crotonic chloral with caustic baryta—

or by heating trichlorocrotonic acid with dilute alkalis—

If the aqueous solution of the acid is treated with an excess of silver oxide or alkali, the yield of dichlorallylene is very small, as the action goes further (Judson).

Monochlorocrotonic acid, $C^4H^3ClO^2$.—The zinc-salt of this acid is formed by the action of zinc and hydrochloric acid on trichlorocrotonic acid (p. 397); or by slowly dropping fused trichlorocrotonic acid into a mixture of water and zinc-dust; the mixture then becomes warm, and no gas is evolved; but if too much of the trichlorinated acid is added at once, a gas is evolved which burns with a green flame and probably contains carbon and chlorine. By treating the solution of the zinc salt with hydrochloric or sulphuric acid, crude monochlorocrotonic acid is precipitated; it may be purified by recrystallisation from hot water, in which it easily dissolves. It is easily soluble also in alcohol and ether, melts at 96° , boils at 212° , and sublimes partially even at the heat of the water-bath, forming pearly scales and needles. It is not dechlorinated by treating it in aqueous solution with zinc-dust or silver oxide, or by heating it with ammonia to 120° ; but by treating a concentrated solution of sodium monochlorocrotonate with sodium-amalgam, and decomposing the resulting sodium salt with sulphuric or hydrochloric acid, crotonic acid is obtained, identical in every respect with that which is formed from allyl cyanide or from crotonic aldehyde. On adding a molecule of bromine to a solution containing a molecule of monochlorocrotonic acid, the two unite, forming monochloro-dibromo-butyric acid $C^4H^3ClBr^2O^2$, which separates as a colourless oil, soon becoming crystalline. *Potassium monochlorocrotonate*, $C^4H^3ClO^2K$, is very readily soluble in water, and crystallises therefrom in needles, and from its alcoholic solution in plates. The *sodium salt*, $C^4H^3ClO^2Na$, is uncrystallisable. The *ammonium salt*, $C^4H^3ClO^2(NH^4)$ forms large plates, or six-sided tables, which sublime readily at 100° . The *silver salt*, $C^4H^3ClO^2Ag$, is somewhat difficultly soluble in water, from which it crystallises in long white needles. The *lead salt*, $(C^4H^3ClO^2)^2Pb + H^2O$, forms glistening plates and needles. The *basic cupric salt*, $(C^4H^3ClO^2)^2Cu.Cu(OH)^2$, is precipitated as an amorphous bright blue powder, on adding cupric sulphate to a solution of an alkaline monochlorocrotonate; the *neutral salt*, which forms fine blue prisms, is obtained by evaporating over sulphuric acid a solution of cupric carbonate in the acid; the *calcium salt*, $(C^4H^3ClO^2)^2Ca$, crystallises in thick prisms, and the *barium salt*, $(C^4H^3ClO^2)^2Ba$, in thin plates which are more readily soluble than the calcium salt. *Ethyl monochlorocrotonate*, $C^4H^3ClO^2.C^2H^5$, formed on saturating an alcoholic solution of the acid with hydrochloric acid, is a colourless liquid, having a pleasant fruity odour, and boiling at 176° (Sarnow, *Deut. Chem. Ges. Ber.* iv. 731; v. 467).

Chlorinated acids, $C^4H^3ClO^2$, produced by the action of Phosphorus Pentachloride on Ethyl-diacetic acid (Geuthner, *Jenaische Zeitschrift*, vi. part 4; *Chem. Soc. J.* [2] ix. 812).—When phosphorus pentachloride (33 parts) is gradually

added to ethyldiacetic acid (10 parts), it dissolves without any great evolution of heat, forming a reddish-brown liquid; at the same time large quantities of hydrochloric acid and ethyl chlorido are evolved, but no acetyl chloride is formed. The product, which consists of phosphorus oxychloride and the chlorides of several acids, cannot be successfully separated by fractional distillation, and must therefore be added gradually to water maintained at a low temperature, in which it readily dissolves. On distilling the aqueous solution, an oil first passes over with the vapour of water, which does not solidify; this is succeeded by a milky liquid which deposits crystals on cooling; and ultimately the distillate comes over clear. The first portion of the distillate contains a readily volatile oil, which does not solidify; the milky intermediate portion consists of a volatile acid which solidifies on cooling; the residue in the retort is a very difficultly volatile acid. These three may be more completely separated from one another by repeated fractional distillation with water. The small portion of the volatile acid which accompanies the neutral oil may be removed by agitating it with an excess of a solution of sodium carbonate, and distilling, the crystalline volatile acid being recovered from the sodium salt by distillation with dilute sulphuric acid. To obtain the slightly volatile acid from the residue in the retort in the first distillation, it is neutralised with sodium carbonate, and, after separation of the resinous impurities, concentrated by evaporation. Much of the sodium phosphate may thus be separated by crystallisation; and on evaporating the mother-liquors to dryness, and extracting with alcohol, the sodium salt of the new acid is dissolved, leaving the sodium phosphate and sodium chloride. After the alcohol has been removed by distillation, excess of sulphuric acid is added to the solution, and the whole boiled for some time to remove the last traces of the more volatile acid. On agitating with ether, drying the ethereal solution of the acid with calcium chloride, and evaporating, an oil is left behind, which solidifies over concentrated sulphuric acid to a crystalline mass. To purify this acid it is dissolved in water, decolorised by animal charcoal, and recrystallised.

Both the acids thus obtained have the composition $C^4H^5ClO^2$. The less volatile acid melts at 94° , boils at $206^\circ-211^\circ$, and is identical in every respect with the monochlorocrotonic acid above described. Geuther, however, designates it as chlorotetraacrylic acid. By reduction with sodium amalgam, it is converted into solid crotonic acid (Geuther's tetraacrylic acid) melting at 71.5° and boiling at 187.4° (corr.) By the action of potassium hydrate it is converted, according to Geuther, into an acid $C^4H^5O^2$, which he calls tetrolic acid, melting at 76.5° and boiling at 203° . This, however, is very doubtful, as, according to all other authorities, crotonic acid fused with potash yields nothing but acetic acid.

The more volatile chlorinated acid designated by Geuther as chloro-quartenylic acid may be boiled with excess of potash without undergoing decomposition. A saturated solution of its sodium salt treated with sodium amalgam yields the sodium salt of 'quartenylic acid,' or liquid crotonic acid, $C^4H^5O^2$, from which that acid may be obtained as a colourless oil which boils after rectification at 171.9° (corr.), has a density of 0.1018 at 25° and does not solidify at -15° .

As there are but three possible isomerides of the acid $C^4H^5O^2$, viz., crotonic acid $CH^3-CH=CH-CO^2$, methacrylic acid $\begin{matrix} H^2C \\ H^2C \end{matrix} \equiv C-CO^2H$, and the acid $CH^2=CH-CO^2H$, the last formula would seem to belong to quarternylic acid; but this acid, when fused with potash, should yield formic and propionic acids (p. 397), whereas according to Geuther, it yields nothing but acetic acid, whence it should have the constitution $CH^2-CH=CH-CO^2H$. Its separate existence must, therefore, for the present, be regarded as doubtful.

The neutral oil above mentioned as one of the products of the action of phosphorus pentachloride on ethyl-diacetic acid is, according to Geuther, a mixture of the ethylic ethers of chloroquartenylic and chlorotetraacrylic (chlorocrotonic) acids, which acids may be obtained from it by heating it for several days with strong hydrochloric acid, and distilling the product with water.

According to these results, the action of phosphorus pentachloride on ethyl-diacetic acid gives rise to monochlorocrotonic chloride (or two isomeric chlorides) which is converted into chlorocrotonic acid by treatment with water, and to the corresponding ethylic ether (or two isomeric ethers) thus:

A brown resin is also formed, probably a secondary product.

CROTONIC ALDEHYDE, C^3H^4O . The formation of this compound by condensation of 2 mols. acetic aldehyde, under the influence of dehydrating agents has been already explained (pp. 34, 396). The best yield is obtained as follows:—Pure aldehyde is heated in soda-water bottles with very little zinc chloride and a few drops of water for a day or two at 100° . The unchanged aldehyde is then distilled off, and the distillation continued in a current of steam; the residue contains higher condensation-products. The crotonic aldehyde distils over with the steam and partly floats on the water in the receiver, partly dissolves in it; by redistilling the solution, and collecting the first portion apart, the greater part may however be recovered.

It has been stated by Paternò n. Amato that crotonic aldehyde is formed by heating aldehyde with ethyldene chloride (1st Suppl. 513). According to Krämer n. Pinner (*Deut. Chem. Ges. Ber.* iii. 75; *Zeitschr. f. Chem.* [2] vi. 470), no such result is obtained if the ethyldene chloride has been previously purified from phosphorus oxychloride; in the contrary case, however, hydrochloric acid is formed, and acts upon the aldehyde in the manner already explained, producing crotonic aldehyde and other condensation-products.

Crotonic aldehyde is contained in small quantity in the "first runnings" of the distillation of spirit (Krämer n. Pinner, p. 32).

CROTONIC CHLORAL, $C^3H^3Cl^2O$. *Trichlorocrotonic Aldehyde* (Krämer n. Pinner, *Ann. Ch. Pharm.* clviii. 37).—This compound is formed by the action of chlorine on acetic aldehyde. When chlorine is passed into aldehyde, at first carefully cooled in a freezing mixture, and heated to 100° only at the close of the reaction, the first few bubbles cause the separation of a small quantity of solid metachloral; after a short time, however, evolution of hydrochloric acid sets in and every trace of chlorine is absorbed. The resulting brown mass consists of two layers: a lower, darker, almost solid, and an upper, lighter-coloured liquid layer, the latter being a saturated aqueous solution of hydrochloric acid and the bodies of the lower layer. As it was found impossible to separate these two completely, the whole was submitted to distillation. A considerable quantity passed over between 90° and 100° ; the thermometer then rose rapidly to 160° ; and the main product distilled over between this point and 180° ; the temperature then rose to about 210° , but only decomposition-products were obtained, and a considerable carbonaceous residue remained in the flask. The portion which passed over between 160° and 180° yielded by systematic fractional distillation a liquid boiling between 163° and 165° and having the composition of crotonic chloral, $C^3H^3Cl^2O$. The formation of this compound is easily explained. By the first action of chlorine on aldehyde, hydrochloric acid is produced; and this acid, reacting on the aldehyde in the manner already explained (p. 34), converts it into crotonic aldehyde, C^3H^4O , which then, by the further action of the chlorine, is gradually converted into crotonic chloral.

Crotonic chloral is a colourless oil of peculiar odour, somewhat recalling that of ordinary chloral; it combines with water, forming a crystalline hydrate, the reaction being attended with considerable rise of temperature; on mixing it with alcohol, much heat is evolved, but no crystalline compound is formed. Fuming nitric acid converts it into trichlorocrotonic acid $C^3H^2Cl^3O^2$. In short, in chemical behaviour, it corresponds in every respect with the trichloraldehyde of the acetic series, excepting in its reaction with alkalis. Ordinary chloral treated with alkalis yields formic acid and chloroform, and therefore crotonic chloral might be expected to yield formic acid and allylic chloroform, $C^3H^3Cl^2$, according to the equation:

instead of this, however, it yields dichlorallylene, $C^3H^2Cl^2$ or $CCl^2=C=CH^2$, the alkali removing a molecule of hydrogen chloride (Krämer n. Pinner).

When crotonic chloral is digested with aqueous *hydrocyanic acid* in a vessel having a condenser attached to it, the cyanhydrin, $CCl^3-CH=CH-CH \begin{smallmatrix} OH \\ CN \end{smallmatrix}$, is formed by direct addition, and this compound, by prolonged digestion with strong hydrochloric acid, is converted into trichlorangelic acid, $CCl^3-CH=CH-CH \begin{smallmatrix} OH \\ CO^2H \end{smallmatrix}$, a solid substance melting at 40° (Bischoff n. Pinner, *Deut. Chem. Ges. Ber.* v. 208).

Crotonic Chloralhydrate, $CCl^3-CH=CH-CH \begin{smallmatrix} OH \\ OH \end{smallmatrix}$ may be easily recrystallised from water, forming thin, dazzling white, shining plates, which pertinaciously retain water and melt at 78° . It is very volatile in a current of steam. It is difficultly soluble in cold, readily in hot water, very soluble in alcohol. Its vapour powerfully attacks the mucous membrane and the eyes. When heated it seems to

split up into water, carbon monoxide, hydrogen chloride, and dichlorallylene (Kramer a. Pinner).

The constitution of crotonic chloral is not quite settled. From the mode of formation, as above explained, it would seem to be that which is represented by the formula $\text{C}^1\text{H}^2=\text{CH}^3-\text{CHO}$. Pinner, however (*Deut. Chem. Ges. Ber.* v. 205), from the behaviour of the dichlorallylene obtained from it, infers that it has a different constitution. When this dichlorallylene is treated with bromine, Br^2 is first taken up and then Br is substituted for H , yielding a derivative, not of propane, C^3H^6 , but only of propylene, C^3H^4 . Dichlorodibromopropylene $\text{C}^3\text{H}^2\text{Cl}^2\text{Br}^2$, thus produced by addition of Br^2 , is converted by alcoholic potash into dichloromonobromallylene, $\text{C}^3\text{H}^2\text{Cl}^2\text{Br}$, and this body takes up Br^2 and no more, yielding crystalline dichlorotribromopropylene $\text{C}^3\text{H}^2\text{Cl}^2\text{Br}^3$, from which alcoholic potash removes, not HBr , but the Br^2 just added, reproducing dichloromonobromallylene; and by digesting the dichlorotribromopropylene with bromine at 160° in a sealed tube, the last hydrogen atom is replaced, and dichlorotetrambromopropylene $\text{C}^3\text{H}^2\text{Cl}^2\text{Br}^4$ is formed. In all this series of reactions only propylene derivatives are produced. Impure crotonic chloral, however, when treated with potash, yields—besides dichlorallylene—trichloropropylene $\text{C}^3\text{H}^2\text{Cl}^3$, which takes up Br^2 , forming a propane derivative, $\text{C}^3\text{H}^2\text{Cl}^3\text{Br}^2$, and is converted, by caustic potash, into dichlorallylene.

From these reactions Pinner infers that dichlorallylene has a constitution represented by an annular formula :

that the trichloropropylene which is converted into dichlorallylene by potash, is either $\text{CHCl}=\text{CCl}-\text{CH}^2\text{Cl}$, or $\text{CCl}^2=\text{CCl}-\text{CH}^2$;

and that crotonic chloral is either—

CROTONITRIL, $\text{C}^4\text{H}^5\text{N}$. Syn. with ALLYL CYANIDE. See CYANIDES.

CROTONYLENE, C^4H^6 . This hydrocarbon, originally obtained by Caventon by the action of sodium ethylate on butylene bromide (p. 224), has the constitution of ethyl-acetylene, $\text{HC}\equiv\text{C}-\text{CH}^2\text{CH}^3$, inasmuch as its tetrabromide $\text{C}^4\text{H}^2\text{Br}^4$, is identical in properties with that which is formed by the action of bromine on ethyl-acetylene synthetically prepared by passing a mixture of acetylene and ethylene through a tube heated to low redness. The tetrabromide melts at $113^\circ-115^\circ$. Crotonylene is also produced by the action of a low red heat on the hydrocarbons obtained from petroleum (Prunier, *Compt. rend.* lxxvi. 1410).

Crotonylene dichloride, $\text{C}^4\text{H}^4\text{Cl}^2$, is formed by the action of phosphorus pentachloride on crotonic aldehyde. It is a colourless liquid, boiling at $125^\circ-127^\circ$, and having a specific gravity of 1.131 at 20° . It is decomposed by alcoholic potash, but no definite products of the reaction have yet been obtained (Kokulé, *Ann. Ch. Pharm.* clxii. 98).

Tetrachloro-crotonylene, $\text{C}^4\text{H}^2\text{Cl}^4$, is obtained by heating crotonic chloral to $110^\circ-120^\circ$ with phosphorus pentachloride, and subjecting the resulting liquid, which boils between 130° and 140° , to fractional distillation (Judson, *Zeitschr. f. Chem.* [2]. vii. 40).

CROTYL ETHERS. *Isocrotyl Bromide*, $\text{C}^4\text{H}^7\text{Br}$ = $\text{C}(\text{CH}^3)^2=\text{CHBr}$, is produced by heating isobutylene bromide with alcoholic potash (p. 224). It is a colourless, heavy, aromatic liquid, insoluble, or nearly so, in water, boiling at $88^\circ-92^\circ$. Heated in sealed tubes to 160° with concentrated alcoholic potash, or crystallised sodium ethylate, it is converted, by exchange of Br for OC^2H^5 , into ethyl-isocrotyl ether $(\text{C}^2\text{H}^5)(\text{C}^4\text{H}^7)\text{O}$, or $\text{C}(\text{CH}^3)^2=\text{CHOC}^2\text{H}^5$, which, when precipitated by water, and purified by fractional distillation, forms a colourless mobile liquid, lighter than water, boiling at $92^\circ-94^\circ$, having a peculiar but not irritating odour resembling that of common ether and that of the distillation-products of the fats. Heated to 100° with fuming hydriodic acid, it yields ethyl iodide. It does not attack ammoniacal silver solution or unite with sodium bisulphite, but unites energetically with bromine, forming the compound $\text{C}^4\text{H}^7\text{Br}^2\text{O}$ (Butlerow, *Zeitschr. f. Chem.* [2] vi. 523).

CRYPTOPINE. See OPIUM ALKALOIDS.

CRYSTALLINE DISSOCIATION. See CHEMICAL ACTION (pp. 202-304).

CRYSTALLISATION. Observations on the crystallisation of several metallic oxides from fusion with borax and microcosmic salt have been made by Knop (*Ann. Ch. Pharm.* clvii. 363; clix. 36). See TRN. TITANIUM, and ZIRCONIUM.
2nd Sup.

CUBEBENE, $C^{13}H^{22}$, heated to 280° with 56 parts of highly concentrated hydrochloric acid, yields pentane, C^5H^{12} , decane $C^{10}H^{22}$, pentadecane $C^{15}H^{32}$, and an oil volatilising at about 360° (Berthelot, *Bull. Soc. Chim.* [2], xi. 3).

CUBEBIC ACID. This name is given to a resinous acid first obtained by Bernatzik (*Chem. Centr.* 1864, 191) from the ethereal extract of cubeb. The extract, after being freed from volatile oil by distillation with water, was dissolved in weak spirit; the solution, mixed with a little potash, was precipitated with barium chloride; and the resulting barium salt, purified by recrystallisation from water, was decomposed by sulphuric acid. Cubebic acid was thus obtained as an easily fusible resin, insoluble in water and acids, easily soluble in alcohol, chloroform and ether, and forming, with the alkalis, neutral salts soluble in water and precipitated by the salts of the alkaline earths and heavy metals.

C. F. Schulze (*Arch. Pharm.* [3], ii. 388) prepares cubebic acid by saponifying the alcoholic extract of cubeb with caustic soda, leaving the resulting soap-cake to itself for some time till crystals of sodium cubebate separate from it, converting this salt into the corresponding lead salt, and decomposing the latter with sulphuretted hydrogen. The filtered solution, when evaporated, left the cubebic acid as a resinous mass which could not be made to crystallise from any solvent.

Cubebic acid thus prepared was found to have the composition $C^{13}H^{14}O^4$ (according to E. A. Schmidt, *Arch. Pharm.* [2], xli. 1) Heft, its formula is $C^{13}H^{14}O^7$. The sodium salt has the composition $C^{13}H^{13}NaO^4 + 2H^2O$. The acid melts at 45° ; cannot be sublimed; gives with sulphuric acid a crimson colour, which disappears on dilution, and changes to brown on addition of nitric acid. The aqueous solution gives precipitates with the salts of the alkaline earths and heavy metals.

The aqueous solution of the soap gave, on treatment with alcohol, a fatty oil and cubebene; and the residue, treated with hydrochloric acid, yielded a brown resin (Schulze).

CUCUYOS. The luminous organs of the Mexican cucuyos have been analysed by C. Heisemann (Pflüger's *Archiv. f. Physiologie*, vii. 365). The organs, after being carbonised at a low heat, were treated with boiling water. The water was found to contain phosphoric acid and potash, also traces of chlorine, and on the addition of hydrochloric acid, a gas was given off, whose nature could not be determined, owing to the small quantity. The residue, insoluble in water, was almost entirely soluble in hydrochloric acid, and gave distinct evidence of carbonic acid and lime.

Uric acid occurs in these organs in two combinations, first as calcium urate, forming the granular masses; and secondly, as potassium urate, which is referred to the crystalline portion. The carbonic acid contained in the insoluble ash-residue may be regarded as the product of combustion of the uric acid, and the phosphoric acid is, probably, derived from the luminous cells; but the important question whether it occurs preformed and combined with potash, or is produced by the combustion of organic bodies containing phosphorus, remains as yet undecided.

CUMENE, C^9H^{12} . Determinations of the specific gravity of cumene, prepared by distilling cumic acid with lime, have lately been made by Pisanti a. Paternò (*Gazzetta chimica italiana*, iii. 574), with the following results:

Temperature	0°	25°	50°	75°	100°
Specific gravity	0.87976	0.85870	0.83756	0.81555	0.79324

Coefficient of Expansion = $0.90096302 + 0.0000010218t + 0.00000002297t^2$.

Observations on the xylenes and cumenes of coal-tar naphtha have been made by Rommieu (*Compt. rend.* lxx. 641). Coal-tar naphtha, boiling between 130° and 200° , was dissolved in sulphuric acid, the solution partially saturated with soda and then distilled. The mass gradually carbonised, swelled up and yielded a distillate consisting of two liquid layers, together with torrents of sulphur dioxide. The lower layer consisted of acid water, the upper of a compound (?) of sulphurous acid and several homologues of benzene, easily decomposable by sodium carbonate. The hydrocarbons thus separated boiled between 130° and 200° . Of 12 litres of these hydrocarbons, 10 litres dissolved in sulphuric acid, and the solution, when distilled, yielded 2.7 litres of a liquid which gave by fractional distillation 350 c.c. of a hydrocarbon boiling at 130° – 140° , and having the composition of xylene; 150 c.c. boiling at 165° – 167° , and having the composition of cumene, and 200 c.c. of a liquid boiling at 170° – 200° which was not further examined. The xylene thus obtained is said by Rommieu to yield, with fuming nitric acid, a dinitroxylene different from that which is obtained from xylene not previously treated with sulphuric acid. The two dinitrocumenes melt at 86° [which is the melting point of dinitromesitylene (*1st Suppl.* 299)]; but whereas ordinary cumene, or mesitylene (?), requires only 4 to 5 times its weight of nitric acid

to convert it into the dinitrocompound, the cumene separated from the sulphuric acid compound is not completely converted into dinitrocumene, even by 20 times its weight of the fuming acid. According to measurements by Descloizeaux (*Compt. rend.* lxx. 587) the two dinitroxylenes and the two dinitrocumenes exhibit differences in their crystalline forms.

CUMIC ACID, $C^{10}H^{12}O^2 = C^6H^4.C^4H^8.COOH$. To prepare this acid from Roman cumin oil, Beilstein a. Kupffer (*Deut. Chem. Ges. Ber.* vi. 1184) proceed as follows: The oil is dropped through a tap-funnel on potassium hydrate melted in an iron pot like those used in the preparation of ammonia. Into the lid of this pot is fitted a Wurtz's boiling tube, the lateral tube of which is connected with a condenser. When the evolution of hydrogen has ceased, water is poured into the pot, and the cumene is distilled off. The alkaline solution is precipitated with hydrochloric acid, and the filtrate thrown away, as cumic acid is but very slightly soluble in cold water. By combining the cumic acid with lime and decomposing the resulting salt with hydrochloric acid, the cumic acid is easily obtained pure, with the melting point 114° (115° according to Gerhardt).

Barium Cumate, $Ba(C^{10}H^{11}O^2)^2 + 2H^2O$, forms nacreous tabular laminæ, which give off their water over sulphuric acid: 100 parts of water at 20.5° dissolve 0.810 part of the anhydrous salt.

Calcium Cumate, $Ca(C^{10}H^{11}O^2)^2 + 5H^2O$, forms hemispherical tufts of needles having a silky lustre; effloresces very readily in the air; gives off $2H^2O$ over sulphuric acid.

Magnesium Cumate, $Mg(C^{10}H^{11}O^2)^2 + 6H^2O$, forms thin, tabular, nacreous laminæ, which do not give off water over sulphuric acid: 100 parts of water at 20.5° dissolve 0.825 part of the anhydrous salt.

Bromocumic acid, $C^{10}H^{11}BrO^2 = C^6H^4.C^4H^8.Br.COOH$, is formed by heating cumic acid with hydrobromic acid and bromine in a sealed tube for two hours to 120° . It may be crystallised from light petroleum oil, and is very apt to creep over the sides of the containing vessel in crystals. When boiled with alcoholic potash, it yields chiefly oxethyl-cumic acid $C^6H^4.C^4H^8OC^2H^5.CO^2H$, oxycumic acid $C^6H^4.C^4H^8OH.CO^2H$ being, however, formed at the same time. The brominated acid heated in a stream of carbon dioxide gives off hydrogen bromide and yields allyl-phenyl-formic acid: the barium salt has the composition $C^{20}H^{18}BaO^4 + H^2O$ (Czampelik, *Deut. Chem. Ges. Ber.* 1870, 476).

CUMIDIC ACID, $C^{10}H^{10}O^4$, and **CUMYLIC ACID**, $C^{10}H^{12}O^2$, are produced by oxidation of durene or tetramethyl-benzene (1st Suppl. 828).

CUPRITE. Native cuprous oxide. See COPPER (p. 389).

CURARINE. Curarine gives with sulphuric acid and potassium dichromate a blue-violet tint, not unlike that produced by strychnine under the same circumstances, but more permanent; the brown colouring matters apt to be present in crude curarine interfere much with the reaction; neither precipitation by lead acetate nor treatment with animal charcoal is sufficient to purify an alkaloid thus contaminated.

Curarine extract (best prepared by means of glycerin) yields an amorphous precipitate of curarine chromate with potassium-dichromate (neutral chromate does not answer so well): this precipitate is more soluble in water than the corresponding strychnine compound, which, moreover, is crystalline; when air-dry, it dissolves in sulphuric acid with a pure and deep blue colour, whereas the strychnine salt gives a violet tint; in neither case could the colouring matter be separated and examined by itself. Phosphoric acid cannot be substituted for sulphuric acid in this reaction.

Potassio-mercuric iodide and potassium platinoeyanide precipitate curarine from its glycerin solution, as amorphous flakes, which do not become crystalline when dissolved in alcohol, and separated from this solution; the corresponding strychnine compounds readily become crystalline by this treatment.

Curarine may be separated from strychnine by means of benzene, in which the former is insoluble; it is readily soluble in water (Flückiger, *N. Repert. Pharm.* xxii. 65).

On the detection of curarine in the animal body, see Koch (*Chem. Centr.* 1871, 219; *Chem. Soc. J.* [2], ix. 600); also Salomon (*Zeitschr. anal. Chem.* x. 451; *Chem. Soc. J.* [2], x. 331).

CURCUMIN, $C^{20}H^{16}O^2$ (F. Daube, *Deut. Chem. Ges. Ber.* iii. 609). The substance hitherto described as the colouring matter of turmeric is a mixture of different resins with the pure compound, which may be obtained in the crystalline state by passing a strong current of steam over coarsely powdered turmeric, to remove the essential oil, washing the residue with hot water as long as colouring matter is extracted, then

drying it, and treating it with boiling benzene. On cooling, crude curcumin separates in crystalline crusts, which must be pressed between filtering paper and dissolved in cold alcohol, a small quantity of a yellow body being left behind. To the filtrate a solution of neutral lead acetate is added, and then so much basic acetate that the solution just shows a faint acid reaction. The brick-red precipitate, after being washed, is suspended in water and decomposed by sulphuretted hydrogen. From the precipitate the curcumin is extracted with boiling alcohol, and the solution allowed to evaporate very slowly.

Pure curcumin crystallises in shining prisms, apparently belonging to the orthorhombic system, and appearing of a hock or amber colour by transmitted light, orange-red by reflected light. The alcoholic solution is fluorescent, like tincture of turmeric; the spectrum of the reflected light does not show any alteration from the red end to F, but the blue, violet, and ultra-violet portions are replaced by a greyish green band, in which the lines H, L, M, N, &c., are distinctly visible. By analysing this modified spectrum with a prism it was found to contain very little red, and the blue end had nearly disappeared. This secondary spectrum agrees very nearly with that of uranium glass.

Curcumin begins to melt at 165°, and is completely decomposed at a higher temperature. It is very readily soluble in alcohol and ether, but these solvents cannot be used for extracting it from turmeric, as they also dissolve resinous matters. In benzene it is very little soluble (1 part in 2,000 parts), but as the resins are quite insoluble in this liquid, it may be used to obtain the pure compound. It is also slightly soluble in concentrated mineral acids, which, however, act on it. In alkalis it dissolves with a bright reddish brown colour; acids precipitate from this solution the original substance; calcium- and barium-salts produce reddish-brown precipitates. The lead-compound, which has a bright red colour, is soluble in acetic acid, and is slowly decomposed by carbonic acid. The analyses of the lead-compound did not give concordant results, but they make the formula $C^{20}H^{18}PbO^8$ probable.

Hot dilute nitric acid oxidises curcumin to oxalic acid. Sodium-amalgam decolorises the alcoholic solution completely. The colour reactions of pure curcumin are much purer than those of turmeric solution. They are best seen with curcumin paper, prepared with Swedish filter-paper free from lime. Alkalis change the yellow into a brownish red, which, after drying, assumes a violet tinge; dilute acids restore the original yellow. A solution of boric acid produces a pure orange, which appears only after drying; if the paper has been previously dipped in a dilute acid, the coloration becomes darker, as dilute acids alone produce a blackish tinge after drying. The orange colour is not changed by diluted acids, but dilute alkalis convert it into a blue, which soon changes into a dirty grey.

By acting on curcumin with boric acid and concentrated sulphuric acid, E. Schlumberger obtained a substance which he called rosocyanin, as its solution has the colour of a rosaniline salt, and its metallic compounds are blue. Daube has obtained the same results with pure curcumin.

Kachler (*Deut. Chem. Ges. Ber.* iii. 713) believes that he has obtained anthracene by treating impure yellow curcumin with zinc-dust. The action of sodium-amalgam on curcumin gave rise to a number of resinous and syrupy products.

By oxidation with chromic acid mixture, curcumin is converted into terephthalic acid (*J. Gajevsky, Deut. Chem. Ges. Ber.* vi. 196).

CYANAMIDE, CN^2H^2 (E. Mulder, *Deut. Chem. Ges. Ber.* vi. 655). An aqueous solution of this compound yields with ammoniacal silver nitrate a yellow precipitate, which has the composition CN^2Ag^2 , and is reconverted into cyanamide when suspended in water and decomposed by sulphuretted hydrogen. From this Mulder infers that

the formula of cyanamide is, not $N \equiv C - NH^2$, as commonly supposed, but $C \begin{smallmatrix} \nearrow NH \\ \searrow NH \end{smallmatrix}$,

and he proposes to call it carbodiimide or cardimide. It is not easy to see, however, why the simultaneous replacement of the two atoms of hydrogen by silver in cyanamide is more easily explained by the proposed formula than by the ordinary one, inasmuch as the two hydrogen-atoms are similarly placed in the latter as well as in the former. Mulder further points out that the proposed formula of cyanamide affords an easy explanation of the conversion of that compound into guanidine by the action of ammonia (*1st Suppl.* 634):

and into urea (regarded as carbamide) by the action of water;

also of its polymerisation to dicyano-diamide :

Silver-carbodiimide or argento-cyanamido is insoluble in water, slightly soluble in ammonia, soluble in dilute nitric acid, and reprecipitated by ammonia or potash. It is not decomposed by boiling with potash, or by exposure to light. It undergoes no change at 220°, but explodes at a higher temperature, with formation of cyanogen

Cyanamide also gives a precipitate with ammoniacal cupric sulphate (Mulder). The silver and copper compounds were described in 1858 by Beilstein & Geuther (ii. 188).

Cyanamide unites with *alanine*, forming a compound called *alacreatine* isomeric with creatine (p. 393). It does not combine with *ethyl carbonate* (*urethane*) when heated with it either in the dry state or in aqueous solution; hence it seems probable that in the formation of creatine from cyanamide and *sarcosine*, the cyanamide unites with the carboxyl, and not with the amido-group (Baumann, *Ann. Ch. Pharm.* clxvii. 77).

CYANBENZYLAMIDE and **CYANBENZYLAMINE**. See BENZYLAMINE (pp. 181, 182).

CYANETHYLPHOSPHINE, $\text{C}^2\text{H}^5\text{NP} = \text{P} \begin{Bmatrix} \text{H} \\ \text{C}^2\text{H}^5 \\ \text{CN} \end{Bmatrix}$. When an ethereal solu-

tion of phosphine is heated for some hours to 100° in a sealed tube with cyanogen chloride, and the ether afterwards distilled off, there remains a syrupy liquid which solidifies after a short time over sulphuric acid. This product recrystallised several times from ether yields cyanethyl-phosphine in coherent masses of rhombic plates, which melt at 49°–50°, and dissolve in water, alcohol, and ether. When treated with oxidising agents, it gives off aldehydo (Darmstädter & Henniger, *Deut. Chem. Ges. Ber.* iii. 179, 404).

CYANIC ACID. On the action of cyanic acid on chloral, see CHLORAL (p. 310).

According to Rabuteau & Massul (*Compt. rend.* lxxiv. 57), the metallic cyanates are not poisonous; they are converted into carbonates in the animal organism.

On the Heat of Formation of Cyanates, see HEAT.

Potassium Cyanate.—According to A. Bannow (*Deut. Chem. Ges. Ber.* iv. 253; *Chem. Soc. J.* [2], ix. 391), a salt having the composition of potassium cyanate, but differing from it in some of its properties, is formed by the action of potash on paracyanogen, also by heating the ordinary cyanate with iodide of cyanogen. It crystallises in needles, and its aqueous solution, heated for a long time with alkali, and then neutralised, gives with silver nitrate a white precipitate, unaffected by light, and having the composition $\text{C}^2\text{N}^2\text{Ag}$. The reaction may, perhaps, be expressed by the equation :

[If this be correct, the new salt is probably tripotassic cyanurate $\text{C}^2\text{N}^2\text{K}^3\text{O}^2$.]

Cahours & Gal (*Bull. Soc. Chim.* [2] xiv. 449) have studied the action of potassium cyanate and cyanic ethers on the ethers of aromatic amido-acids, and have obtained compounds analogous to those prepared by Griess and Menchutkin (*1st Suppl.* 318). To prepare these compounds, an aqueous solution of potassium cyanate is gradually poured into a warm solution of the sulphate of the acid ether; the separated oil, which soon solidifies in the crystalline form, is mixed with water; and the product is crystallised from alcohol or hot water. When an alcoholic cyanate is used, it is mixed with about its own volume of the liquid or fused ether of the amido-acid, and the resulting crystals, after being pressed, are recrystallised from alcohol or ether.

Dicyanic Acid, $\text{C}^2\text{H}^2\text{N}^2\text{O}$ (Poensgen, *Ann. Ch. Pharm.* cxviii. 339).—Formed by the action of nitrous acid on cyanurea suspended in water (p. 417):

It is slightly soluble in cold, more soluble in hot water, and crystallises therefrom in

hard, mostly light yellow monoclinic prisms in which, according to Carius, the angle $\infty P : \infty P$ in the clinodiagonal principal section is $79^\circ 36'$, in the orthodiagonal section, $100^\circ 10'$; $OP : \infty P$ in front = $103^\circ 30'$; angle of inclined axes = $68^\circ 20'$; ratio of orthodiagonal to clinodiagonal = $0.772 : 1$. The crystals contain $2C^2N^2H^2N^2O^2 + 3H^2O$; they effloresce very quickly, and give up their water of crystallisation even when boiled under water. From nitric acid, dicyanic acid crystallises unaltered in long prisms, from hydrochloric acid in green, shining spangles. When heated, it is converted into cyanic acid at the same temperature as cyanuric acid; by boiling with alkalis, it is resolved into carbonic acid and ammonia.

The metallic dicyanates are either neutral or acid; those of the alkali-metals are easily soluble in water; the ammonium salt is crystalline and easily decomposable. The barium salt $(C^2N^2HO)^2Ba + H^2O$ separates in monoclinic laminae on mixing the ammonium salt with baryta-water; it is also formed on heating cyanurea with barium hydrate. The acid and neutral silver salts $C^2N^2HAgO^2$ and $C^2N^2Ag^2O^2$ are white amorphous precipitates, insoluble in water. The neutral salt, treated with ethyl iodide, yields a viscid ether having a peculiar odour.

According to Hallwachs (*Zeitschr. f. Chem.* vi. 354), Poensgen's dicyanic acid is nothing but cyanuric acid. It certainly agrees very closely therewith in many of its properties, especially in its crystalline form. (The crystals of cyanuric acid are monoclinic, having the angle $\infty P : \infty P$ (clinod.) = $77^\circ 13'$; $OP : \infty P$ = $99^\circ 59'$; ratio of ortho- to clinodiagonal = $0.772 : 1$ or = $0.573 : 0.781$; see ii. 289). Nevertheless, the existence of amidodicyanic acid and of Hofmann's dicyanic ethers renders the existence of dicyanic acid highly probable. The question, however, can only be decided by a more exact comparison of the salts of Poensgen's acid with the cyanurates.

Amido-dicyanic or Dicyanamic acid, $C^2N^2H^2O = C^2N^2 \begin{smallmatrix} NH_2 \\ HO \end{smallmatrix}$ (Hallwachs, *Ann. Ch. Pharm.* cliii. 293). This acid was originally obtained by boiling dicyanodiamide with a moderately dilute solution of baryta (*1st Suppl.* 518); part of it, however, is resolved during the process into cyanamide and cyanic acid. If a hot saturated solution of baryta or strong potash-ley be used, the products are melamine, cyanamide and cyanic acid, with only a small quantity of amidodicyanic acid. This acid may also be prepared by direct combination of cyanamide CN^2H^2 and cyanic acid $CNHO$. The two bodies are mixed in aqueous solution in the proportion of 1 : 2 and left to stand for 24 hours, or mixed dry and heated to 60° in a water-bath.

The free acid, separated from the silver salt by hydrochloric acid, crystallises in groups of small crystals, or in spicular needles. It decomposes at 100° . Its aqueous solution has an acid reaction, dissolves cuprous oxide and barium carbonate, is precipitated by silver nitrate, and decomposed with effervescence by concentrated acids. The ammonium salt forms colourless needle-shaped crystals. The potassium salt $(C^2N^2H^2KO)$ is easily soluble in water, and crystallises with difficulty; the sodium salt, $C^2N^2H^2NaO$, resembles it. The silver salt, $C^2N^2H^2AgO$, obtained by precipitation from the potassium salt is a white, amorphous powder, insoluble in water either hot or cold, slightly soluble in dilute nitric acid, easily soluble in ammonia. From hot dilute nitric acid it separates as a heavy crystalline powder; from dilute ammonia, by spontaneous evaporation, in small shining needles. When warm, moderately strong aqueous ammonia is saturated with the silver salt, the solution, on standing, deposits tabular crystals which give off ammonia on exposure to the air. The copper salt, $(C^2N^2H^2O)^2Cu + 4H^2O$, forms large sky-blue crystals sparingly in cold, more easily in hot water. The aqueous solution, on boiling, deposits an insoluble dark green powder, having the composition $C^2N^2H^2CuO + 2H^2O$, and easily soluble in mineral acids, the solution, on cooling, depositing the original blue salt. Both these copper-salts blacken at 100° , and at a red heat give off vapours containing copper. The barium salt, $(C^2N^2H^2O)^2Ba + 3H^2O$, is a white radiate-crystalline mass, very soluble in water, and crystallises from absolute alcohol in small cubic crystals.

Tricyanic or Cyanuric acid, $C^3N^3H^3O^3$.—*Detection*.—This acid, if present in the free state and in any considerable quantity, is most readily detected by heating the highly dried substance in a short narrow tube. The smell of the vapour of cyanic acid thereby evolved is so characteristic, that there is little room for doubt as to presence or absence of cyanuric acid. To detect this acid when in solution and present in extremely small quantity, advantage may be taken of the sparing solubility of sodium cyanurate in hot concentrated soda-ley. The liquid to be tested is placed in a watch-glass, mixed with strong soda-ley, and warmed for a moment over a pointed flame. If cyanuric acid is present, splendid delicate needles of trisodic cyanurate $C^3N^3Na^3O^3$ at once make their appearance, spreading from the point at which the flame is applied, and disappearing again as the liquid cools, provided the solution is not too strong. The formula of sodium cyanurate is $C^3N^3Na^3O^3$ (Hofmann, *Deut. Chem. Ges. Ber.* iii. 601).

CYANIC, DICYANIC, and CYANURIC ETHERS. AROMATIC ISO-CYANATES; * (Hofman, *Proc. Roy. Soc.* xix. 108). *Phenyl Isocyanate* or *Phenylcarbinide*, $N \begin{Bmatrix} CO \\ C^2H^3 \end{Bmatrix}$.—This substance, originally obtained by the dry distillation of melonoximide or oxalyl-diphenylguanidine, and afterwards more easily by heating diphenyl-carbamide with phosphoric anhydride (1st *Suppl.* 197), is also produced when ethyl phenyl-carbamate or phenyl-urothane (which Wilm a. Wischin have lately obtained by the action of ethyl-chlorocarbonate on aniline, p. 252) is distilled with phosphoric anhydride, whereupon it splits up into phenyl cyanate and ethyl alcohol.

The alcohol then remains behind, and the isocyanate distils over as a colourless liquid, which may be purified by rectification. It has a very pungent odour, a specific gravity of 1.092 at 15°, and boils at 163° (not at 178° as formerly stated).

With water it yields carbon dioxide and diphenylcarbamide; it unites with alcohols, forming urethanes; and with ammonia and its derivatives it forms various carbamides or ureas. But its most characteristic reaction is with triethylphosphine. On dipping a glass rod moistened with this base into a large quantity of the isocyanate, it becomes very hot and quickly solidifies to a mass of beautiful crystals, consisting of phenyl cyanurate; it is not, however, yet decided which of the isomeric modifications of that compound is hereby produced.

The isocyanates of *tolyl*, *xylyl*, and *naphthyl*, are obtained in like manner by distilling the corresponding urethanes with phosphoric anhydride.

Tolyl Isocyanate, $N \begin{Bmatrix} CO \\ C^2H^3 \end{Bmatrix}$, is a colourless liquid, boiling at 185°, and showing in all its properties the greatest resemblance to the phenyl compound; triethylphosphine acts on it, however, more slowly.

Xylyl Isocyanate, $N \begin{Bmatrix} CO \\ C^2H^4 \end{Bmatrix}$, is a colourless, highly refractive liquid, boiling at about 200°, and having only a feeble odour; it exhibits reactions similar to those of the other aromatic isocyanates, but they often require days for their completion.

Naphthyl Isocyanate, $N \begin{Bmatrix} CO \\ C^{10}H^7 \end{Bmatrix}$, is a colourless, not very mobile liquid, boiling at about 260°–270°. At the ordinary temperature it is almost odourless, but its vapour has the pungent smell peculiar to the isocyanic ethers. With water, alcohols, and ammonias, it gives the characteristic reactions of that class of bodies, and acts with incomparably greater quickness and precision than the xylyl compound. This is particularly shown in the action of triethylphosphine, which causes the isocyanate of the naphthyl series to solidify almost instantaneously.

Isodicyanic Ethers, $N^2 \begin{Bmatrix} (CO)^2 \\ H^2 \end{Bmatrix}$ (Hofmann, *Deut. Chem. Ges. Ber.* iv. 246).

These ethers are intermediate between the isocyanic and isocyanuric ethers. The *phenylic compound*, $C^{10}H^6N^2(C^2 = N^2(CO)F(C^2H^3))^2$, the only one yet obtained, is formed as a crystalline mass when a drop of triethylphosphine is let fall into liquid phenyl isocyanate. It dissolves sparingly in boiling ether, and the solution, on cooling and evaporation, deposits the pure substance in very thin beautiful iridescent plates. All other solvents alter it more or less. It melts at 175° and is thereby distinguished from phenyl isocyanurate (for which it was formerly mistaken), which melts at 260°, and from the normal cyanurate, which melts at 224°. Its molecular weight cannot be determined by the vapour-density, since it does not volatilise unaltered, but is converted, on distillation, into liquid phenyl isocyanate, which, however, after standing for 24 hours, resolidifies so completely that not the faintest smell of the liquid isocyanate remains. This effect appears to be due to the presence of small quantities of the original solid substance carried over with the liquid; and, in fact, the direct addition of crystals to the liquid induces partial solidification.

The molecular weight of the compound may, however, be determined by its behaviour with alcohol. On attempting to dissolve the crystals in boiling alcohol, part remains

* Called 'Cyanates' in the original paper, and in the Abstract given in the *Journal of the Chemical Society* [2] ix. 138. This designation, however, is contrary to analogy; the alcoholic derivatives of cyanic acid, $N \begin{Bmatrix} (CO) \\ R \end{Bmatrix}$, formed on the ammonia type, are *carbinides* or *isocyanates*, analogous to the carbamides or isocyanides $N \begin{Bmatrix} C \\ H \end{Bmatrix}$; the true cyanic ethers $C \begin{Bmatrix} N \\ OR \end{Bmatrix}$ are those which are produced by the action of cyanogen chloride on the sodium-alcohols (see 1st Supplement, pp. 319, 322).

for hours undissolved in the boiling liquid, however great an excess of alcohol may be used. Suddenly, however, the liquid becomes clear, and if then left to cool deposits slender needles, which may be purified by one recrystallisation from boiling alcohol. The crystals thus obtained are slightly soluble in ether, insoluble in water, and differ from the original body, not only by their form and their solubility in alcohol, but likewise by their lower melting point (98°). The analysis of these crystals leads to the formula $C^{10}H^{16}N^2O^2$, which is that of the ethylic ether of diphenylallophanic acid, containing the elements of 2 mols. phenyl cyanate and 1 mol. ethyl alcohol. It may, therefore, be assumed with great probability that the polymorphic cyanate is a diacyanate, and that the crystalline compound just mentioned is formed by combination of 1 mol. of this diacyanate with 1 mol. alcohol:

The isodicyanate, indeed, reacts with alcohols just like the unpolymerised cyanate, which likewise takes up 1 mol. alcohol to form urethane. In whatever way, therefore, we may suppose the elements of the diacyanate to be grouped, it is clear that it is related to the original liquid cyanate in the same manner as Liebig u. Wöhler's ethyl allophanate to cyanic acid.

The diphenylallophanic ether splits up, on distillation, into alcohol and phenyl isodicyanate, the latter being almost entirely converted into the simple isocyanate.

Methylic Diphenylallophanate, $2C(C^6H^5)NO.CH^3O$, easily obtained pure by dissolving phenyl isodicyanate in methylic alcohol and recrystallising from alcohol, forms difficultly soluble needles, which melt at 231° , or 133° higher than the corresponding ethyl compound.

Amylic Diphenylallophanate, $2C(C^6H^5)NO.C^6H^{11}O$, obtained by dissolving the isodicyanate in amylic alcohol, forms colourless and scentless crystals insoluble in water, easily soluble in ether and alcohol, and melting at 58° . This compound often remains fluid for a long time.

Sulphuretted Amylic Diphenylallophanate, $2C(C^6H^5)NO.C^6H^{11}S$.—The isodicyanate unites with mercaptans as well as with alcohols. Heated with amylic mercaptan for some hours to 160° it dissolves, and the mixture gradually solidifies to a white crystalline mass which, when recrystallised from alcohol or ether, yields the sulphuretted ether in colourless and scentless needles, which are insoluble in water and melt at 70° .

Action of Phenol on Phenylic isodicyanate.—These two substances act on one another at 150° , but the product does not consist of phenylic diphenylallophanate. On digesting the isodicyanate with excess of phenol in ethereal solution for some hours, needles are produced which are slightly soluble in water, easily in alcohol, melt in contact with boiling water and in the dry state at 122° . These crystals consist of phenylic phenylcarbamate:

obviously produced by the splitting up of the isodicyanate into 2 mol. of isocyanate which then unite with 2 mol. of phenol:

The same result is obtained when only 1 mol. phenol is heated with 1 mol. of the isodicyanate, half of the latter then reappearing as free phenyl isodicyanate and no phenylic diphenylallophanate being formed. The phenylic phenylcarbamate prepared in the manner just described agrees exactly with that which is obtained directly by the action of phenylic isocyanate on phenol.

The molecular weight of phenylic isodicyanate is further corroborated by its reaction

with ammonia. Just as a molecule of alcohol, by uniting with 1 or 2 mols. of cyanic acid, yields respectively urethane or ethylallophanate, so does ammonia by combining with 1 or 2 mols. cyanic acid yield urea or biuret. If, then, the polymerisation of the cyanate in the case under consideration consists in the union of two molecules of cyanate into one, the resulting dicyanate will, by uniting with ammonia and the various amines, give rise to an endless series of alcoholic biurets. Thus, with ammonia, it gives rise to diphenyl-biuret:

and, with aniline, to triphenyl-biuret:

For the description of these compounds see BIURET (p. 193).

Cyanuric Ethers. Of these ethers there are two modifications, viz. :—

Normal Cyanurates $C^3 \left\{ \begin{smallmatrix} N^2 \\ (OR)^2 \end{smallmatrix} \right.$

Isocyanurates, or Carbo-triamides $N^3 \left\{ \begin{smallmatrix} (CO)^2 \\ R^2 \end{smallmatrix} \right.$

The isocyanurates, discovered by Wurtz in 1848, are formed by distilling a mixture of potassium cyanate or cyanurate with potassium methylsulphate, ethylsulphate, &c., or by heating silver cyanate with the iodide of an alcohol-radicle (ii. 292). The normal cyanurates are produced by the action of cyanogen chloride on the sodium alcohols, &c. Cloez, in 1857, by acting on sodium ethylate with gaseous cyanogen chloride, obtained a compound isomeric with ethyl cyanate, which he called cyanetholine. Subsequently, in 1866, he obtained the corresponding methyl-compound, though in an impure state, and showed that both these compounds are resolved by heating with potash, into methyl or ethyl alcohol, and cyanuric acid. H. Gal also found (*Compt. rend.* lxi. 527) that cyanetholine, treated with gaseous hydrochloric or hydrobromic acid, yields cyanuric acid and chloride or bromide of ethyl. Nevertheless, these compounds were regarded both by Cloez and by Gal as normal cyanic ethers, CNOR (1st Suppl. 519), and their true molecular weight was first established by Hofmann & Olshausen (*Proc. Roy. Soc.* xviii. 493), who obtained the methyl and phenyl compounds in the pure state.

Methyl Cyanurate, $C^3 \left\{ \begin{smallmatrix} N^2 \\ (OCH^3)^2 \end{smallmatrix} \right.$ or $\left\{ \begin{smallmatrix} (CN)^2 \\ (CH^3)^2 \end{smallmatrix} \right\} O^2$.—When gaseous cyanogen chloride is passed into a dilute solution of sodium methylate in methyl alcohol till the liquid smells strongly of it, sodium chloride separates out, and after the methyl alcohol has been distilled off, there remains a brown oil which often retains the liquid form for a long time, but ultimately solidifies. Sometimes, again, little or no oil is formed, but on distilling off the methyl alcohol, there remains a brown crystalline mass which may be purified by recrystallisation from hot water, and treatment with animal charcoal. From the purified mass ether extracts the methyl cyanurate, leaving undissolved rhombic tablets consisting of dimethyl amidocyanate.

Methyl cyanurate crystallises from alcohol, or better from hot water, in slender needles, melts at 132°, boils between 160° and 170°, but appears to be converted, by distillation, into the isocyanurate, which melts at 175°. Before distillation it is resolved, by heating with potash, into cyanuric acid and methyl alcohol; but after distillation into carbon dioxide and methylamine.

Dimethyl Amidocyanurate, $C^3H^4N^4O^2 = C^3N^3 \left\{ \begin{smallmatrix} OCH^3 \\ NH^2 \end{smallmatrix} \right.$, is formed, together with several

other compounds, by the action of ammonia on methyl cyanurate, but is more easily obtained as a secondary product in the preparation of the cyanurate, constituting in fact, the rhombic tables above mentioned. It crystallises from hot water in beautiful rhombic tables which melt at 212°, dissolve sparingly in cold water and cold alcohol, and are nearly insoluble in ether. Silver nitrate added to its solution in nitric acid throws down the silver salt $C^3H^4N^4O^2.AgNO^3$, which crystallises in beautiful needles.

In preparing methyl cyanurate from somewhat impure methyl alcohol, Cloez once obtained a crystalline substance, which he called *methylantoin*, and to which he assigns the composition of *dimethyl-allantoin* $C^4H^6N^4O^3$ (1st Suppl. 520). Hofmann (*Compt. rend.* lxxi. 35) suggests that this substance was probably a mixture of methyl cyanurate and dimethyl amidocyanurate.

Ethyl Cyanurate, $C^3N^3(OC^2H^5)^2$, has not been obtained in the pure state. The action of cyanogen chloride on sodium ethylate goes on in the manner described by Cloez; the resulting liquid deposits variable mixtures of crystals consisting essentially of the ethylic ethers of amido- and diamido-cyanuric acids.

Diethyl Amidocyanurate, $C^2N^2 \begin{cases} OC^2H^4 \\ OC^2H^3 \\ NH^2 \end{cases}$, is obtained from the crude crystals by treat-

ment with animal charcoal, and repeated crystallisation from water, in delicate white prisms, which melt at 97° and are soluble in alcohol and ether. It is also produced when crude cyanetholine is heated for some hours in a sealed tube with aqueous ammonia. With silver nitrate, it forms the two compounds, $2C^2H^3N^2O^2 \cdot AgNO^3$, and $C^2H^2N^2O^2 \cdot AgNO^3$.

Ethyl Diamidocyanurate, $C^2N^2 \begin{cases} OC^2H^3 \\ NH^2 \\ NH^2 \end{cases}$, separates from a solution of the preceding

compound mixed with strong aqueous ammonia, after standing for some time, in white crystals, melting between 190° and 200° , very slightly soluble in alcohol. With silver nitrate it forms a compound which crystallises in slender needles.

The composition of these amidated ethers shows clearly that the compounds formed by the action of cyanogen chloride on the sodium alcohols, are really cyanurates and not cyanates.

Amyl Cyanurate.—The product of the action of cyanogen chloride on sodium amylate, resembles cyanetholine. It distils at 200° , apparently with decomposition.

Phenyl Cyanurate.— $C^2N^2(OC^2H^3)^2$. Cyanogen chloride acts on phenol, forming an oil which at first yields phenol by distillation; the later portions of the distillate, however, solidify, and on leaving the whole to cool, washing the residue of the distillation with alcohol, and crystallising from a large quantity of hot alcohol, the phenyl cyanurate is obtained in long slender needles, melting at 224° , nearly insoluble in water and ether, soluble in benzene.

CYANIDE OF HYDROGEN. The formation of this compound by the direct union of acetylene and nitrogen (*1st Suppl.* 35, 520), may be easily demonstrated by taking advantage of the property of nearly all hydrocarbons to yield acetylene when a series of electric sparks is passed through their vapours. On passing nitrogen into benzene, exposing the gas charged with the hydro-carbon to the action of the electric spark, and then passing it into silver nitrate, the formation of hydrocyanic acid becomes evident in a few seconds. The same result is obtained when the spark is passed through a mixture of ammonia gas and ether-vapour, not, however, when nitrogen is used instead of ammonia, although acetylene is formed in this case also (Perkin, *Chem. News*, xxi, 66).

Formation from Nitro-compounds.—The formation of hydrocyanic acid from picric acid by the action of baryta-water, was pointed out by Wöhler in 1828. The same result is obtained with caustic potash-solution. Dinitrobenzene is also decomposed with production of hydrocyanic acid, by boiling with aqueous potash or soda, and mononitrobenzene is similarly acted upon by the alkaline hydrates in the state of fusion (Post and Hübner, *Deut. Chem. Ges. Ber.* v. 408).

Respecting the quantities of heat evolved or absorbed in the formation and decomposition of hydrogen cyanide, see **HEAT**.

Spontaneous decomposition of Aqueous Hydrocyanic acid.—A quantity of aqueous hydrocyanic acid having been left in a glass cylinder merely covered with a funnel and a glass plate, till the liquid had evaporated, a solid residue was found at the bottom, consisting partly of brown amorphous matter, partly of yellowish crystals, which in form, taste, reaction with mercuric nitrate, mercuric chloride and potash, &c., exhibited all the characters of urea (Campani, *Gazzetta chimica italiana*, i. 472).

Action of Chlorine.—Wurtz, by passing chlorine into dilute hydrocyanic acid, obtained a product which he regarded as a hydrocyanide of cyanogen chloride $2CNCl$. CNH (ii. 218). According to Naumann u. Vogt, however (*Deut. Chem. Ges. Ber.* iii. 523), this product is not a definite compound, but only a mixture of cyanogen chloride and hydrogen cyanide. This conclusion is inferred from the vapour-densities of a product prepared according to Wurtz's directions, and containing a quantity of chlorine (45.4 p.c.) nearly corresponding with the formula $2CNCl.CNH$. The observed vapour-densities were 1.65 at 0° , 1.66 at 12° , 1.64 at 16° , and 1.67 at 100° . The formula above-mentioned requires 1.67; a mixture prepared exactly according to the formula would require 1.73; the chemical compound requires 6.18.

Stenhouse described a crystalline compound $C^2H^{14}Cl^2N^2O^4$, obtained by passing chlorine gas into a mixture of strong aqueous hydrocyanic acid and alcohol, or into an alcoholic solution of mercuric cyanide (ii. 218). C. Bischoff, on the other hand (*Deut. Chem. Ges. Ber.* iii. 760; v. 80), finds that the dichlorinated compound is produced in the latter case only, but that when chlorine is passed into a mixture of hydrocyanic acid and alcohol, the product mostly consists of the monochlorinated compound $C^2H^{14}ClN^2O^4$. This latter closely resembles Stenhouse's compound. It crystallises in white silky

needles, longer and softer than those of the dichlorinated compound; melts at 147° ; dissolves easily in ether and alcohol, also in warm nitric acid, from which it is precipitated by water. It is insoluble in hydrochloric acid; sulphuric acid dissolves it, with evolution of heat, forming a yellow solution, and on heating this liquid, the compound is broken up, alcohol and carbon dioxide being eliminated, with simultaneous formation of ammonium sulphate and sulphur dioxide. Potash, soda, and baryta, likewise resolve the compound, when heated with it, into alcohol, carbon dioxide, and ammonia. Heated to 150° with alcoholic ammonia, it yields a mixture of organic bases not yet investigated. Digested with hydrochloric acid for 24 hours at 100° , it forms ethyl chloride and carbon dioxide, which escape on opening the tubes, and glycolic chlorhydrin and other glycol-compounds, which remain dissolved in the aqueous hydrochloric acid.

These modes of decomposition suggest the following view of the formation of the compound.

It is well known that chlorinated acetals are formed by the action of chlorine on aqueous alcohol, and that urethane is produced by cyanogen chloride under similar circumstances, so that when both reactions take place simultaneously, compounds are formed in which the chlorethylidene group is combined with the urethane residue in place of the alcohol residue (ethoxyl) in chlorinated acetal, namely--

This view readily accounts for the splitting up of the chlorinated compound into alcohol, carbonic acid, and ammonia, and also for the formation of glycol-compounds. The attempts to obtain the corresponding compounds in other series were fruitless, chlorinated acetones and methyl-urethane being obtained with methyl alcohol, whilst amyl alcohol yielded amyl urethane.

When a slight excess of bromine is added to an alcoholic solution of hydrocyanic acid, and the mixture is gently heated, a violent reaction ensues, cyanogen bromide volatilising, and ammonium bromide separating from the solution. On addition of water, an oil separates, which consists chiefly of a solution of the bromine-compound in ethyl bromide, and leaves the former on being allowed to evaporate spontaneously. Bischoff only once obtained the monobrominated compound $\text{C}^2\text{H}^{12}\text{BrN}^2\text{O}^4$, which melts at 142° , and crystallises in larger needles than the easily prepared dibrominated compound. The dibrominated compound $\text{C}^2\text{H}^{14}\text{Br}^2\text{N}^2\text{O}^4$ melts at 115° – 116° , and crystallises from ether in long needles.

Iodine, alcohol, and hydrocyanic acid gave a negative result, as did also the digestion of the bromine-compound with potassium iodide. Neither the chlorine- nor the bromine-compound is altered by the action of nascent hydrogen.

On the reaction of hydrocyanic acid with *Chloral* and *Crotonic Chloral*, see pp. 310, 400.

On the detection of hydrocyanic acid, see *ALMEN* (*Chem. Centr.* 1872, 442; *Chem. Soc. J.* [2], xi. 93).

Polymeride of Hydrocyanic acid. When a mixture of equal parts of anhydrous hydrogen cyanide and epichlorhydrin is heated in sealed tubes for a fortnight to 40° – 60° , a solid body is formed, which, after treatment with ether and recrystallisation from water and alcohol, is obtained in reddish-brown crystals, the analysis of which has not given concordant results. Treated with baryta-water, it yields ammonia, barium carbonate, and a crystalline body having the composition and properties of glycocine, whence it may be inferred that the original substance is a polymeride of hydrocyanic acid:

(O. Lange, *Deut. Chem. Ges. Ber.* vi. 99).

CYANIDES, ALCOHOLIC. See the several radicles, *ALLYL*, *METHYL*, *PROPYL*, *ETHYLENE*, *NAPHTHALENE*, &c.

CYANIDES, METALLIC. Weselsky (*Zeitschr. f. Chem.* [2] vii. 61) prepares double cyanides, containing barium, the platinum compounds, for example, by passing a stream of gaseous hydrogen cyanide through a mixture of barium carbonate and a salt of another metal: e.g.

In this manner the following salts have been obtained:—

1. *Barium-silver cyanide*, $\text{BaCy}^2.2\text{AgCy} + \text{H}^2\text{O}$. This salt, prepared from barium carbonate and silver carbonate, forms warty crystalline masses, which lose their water at 100° . 2. *Barium-zinc cyanide*, $\text{BaCy}^2.\text{ZnCy}^2 + 2\text{H}^2\text{O}$, obtained from barium carbonate and zinc sulphate, forms large colourless crystals easily decomposed by exposure to the air. 3. *Barium-palladium cyanide*, $\text{BaCy}^2.\text{PdCy}^2 + 4\text{H}^2\text{O}$. This salt, already described by Rossler (1st Suppl. 536), is formed from barium carbonate and palladium cyanide. 4. *Barium-nickel cyanide*, $\text{BaCy}^2.\text{NiCy}^2 + 3\text{H}^2\text{O}$. This well-known salt was prepared by the above-described method from nickel sulphate. 5. *Barium-cuprous cyanide*, $\text{BaCy}^2.\text{Cu}^2\text{Cy}^2 + \text{H}^2\text{O}$, prepared in like manner, forms large colourless crystals, which are decomposed by exposure to the air. A salt crystallising in fine needles is obtained from the mother-liquors. 6. *Barium-cadmium cyanide*, $2\text{BaCy}^2.3\text{CdCy}^2 + 10\text{H}^2\text{O}$, obtained from cadmium sulphate, crystallises well, but is very readily decomposed.

On the Cobaltcyanides prepared in like manner, see 1st Suppl. 536.

Ferrocyanides (Wyruboff, *Ann. Chim. Phys.* [4], xvi. 280; xxi. 271). The salts were generally prepared by saturating hydroferrocyanic acid with the other corresponding oxides or carbonates. To obtain the easily soluble salts in distinct crystals the crystallising vessel containing the warm concentrated solution was covered with a sheet of filtering paper, and this with a large glass plate, which was turned round as soon as its lower surface became covered with drops of water, this treatment being repeated five or six times, without shaking the vessel.

Potassium Ferrocyanide, $\text{K}^4\text{FeCy}^6 + 3\text{H}^2\text{O}$, is usually regarded as belonging to the quadratic system (ii. 239). Wyruboff finds, however, that small, perfectly transparent crystals which separate from a solution of the salt mixed with neutral potassium chromate belong to the monoclinic system, having the axial ratio $a : b : c = 0.401 : 1 : 0.395$, and the angle ac 89.27° . Under the microscope, these crystals appear optically biaxial; the apparent monoaxial character of the ordinary crystals of the salt is attributed by Wyruboff to the superposition of lamellae, in which the plane of the optic axis of one lamella is perpendicular to that of the next.

When potassium ferrocyanide is boiled with sal-ammoniac, the following reaction takes place (?):

The ferric cyanide, $\text{Fe}^3\text{Cy}^6.3\text{H}^2\text{O}$, is said to be precipitated as an extremely fine green powder, which does not alter when dried at 100° . The same green powder is said also to be frequently produced from the ferrocyanides of the earthy-alkali metals when they are exposed to the air, hydrocyanic being liberated at the same time. The crystals under these circumstances acquire a green colour and become yellow again, only after two recrystallisations.

A double salt of potassium ferrocyanide with the nitrates of potassium and sodium, having the composition $\text{K}^4\text{FeCy}^6.2\text{NaNO}^3.2\text{KNO}^3$ or $\text{K}^2\text{Na}^2\text{FeCy}^6.4\text{KNO}^3$, is described by C. A. Martius (*J. pr. Chem.* xcvii. 502), as sometimes separating from the mother-liquors of saltpetre in the preparation of which waste potash-salts from the manufacture of yellow prussiate have been used; also as formed when a boiling solution of the nitrates of potassium and sodium is mixed with potassium ferrocyanide, and the mother-liquor which remains after the greater part of the potassium nitrate has crystallised out, is left to evaporate gradually. It is easily soluble in water, and separates therefrom in large, well-defined crystals of the hexagonal system, which exhibit the faces of several rhombohedrons in combination with the basal end-face ($OR : R = 135^\circ 15'$) and acquire a tubular form from predominance of the end-face. The crystals are light yellow, hard, brittle, and yield a white powder. When exposed for some time to light, they become covered with a greenish coating, and when shaken or rubbed in the dark they shine with a faint, greenish light. They decrepitate when slightly heated, and detonate at a higher temperature, almost as strongly as gunpowder. Wyruboff did not succeed in preparing this double salt, and therefore assumes that it is a mere mixture.

Sodium Ferrocyanide, $\text{Na}^4\text{FeCy}^6 + 12\text{H}^2\text{O}$, which is less soluble than the potassium salt, may be prepared by double decomposition of the latter with any salt of sodium.

Lithium Ferrocyanide, $\text{Li}^4\text{FeCy}^6 + 9\text{H}^2\text{O}$, is extremely deliquescent, and therefore its amount of water is difficult to determine.

Lithium-ammonium Ferrocyanide, $\text{Li}^2(\text{NH}^4)^2\text{FeCy}^6 + 3\text{H}^2\text{O}$, is prepared by dissolving equivalent proportions of the ferrocyanides of lithium and ammonium in water, and leaving the solution, which is decomposed by heat, to evaporate in a vacuum. The crystals, which are never very well defined, are identical in form with those of the following salt.

Lithium-potassium Ferrocyanide, $\text{Li}^2\text{K}^2\text{FeCy}^6 + 3\text{H}_2\text{O}$, is prepared by treating commercial Prussian blue—which generally contains potassium ferrocyanide—with caustic lithia, concentrating the solution to a syrup, and then leaving it to evaporate over oil of vitriol. The mother-liquors, which contain pure lithium salt, yield a further quantity of the double salt on addition of potassium ferrocyanide. The salt dissolves in about $1\frac{1}{2}$ part of water at ordinary temperatures, gives off 2 mols. water at 100° , and the rest at 250° , when also it begins to decompose. The crystals are monoclinic. Axes $a : b : c = 1.353 : 1 : 1.516$. Angle $bc = 56^\circ 18'$.

Rubidium Ferrocyanide, $\text{Rb}^2\text{FeCy}^6 + 2\text{H}_2\text{O}$, is isomorphous with the following salt, and dissolves at ordinary temperatures in less than its own weight of water.

Thallium Ferrocyanide, $\text{Tl}^2\text{FeCy}^6 + 2\text{H}_2\text{O}$, may be prepared by double decomposition, and obtained by slow cooling, in small highly lustrous crystals of the triclinic system, having the axes $a : b : c = 1.2562 : 1 : 1.0547$; and the axial angles $bc = 89^\circ 23'$; $ac = 80^\circ 21'$; $ab = 76^\circ 20'$.

Barium Ferrocyanide, $\text{Ba}^2\text{FeCy}^6 + 6\text{H}_2\text{O}$, prepared by double decomposition with potassium ferrocyanide, and a large excess of a barium salt, requires for solution about 1,000 parts water at 15° , and 100 parts at 75° . Crystals monoclinic : $a : b : c = 1 : 1.0017 : 0.9536$. Angle $bc = 72^\circ 48'$.

Barium-potassium Ferrocyanide, $\text{BaK}^2\text{FeCy}^6 + 5\text{H}_2\text{O}$, which crystallises in the hexagonal system, is regarded by Wyruboff, as identical with the double salt prepared some years ago by Bunsen, although the latter found it to contain only 3 mols. water (ii. 221).

Calcium Ferrocyanide, $\text{Ca}^2\text{FeCy}^6 + 12\text{H}_2\text{O}$, prepared by saturating ferrous acid with calcium carbonate, dissolves in 0.66 pt. water at 90° , and crystallises easily and well in a vacuum; nevertheless the crystals effloresce at 25° – 30° , and give off $11\frac{1}{2}$ mols. water at 100° , the rest only when they begin to decompose. Triclinic. Axial ratio, $a : b : c = 1.2524 : 1 : 0.5435$. Angle $bc = 77^\circ 12'$; $ac = 75^\circ 32'$; $ab = 43^\circ 6'$.

Calcium-sodium Ferrocyanide, $\text{CaNa}^2\text{FeCy}^6$, is difficult to prepare, and has been obtained only in small quantity. When a solution of the calcium and sodium salts in equivalent proportions is left to evaporate, it first deposits a large quantity of the sodium salt, after which a crust forms, made up of small, very regular quadrate crystals, consisting of the double salt contaminated with calcium ferrocyanide. The crystals are square prisms, approaching very closely to the cube, if they are not actual cubes. Their relation to polarised light, however, shows that they have a very complex structure, being made up of four, or even a larger number of separate crystals of various sizes.

Strontium Ferrocyanide, $\text{Sr}^2\text{FeCy}^6 + 15\text{H}_2\text{O}$, prepared like the calcium salt, is extremely soluble in water, and crystallises from a hot solution cooled to 8° or 10° in very fine monoclinic crystals, having the axes $a : b : c = 1.645 : 1 : 1.061$, and the angle $bc = 58^\circ 24'$. By dissolving this salt in water containing lithium ferrocyanide, and leaving the solution to evaporate in a vacuum over oil of vitriol, a 8-hydrated salt, $\text{Sr}^2\text{FeCy}^6 + 8\text{H}_2\text{O}$ is obtained in triclinic crystals, having the axes $a : b : c = 0.6753 : 1 : 0.2529$; and the angles $bc = 84^\circ 42'$; $ac = 88^\circ 34'$; $ab = 63^\circ 38'$.

Strontium-potassium Ferrocyanide, $\text{Sr}^2\text{K}^2\text{FeCy}^6 + 3\text{H}_2\text{O}$, may be prepared like the lithio-potassic salt; but the solution must be left to evaporate spontaneously, as when heated, it deposits the anhydrous double salt in the form of a white powder. The hydrated salt is slightly soluble in alcohol, begins to give off water at 100° , loses $1\frac{1}{2}$ mol. at 110° , and the rest when it begins to decompose. The crystals, which are not very distinct, are monoclinic. Axes $a : b : c = 0.64487 : 1 : 0.8944$, Angle $bc = 37^\circ 12'$.

Strontium-calcium Ferrocyanide, $\text{SrCaFeCy}^6 + 10\text{H}_2\text{O}$, is prepared by direct union of the constituent salts. The solution, evaporated in a vacuum, yields large crystals which give off part of their water at ordinary temperatures and the whole at 80° . It dissolves very easily in about a third of its weight of water. Triclinic. $a : b : c = 0.3534 : 1 : 0.3423$. Angle $bc = 89^\circ 18'$; $ac = 77^\circ 9'$; $ab = 82^\circ 34'$.

Cobalt Ferrocyanide. An ammoniacal solution of cobalt nitrate forms with potassium ferrocyanide a precipitate of a fine green colour, which, on addition of a large excess of ammonia, is converted into a rose-red crystalline powder, $\text{Co}^2\text{FeCy}^6 \cdot 12\text{NH}_3 + 9\text{H}_2\text{O}$, which gradually changes to a brown mass, almost wholly soluble in acids, and when treated with a large quantity of water, is immediately converted into a dark green substance having the composition $\text{Co}^2\text{FeCy}^6 \cdot 8\text{NH}_3 + 10\text{H}_2\text{O}$ (F. Curda, *Wien. Akad. Ber.* lviii. [2], 149).

Copper Ferrocyanide. According to Reindel (*J. pr. Chem.* ciii. 166), the so-

called 'Hatchett's Brown' produced by the reaction of potassium ferrocyanide with cupric salts, is not Cu^2FeCy^6 , as generally supposed, but a double ferrocyanide, $\text{Cu}^2\text{K}^2\text{FeCy}^{12}$, even when formed in a solution containing excess of copper salt; when dried in the air, it has the composition $\text{Cu}^2\text{K}^2\text{FeCy}^{12} + 12\text{H}^2\text{O}$. In drying, its temperature should not exceed 110° , as decomposition takes place between 130° and 140° . Wyruboff on the other hand (*Bull. Soc. Chim.* [2], xii. 98; xiv. 145) denies that the precipitate contains potassium, unless a very large excess of potassium ferrocyanide is used in the precipitation. In all other cases it has the composition Cu^2FeCy^6 , probably with 6 mols. H^2O . With regard to this controversy, it is remarked in the *Jahresbericht für Chemie*, 1869, p. 321, that a very important point appears to have been overlooked, viz. as to whether the solution of potassium ferrocyanide was gradually added to the copper solution or the copper solution to the ferrocyanide: in the latter case the precipitate always contains potassium, whereas in the former it may be free from that element.

Silver Ferrocyanide, Ag^4FeCy^6 . According to Weith (*Zeitschr. f. Chem.* [2], v. 381), this salt is but slightly acted on by mercuric oxide; neither is it completely decomposed by potash. When, however, it is boiled with aqueous ammonia, complete decomposition takes place, according to the equation:

As the insolubility of silver ferrocyanide in ammonia is usually regarded as decidedly characteristic of that salt, ignorance of the reaction just noticed may easily lead to errors in qualitative analysis, especially when warm solutions are used, or even when the precipitated ferrocyanide is merely left for a short time in contact with the ammoniacal liquid.

When silver ferrocyanide is brought in contact with an ammoniacal solution of silver nitrate, ferric oxide is separated, and the whole of the silver is dissolved as cyanide; the same reaction takes place with ferrocyanide or ferricyanide of potassium, Prussian blue, &c.; even potassium cobalticyanide, which resists the action of mercuric oxide, is acted upon in the same way, if the temperature of the liquid be raised to 150° . The reaction is definite enough to be used for the quantitative estimation of cyanogen. For this purpose it is convenient to use sealed tubes heated for about four hours in the water-bath (Weith).

Ammonio-ferricyanide of Silver, $\text{Ag}^4\text{FeCy}^6 \cdot 2\text{NH}^3$, is precipitated as a white, heavy, distinctly crystalline powder, when potassium ferrocyanide is added to a solution of silver nitrate containing an excess of ammonia. It is also formed by the action of ammonia on moist silver ferrocyanide, and when ammonio-ferricyanide of silver $\text{Ag}^4\text{FeCy}^{12} \cdot 3\text{NH}^3$ (*1st Suppl.* 534) is digested for some time, or warmed, with a large excess of ammonia, nitrogen gas being at the same time evolved. When dried over quick lime, it has the composition $\text{Ag}^4\text{FeCy}^6 \cdot 2\text{NH}^3 + 6\text{H}^2\text{O}$. It smells slightly of ammonia, retains its white colour unaltered at 100° or a little above, but at higher temperatures turns brown, and ultimately glimmers, giving off nitrogen and ammonium cyanide, and leaving a loose black mixture of paracyanogen, iron carbide, and silver carbide. It is nearly insoluble in boiling water, and very sparingly dissolved even by a large excess of ammonia (*Genth J. pr. Chem.* cviii. 109). The formation of the ammonio-ferricyanide of silver is contradictory to Wittstein's statement (*Gmelin's Handbook*, viii. 32), that silver ferrocyanide dissolves in ammonia, forming an opalescent liquid. Compare also Weith, (*supra*).

Ferricyanides. **Lead Ferricyanide**, formed by precipitation, is, according to Genth (*Wien. Akad. Ber.* lix. [2] 800), not anhydrous, as stated by Gmelin (*Handbook*, vii. 401), but hydrated, having the composition $\text{Pb}^2\text{FeCy}^{12} + 10\text{H}^2\text{O}$, and gives off its water at 110° . When prepared from sugar of lead containing lime, the crystals, without essential alteration of form, retain about 1 p.c. calcium. According to measurements by v. Zepharovich, they are monoclinic, having the axes $a : b : c = 0.6558 : 1 : 1.0680$, and the angle $b c = 71^\circ 32' 33''$.

Potassium Ferricyanide.—Solutions of this salt are well known to decompose readily, with formation of ferrocyanide and a blue precipitate. The presence of organic matter facilitates this decomposition considerably, but light seems to be the chief cause. A solution of 1 part freshly prepared potassium ferricyanide in 10 parts of water, when exposed to diffused daylight, becomes darker in colour in the course of a few hours, while, if it is exposed to direct sunlight, the production of ferrocyanide may be demonstrated by means of ferric chloride, even after the lapse of only thirty seconds. Yellow light is without action on the solution, and no alteration was observed to take place in the solid salt. The action may be made use of for the production of photographic pictures, but this, owing to the unstable character of cyanogen compounds, is not likely to be of any practical importance at present. Manufacturers may, however, find it advantageous to evaporate and crystallise solutions of red prus-

state in the dark, or by lamp-light, and test-solutions of ferricyanide should be kept in bottles of yellow glass (H. Vogel, *Deut. Chem. Ges. Ber.* iv. 90).

On the use of potassium ferricyanide as a test for cobalt, nickel, and manganese, see COBALT (p. 362).

CYANITE. A mineral called 'Glance-spar,' having the composition of cyanite $Al^{IV}_2O_3 \cdot SiO_2$, but differing from it in specific gravity and crystalline form, is found at several localities in the Siobengebirge (see GLANCE-SPAR).

CYANOCARBONIC ETHERS. *Ethyl Cyanocarbonate*, $C^2H^3NO^2 = CO \begin{Bmatrix} CN \\ OC^2H^3 \end{Bmatrix}$, is formed by distilling a mixture of 3 parts phosphoric anhydride with 2 parts oxamethane :

It is a colourless mobile liquid of ethereal, but penetrating odour, boiling at 115° – 116° ; almost insoluble in water, but slowly decomposed thereby, with formation of alcohol, carbonic anhydride, and hydrocyanic acid. With alcoholic ammonia it forms a white product which appears to be the amide of cyanocarbonic acid (Weddige, *J. pr. Chem.* [2], vi. 117).

Allyl Cyanocarbonate, $C^3H^3NO^2 = CO \begin{Bmatrix} CN \\ OC^3H^3 \end{Bmatrix}$, is formed, simultaneously with oxamide, by the action of fuming hydrochloric acid on the dicyanide of allyl alcohol. The liquid becomes warm, and on the completion of the reaction, the temperature being kept down, a product is formed from which ammonium chloride and oxamide are deposited in the crystalline form; and on fractional distillation, allyl chloride and allyl cyanocarbonate are obtained.

The reactions by which these bodies are formed seem to go on simultaneously. In the one cyanogen is detached from the allyl alcohol and converted into oxamide, while the alcohol yields allyl chloride :

in the other, ammonia only is removed, and the carbon of one of the cyanogen groups becomes linked, by means of oxygen, to the allyl, forming allyl cyanocarbonate :

Cyanocarbonic acid is intermediate between oxalic acid and cyanogen :

The formation of ethyl cyanocarbonate from oxamethane shows its relation to the former; that of allyl cyanocarbonate from allyl alcohol dicyanide, its relation to the latter (Wagner a. Tollens, *Deut. Chem. Ges. Ber.* v. 1045).

CYANOFORM, $CH(CN)^3$. According to T. Fairley (*Chem. Soc. J.* [2], ii. 362), this compound is formed by heating chloroform with potassium cyanide and a little alcohol to 100° in sealed tubes, as a non-volatile mass, pasty at ordinary temperatures and assuming the consistence of a viscid liquid at 100° . By the reducing action of tin and hydrochloric acid it is converted into a base, $C^2H^3N^3$ or $N^3(C^2H^3)^{III}$, called by Fairley tetrylin-triamine. This base boils above 150° and forms a platinum salt, $2(C^2H^3N^3.3HCl).3PtCl^4$.

According to Pfankuch (*J. pr. Chem.* [2], iv. 387; vi. 97), Fairley's method yields only traces of cyanoform, the main product consisting of a brown tarry mass. Small quantities of cyanoform are also formed by heating chloroform with silver cyanide. By carefully regulating the temperature (120° – 130°), and the amount of alcohol added to the mixture of chloroform and potassium cyanide, a certain quantity of pure cyanoform may be obtained; it crystallises from an alcoholic solution on slow evaporation in small, yellowish-white needles, having a somewhat unpleasant odour. Cyanoform could not be obtained by heating iodoform with either mercury or silver cyanide, but by digesting with mercury cyanide and alcohol for some hours in sealed tubes at 120° , the whole was converted into a double compound of the formula $2CH(CN)^3.3HgI^2$. By treatment with ammonium sulphide this compound is converted into the corresponding ammonium double salt $CH(CN)^3.3NH^4I$, which crystallises in small deliquescent cubes. The greater part of the mercuric iodide may be removed from the mercuric double salt by treatment with water; but it has not yet been found possible to obtain pure cyanoform by this method. Cyanoform heated with soda or with aqueous hydrochloric acid is easily converted into methintricarmonic acid, $CH(COOH)^3$, which crystallises in small needles.

CYANOGEN. *Physical States.*—To liquefy cyanogen, a pressure of 4 atmospheres

is required at 20° and of $1\frac{1}{2}$ atmosphere at 0° . Cyanogen is liquid under the ordinary pressure, at -21° and solidifies at the freezing point of mercury (Hofmann, *Deut. Chem. Ges. Ber.* iii. 658).

The solvent power of liquid cyanogen has been tested by G. Gore (*Proc. Roy. Soc.* xx. 67) as follows:—Highly dried mercuric cyanide in coarse powder was heated in a stout glass tube furnished with a V-shaped bend, and closed by a gutta-serena plug tied down with copper wire, the whole being protected by screens. The liquid cyanogen condensed in the bend, which was kept cool by a wet rag, the body to be tested for solubility having been previously placed in it.

Substances soluble at 15° .—Camphor, chloral hydrate, iodine, picric acid, and the disulphide, monochloride, dichloride, and trichloride of carbon. White phosphorus, cane-sugar, carbon tetrachloride, and water were only slightly soluble.

Substances insoluble at 15° .—Carbon, boron, silicon, sulphur, selenium, zinc, mercury, copper, iron, magnesium, salts, gums, fats, and most inorganic and organic substances.

Iodic acid became pink, cuprous iodide vermilion-red, ammonium carbonate brown. Moisture and alkalis caused the formation of a brown solid body, probably pure cyanogen.

Decomposition of Cyanogen by Hydrochloric acid in presence of Alcohol.—When cyanogen gas is passed into a saturated solution of hydrochloric acid in absolute alcohol, heat is evolved and a white crystalline precipitate forms in quantity proportional to the cyanogen employed. Under these conditions the precipitate consists of pure ammonium chloride; but if the solution be not saturated with hydrochloric acid, more or less oxamide is produced, and the mother-liquor contains oxalic ether together with a small quantity of formic ether, which may be detected by pouring the mother-liquor into dilute aqueous ammonia, separating the oxamide, acidifying the filtrate with sulphuric acid, distilling, saturating the distillate with calcium chloride, saponifying the ether which separates, and finally distilling with sulphuric acid. The distillate thus obtained exhibits the reactions of formic acid. The formation of oxalic ether is represented by the equation:

The formic ether results from the decomposition of part of the oxalic ether.

The reaction of cyanogen with hydrochloric acid in presence of alcohol, is different from that which takes place in presence of water, the cyanogen in the latter case being converted into oxamide, while the hydrochloric acid undergoes no change (*1st Suppl.* 538).

Action of Ammonia on Cyanogen.—Dry ammonia and cyanogen gas combine forming hydrazulmin, $\text{C}^2\text{N}^2\text{H}^2$, in amorphous, jet-black scales, which, when heated, first decrepitate violently, then swell up like Brodie's graphitic acid, giving out gases, and leaving a residue of paracyanogen, which volatilises completely at a higher temperature.

Water acts on hydrazulmin, forming hydrazulmoxin, $\text{C}^2\text{N}^2\text{H}^2\text{O}$:

Hydrazulmoxin is a brown amorphous mass which dissolves but sparingly in water, more freely in presence of ammonia. When the ammoniacal solution is exposed to the air, the hydrazulmoxin separates out again gradually. This compound is identical with the so-called azulmic acid, which is formed by the spontaneous decomposition of an aqueous solution of cyanogen, and by the action of cyanogen on aqueous ammonia. The more concentrated the latter, the greater is the quantity of azulmic acid formed, whilst in more dilute solutions the formation of oxamide preponderates. A hot aqueous solution of azulmic acid exhibits a fine violet fluorescence; on heating it gently with caustic potash or concentrated sulphuric acid, yellowish-brown solutions are obtained, which, after cooling, show a dark green fluorescence.

When azulmic acid is boiled with water and the hot solution filtered, it separates out on cooling with a much lighter colour; and, by repeating this operation several times, a product is at length obtained, forming light yellow amorphous flakes. This body is identical with mycomelic acid, $\text{C}^2\text{N}^2\text{H}^2\text{O}^2$, which Liebig and Wöhler first obtained by the action of ammonia upon alloxan, and which Hlasiwetz afterwards prepared by heating uric acid and water together in sealed tubes to 180° . Mycomelic acid is formed according to the equation:

Mycomelic acid is soluble in boiling water; the solution shows a fine greenish-blue fluorescence.

By oxidising azulmic acid with potassium permanganate or nitric acid two atoms of hydrogen are replaced by oxygen and azoxulmoxin $2\text{C}^2\text{N}^2\text{H}^2\text{O}^2 + \text{H}^2\text{O}$ is formed,

a reddish-yellow, crystalline powder, insoluble in water, but readily soluble in concentrated sulphuric acid. This solution shows an intense light green fluorescence, like uranium glass.

The constitution of these different compounds is most probably as follows:—

(Jacobson and Emmerling, *Deut. Chem. Ges. Ber.* v. 947).

The name *azulmic acid* has also been given to an oxidised acid, which is one of the constituents of the reddish-black mass (azulmin) formed, after long standing, in hydrocyanic acid mixed with a little water and a trace of ammonia or a fixed alkali. According to Gautier (*Ann. Chim. Phys.* [4] xvii. 158) this mass consists of five different parts: (1.) A portion volatile at 100° , containing water, ammonia, and ammonium cyanide. (2.) A portion soluble, with red colour, in alcohol of 99 p.c., and crystallising therefrom in tufts. (3.) A portion soluble in somewhat dilute potash-ley. The dark brown filtered solution mixed with hydrochloric acid, deposits light flocks, while one or more nitrogenous bodies remain dissolved. (4.) A brown-black, uncrystalline, non-hygroscopic mass, forming by far the largest proportion of the whole, insoluble in water either cold or warm, also in alcohol, dilute acids, and dilute potash-ley, very slightly soluble in glacial acetic acid. With strong potash-ley it forms a dark brown solution, from which it is precipitated by hydrochloric, sulphuric, and even carbonic acid. It dissolves at ordinary temperatures in commercial nitric acid, and in strong sulphuric acid, and is separated therefrom by a large quantity of water. Its solution in acids forms brown precipitates with silver nitrate and mercury salts, green with copper salts, white with lead salts. Neither of these precipitates is crystalline. The sulphuric acid solution undergoes alteration when heated above 200° . The mass itself is unalterable at 130° and probably at much higher temperatures. By prolonged boiling with water in which insoluble bases like magnesia and zinc-oxide are suspended, it may be made to unite with those bases and form salts. (5.) A small quantity of a pitchy substance insoluble in concentrated acids.

The brown-black substance (4.) (azulmic acid) has, according to Gautier, the empirical formula $\text{C}^2\text{H}^2\text{N}^2\text{O}$, but its silver salt has the composition $\text{C}^2\text{H}^2\text{AgN}^2\text{O}$, whence it is probable that the acid itself is $\text{C}^2\text{H}^2\text{N}^2\text{O}$. Gautier assigns to it the constitutional formula, $\text{N} \begin{array}{c} \text{CO} \\ | \\ \text{H} \end{array} \cdot 2\text{CNH}$, supposing it to contain a polymerised cyanide of hydrogen.

On the reaction of cyanogen chloride with phosphine, see PHOSPHINE; with *benzyl alcohol*, p. 178.

On the Heat of Formation of Cyanogen-compounds, see HEAT.

CYANUREA, or **CYANCARBAMIDE**, $\text{C}^2\text{H}^2\text{N}^2\text{O} = \text{CH}^2(\text{CN})\text{N}^2\text{O}$. Produced, according to Poensgen (*Ann. Ch. Pharm.* cxxviii. 339), by heating urea (30 parts) with cyanogen iodide (70 parts) for two days to 140° – 150° :

On treating the product with warm water, and removing the separated iodine with sulphurous acid, cyanurea remains as an amorphous light yellow powder, nearly insoluble in water, easily soluble in strong acids and alkalis, not decomposed by acids even at the boiling heat, but resolved by heating with alkalis into ammonia and carbonic acid. Heated with barium hydrate and a little water to 130° , it yields, together with ammonia and barium carbonate, a barium salt containing $(\text{C}^2\text{H}^2\text{N}^2\text{O})^2\text{Ba} + \text{H}^2\text{O}$. Suspended in water and treated with nitrous acid, it is converted into dicyanic acid:

According to Hallwachs (*Zeitschr. f. Chem.* [2], vi. 354), Poensgen's cyanurea is nothing but impure ammeline $\text{C}^2\text{H}^2\text{N}^2\text{O}^2$, and his dicyanic acid is probably cyanuric acid.

CYANURIC ACID AND ETHERS, see pp. 406, 409.

CYCLAMEN (De Luca, *Gazzetta chimica italiana*, ii. 556). The tubers of

E E

Cyclamen europæum contain a fermentable saccharine substance, starch, and gum, together with acrid and poisonous matters, the most abundant of which is a non-nitrosated glucoside called cyclamin, which was prepared and described by De Luca about fifteen years ago (ii. 294). The paper above cited contains nothing new respecting this body, excepting a more expeditious mode of preparation, founded on its property of coagulating like albumin when its aqueous solution is heated. When the expressed juice of the tubers is heated nearly to the boiling point, a white flocculent substance separates on the surface, which may either be skimmed off, or separated by filtering the hot liquid. This substance dissolves in hot alcohol, and the solution filtered while still hot, deposits the cyclamin on cooling in the amorphous aggregations formerly described.

The juice of the tubers left to itself for some days in contact with the air, soon ferments, with evolution of carbon dioxide and formation of alcohol, which may be isolated by simple distillation. The cyclamin in the solution is at the same time coagulated by the heat developed by the fermentation. The filtered liquid evaporated to dryness over the water-bath leaves a brownish residue, the solution of which in cold alcohol yields by spontaneous evaporation, crystals of mannite. The mannite may also be extracted by treating the above-mentioned residue with hot alcohol, and leaving the solution to cool; it appears to be a product of the fermentation above mentioned: for the unfermented juice, treated in the manner just described, does not yield a trace of it. Further experiments must decide whether the mannite is formed by transformation of the cyclamin, or of the numerous other substances contained in the juice.

Other saccharine substances, more or less resembling mannite, have likewise been obtained from the juice of cyclamen. A considerable quantity of the juice having been boiled, the coagulum collected in filters, and these, after the liquid had drained off, having been placed under a bell-jar and surrounded with fragments of quick lime, renewed as it slaked, the whole of the coagulum was found, after some weeks, to be converted into a crystalline substance exhibiting some of the properties of mannite.—Another portion of the expressed juice poured into two glass vessels of 10 litres capacity, began, after a few days, to deposit, on the side more directly exposed to the light, a white, amorphous substance, which gradually increased in quantity; no gas was evolved, and the liquid did not exhibit any sign of putrefaction. On boiling the remaining liquid, only a small quantity of coagulum was obtained, and on separating the liquid therefrom, evaporating to dryness, and treating the blackish residue with hot alcohol, a solution was obtained which gradually deposited a crystalline substance likewise resembling mannite in some of its characters.

Lastly, the remaining portion of the juice was evaporated over the water-bath, the residue, when dry, was digested with cold alcohol, and the filtered liquid, while still hot, was left to itself in a glass vessel: it then deposited an amorphous substance, resembling the cyclamin which separates on cooling from an alcoholic solution.

These experiments seem to show that cyclamin is capable of gradually passing, under the influence of moisture, into a sweet crystallisable substance, similar to, or perhaps identical with, mannite.

The juice of cyclamen tubers may be introduced into the stomach of rabbits in doses of 10 to 20 grams without destroying life, and the tubers are eaten with impunity by pigs, but the juice, mixed with water in the proportion of 1 cub. cent. to 2 or 3 litres acts poisonously on fishes. The toxic action of cyclamin is similar to that of curarine, but less energetic, and, like the latter, it is nearly neutralised by bromine.

CYCLOPIC ACID. An acid obtained from *Cyclopia Vogelii*, a plant used in Africa for the preparation of tea. When about a pound of the dry leaves is tied up in a cloth, immersed in water for some days, and pressed from time to time, the cyclopic acid is deposited in the form of a yellow powder. It may be purified by crystallisation from weak spirit. It exhibits a deep greenish-yellow fluorescence, which is best observed when a few crystals of the substance are immersed in soda-ley, and exposed to sunshine: after a few days, however, the fluorescence disappears. Analysis leads to the formula $C^7H^6O^4$ or $C^4H^4O^3$, the acid being bibasic or quadribasic accordingly (Church, *Chemical News*, xxii. 2).

CYMENE, $C^{10}H^{14}$. The researches of Fittig, Kübrich a. Jilke, of Pott, of Louguine, and quite recently those of Boilstein a. Kupffer (*Deut. Chem. Ges. Ber.* vi. 1181; *Ann. Ch. Pharm.* clxx. 282), have shown that the cymene obtained from cuminal oil, and from the oil of *Cicuta virosa* is identical with that which is produced by dehydration of camphor with zinc chloride, phosphoric oxide, or phosphoric sulphide. The cymene obtained from these sources boils at 175° , has a specific gravity of 0.871–0.873 at 0° , and is converted by oxidation with dilute nitric acid into toluic acid, by oxidation with chromic acid mixture into acetic and terephthalic acids: hence it is

inferred to have the constitution of methyl-propyl-benzene, or methyl-isopropyl-benzene, $C^6H^3(CH^3)(C^3H^7)$ (1st Suppl. 302).

The same cymene is produced by dehydrogenation of various hydrocarbons of the terpene group, $C^{10}H^{16}$, which, in fact, may be regarded as dihydrides of cymene. By adding bromine to oil of turpentine or oil of lemons at a low temperature, or by heating finely powdered turpin to 50° , and then leaving it to itself at the ordinary temperature, terpene dibromide, $C^{10}H^{16}Br^2$, is formed as a heavy oil, which, when heated with aniline to 180° for eight hours, gives up $2HBr$ and yields cymene boiling at 176° – 179° , and converted by oxidation with chromic acid into acetic and terephthalic acids (Oppenheim, *Deut. Chem. Ges. Ber.* v. 34, 628). A similar result has been obtained by Barbier (*Comptes rendus*, lxxiv. 194), by treating crystallised turpin $C^{10}H^{16}$, $3H^2O$ with bromine, and decomposing the product by distillation.

Wright (*Chem. Soc. J.* [2], xi. 686) has examined the cymenes obtained from various members of the terpene family by the following processes:

1. By acting on myristical (the chief constituent of volatile oil of nutmeg) with phosphorus pentachloride, whereby a liquid chloride $C^{10}H^{16}Cl$ is obtained:

and this when heated to 170° – 190° , is resolved into hydrogen chloride and cymene.

2. By the action of zinc chloride on myristical: $C^{10}H^{16}O - H^2O = C^{10}H^{14}$.

3. By digesting the chlorinated product obtained by the action of phosphorus pentachloride on cumphor, in a flask with vertical condenser, as long as hydrogen chloride was given off, then distilling off the remaining hydrocarbon, and digesting it with sodium. A polymoride of cymene appears to be formed at the same time in small quantity, and a viscid tar remains in the retort.

4. By treating the most volatile hydrocarbon of nutmeg oil (boiling at 163° – 164°) with sulphuric acid, the terpenes present are polymerised, and cymene pre-existing in it, remains unaltered: the cymene may then be distilled off.

5. Turpentine oil, treated in the same manner, likewise yields about 3 p.c. of cymene previously contained in it.

6. By adding bromine to hesperidene (from oil of orange-peel) and heating the resulting dibromide: $C^{10}H^{16}Br^2 = 2HBr + C^{10}H^{14}$.

7. From cumin oil, by the usual process of separating the cuminic aldehyde by combination with acid sodium sulphite, and distilling off the cymene.

The cymenes from these several sources all gave by analysis numbers agreeing with the formula $C^{10}H^{14}$, and their boiling points (corrected) though varying one or two degrees, were all about 176° . By oxidation with chromic acid mixture, they all yielded terephthalic and acetic acid, but no isophthalic acid, nor any of the higher homologues of acetic acid. Moreover, these seven samples had all the same odour, and their specific gravity, refractive index, and dispersion were nearly the same, approximating to the following mean values:

Sp. gr.	Refr. Index.	Dispersion.
0.86	1.48	0.035.

The optical properties of these cymenes have been examined by Gladstone (*Chem. Soc. J.* [2], xi. 970), who finds that they are practically the same for all, the specific refractive energy being 0.55, and their mean refraction-equivalent 75.1, the difference of the extremes not being greater than that usually observed between different specimens of the same hydrocarbon. This equivalent, calculated with the common refraction-equivalents for carbon (5) and for hydrogen (1.13), would give 68.2; thus all these specimens of cymene showed a higher equivalent characteristic of the aromatic group. This is particularly remarkable, as some of them were prepared from substances which do not exhibit this abnormal influence on light, affording additional evidence that the retarding power of the carbon in such bodies as these does not arise from any particular internal structure capable of being transmitted from one compound to another.

The boiling points and the specific gravities at different temperatures of the cymenes from several sources, carefully purified by treatment with sodium and subsequent fractional distillation have recently been determined with great care by Pisati & Paternò (*Gazzetta chimica italiana*, iii. 551), the result being to establish their identity with regard to these properties.

	From Cumin Oil.	From Cymyl Alcohol.	From Camphor.	From Thyme Oil.
Boiling point (bar. at 761·4 -761·6 mm.)	175·1°	177·25°	176·55°	
Sp. gr. at 0°	0·87446	0·87227	0·87221	0·87226
25°	0·85457	0·85258	0·85237	0·85244
50°	0·83459	0·82352	0·83251	0·83252
75°	0·81409	0·81209	0·81230	0·81223
100°	0·79307	0·79129	0·79123	0·79124

Bromocymene, $C^{10}H^{13}Br = C^6H^3Br.CH^2.C^4H^7$, is formed by adding bromine, drop by drop to cymene (prepared by the action of phosphorus pentasulphide on camphor). When purified by distillation with water and fractional distillation, it forms a liquid having a faint odour like that of cymene, boiling at 233° – 235° , and having a sp. gr. of 1·269 at $17\cdot5^{\circ}$. The bromine in this compound is retained with great force, not being eliminated by the action of sodium and methyl iodide, or of sodium and carbon dioxide.

Bromocymene is readily oxidised by dilute nitric acid (1 acid to 4 water) forming bromotoluic acid, $C^6H^3Br(CH^3)(COOH)$, melting at 203° – 204° (Landolph, *Deut. Chem. Ges. Ber.* v. 267). See TOLUIC ACIDS.

Chlorocymene is formed when chlorine gas, diluted with carbon dioxide, is passed into cymene. Heated with potassium acetate and alcohol, it yields cymyl acetate, $C^{10}H^{13}.C^2H^3O^2$, a liquid boiling above 236° (Czumpelik, *Deut. Chem. Ges. Ber.* iii. 481).

CYMESE-SULPHONIC ACID, $C^{10}H^{13}.SO^2H$, is mentioned in the *First Supplement* (p. 302), as formed by treating cymene with fuming sulphuric acid. According to H. Müller (*Deut. Chem. Ges. Ber.* ii. 130), it is also very easily produced by treating pure cymene with ordinary sulphuric acid at 90° – 100° . Heated with caustic potash or soda it yields oxycymene or cymic phenol, $C^{10}H^{14}OH$.

Beilstein u. Kupffer (*Deut. Chem. Ges. Ber.* vi. 1181; *Ann. Ch. Pharm.* clxx. 287) have examined several salts of the cymene-sulphonic acids prepared from cymene obtained from cumin oil and from camphor, and have found them to be identical in their properties. The *barium salts*, $(C^{10}H^{13}SO^2)^2Ba + 3H^2O$,* form crystalline laminae, which do not give up their water of crystallisation till heated above 100° . 100 parts of water at $16\cdot2^{\circ}$ dissolve 2·5 parts of the hydrated salt; 100 parts of alcohol at $17\cdot5^{\circ}$ dissolve 5·3–5·5 parts. The *calcium salt*, $(C^{10}H^{13}SO^2)^2Ca + 2H^2O$, crystallises by slow cooling from a not too concentrated solution in splendid large plates which have a vitreous lustre, give off their water of crystallisation over sulphuric acid, and are much more soluble in water than the barium salt. The crystals are monoclinic, exhibiting the combination $\infty P_{\infty} . + P . - P . \infty P . \infty P_3$. Ratio of axes $a : b : c = 1\cdot373958 : 1 : 1\cdot124195$. Angle $bc = 95^{\circ} 13' 17''$. Cleavage very distinct parallel to ∞P_{∞} and (∞P_{∞}) (Jerosfjew, *Ann. Ch. Pharm.* clxx. 297).

The *lead-salt*, $(C^{10}H^{13}SO^2)^2Pb + 3H^2O$, forms shining laminae which give off their water over oil of vitriol. 100 parts water at 16° dissolve 1·34–1·94 parts of the salt. The solution is partially decomposed by evaporation.

According to Paternò (*Gazzetta chimica italiana*, iii. 544), cymene from camphor yields two isomeric sulpho-acids, the barium salt of one of which contains $3H^2O$, while that of the other contains only $1H^2O$. This may perhaps account for the earlier statements respecting this salt (ii. 299), according to which it crystallises sometimes with 2, sometimes with only 1 mol. water.

CYMIC PHENOL or OXYCYMENE, $C^{10}H^{14}O = C^{10}H^{13}OH$, is produced by the action of caustic alkalis on cymene-sulphonic acid (*vid. sup.*, also *1st Suppl.* 302), also, together with camphor, camphoretin and colophene, by the action of iodine on camphor (Claus, *J. pr. Chem.* xxvi. 261; Schweizer, *ibid.* 118). According to Fleischer u. Kekulé (*Deut. Chem. Ges. Ber.* vi. 934), the best mode of preparing it from camphor is the following:

Camphor is heated with about one-fifth of its weight of iodine in a vessel connected with a reversed condenser, and the product submitted to distillation, until the tempe-

* In the *First Supplement* (p. 302) this salt is erroneously stated to contain 6 mol. water.

nature of the vapour is 170° . The residue is treated with concentrated soda-ley, which leaves a resinous body undissolved, and the filtrate is shaken repeatedly with ether; on adding hydrochloric acid to the filtrate, the phenol separates out. It is an oily liquid, which does not solidify at -20° , and boils at 231° – 232° . By the action of phosphorus pentasulphide, it is converted into cymene, and a thiocymene or cymic mercaptan, which is identical with that obtained by distilling camphor with phosphorus pentasulphide. These results show that in cymene-sulphonic acid, and in the phenol and mercaptan derived from it, the inorganic groups occupy the same position as in the cymic phenol and mercaptan derived from camphor (Raderburg, *Deut. Chem. Ges. Ber.* vi. 669).

CYMIC MERCAPTAN or **CYMENYL SULPHYDRATE**, $C^{10}H^{13}SH$, is formed in small quantity, together with other compounds soluble in alkalis, in the preparation of cymene by distilling camphor with phosphoric sulphide (1st Suppl. 302). To free these soluble compounds from hydrocarbons, the alkaline solution is either shaken with ether, or subjected to the action of a current of steam; afterwards the solution is acidified with hydrochloric acid, and the oil which separates is subjected to fractional distillation. The principal product thus obtained is cymene-mercaptan (Flesch). It is also produced by distilling cymic phenol with phosphorus pentasulphide, and by the action of nascent hydrogen on cymene-sulphonic chloride, $C^{10}H^{13}SO_2Cl$, obtained by distilling the potassium salt of cymene-sulphonic acid with phosphorus pentachloride (Raderburg, *Deut. Chem. Ges. Ber.* vi. 669).

Cymic mercaptan is a colourless liquid, having a peculiar aromatic odour, miscible with alcohol, but insoluble in water. It has a sp. gr. of 0.9975, and boils at 235° – 236° . Oxidising agents transform it into cymene disulphide.

The *mercury compound* $Hg(C^{10}H^{13})_2SS^2$, is obtained in long, bright needles, by boiling an alcoholic solution of the mercaptan with mercuric oxide, and cooling the liquid, or as a white precipitate by mixing an excess of an alcoholic solution of the mercaptan with mercuric chloride. On distillation, it yields metallic mercury, mercuric sulphide, and an oil which appears to be a mixture of monosulphide and disulphide of cymene. When an alcoholic solution of cymic mercaptan is added to excess of mercuric chloride, a more soluble compound, $C^{10}H^{13}S.HgCl$ is formed. The *silver-compound* $C^{10}H^{13}AgS$ is obtained as a yellow-crystalline precipitate on adding an excess of solution of the mercaptan to a solution of silver nitrate. If the mercaptan is not in excess, the compound $C^{10}H^{13}Ag_2S.AgNO_3$ is formed, which crystallises from alcohol in leaflets (Flesch, *Deut. Chem. Ges. Ber.* vi. 478).

Cymic Disulphide, $(C^{10}H^{13})_2SS^2$, is formed by oxidation of cymic mercaptan, and is best prepared by dissolving the latter in an alkali, and adding sodium. It then separates as an oil, which does not solidify on refrigeration (Flesch).

When cymic mercaptan or cymic disulphide is treated with nitric acid, two atoms of carbon are eliminated, and sulphotoluic acid, $C^8H^5 \begin{Bmatrix} SO^2H \\ CO^2H \end{Bmatrix}$, is formed (Flesch).

D.

DAMBONITE, $C^4H^5O^3$. This saccharine substance, obtained from the West Coast of Africa (1st Suppl. 541), is converted, by a mixture of nitric and sulphuric acids, into a thick, translucent, gummy nitro-compound, which is precipitated in flakes by water, crystallises from solution in boiling alcohol, and detonates when struck (Champion, *Compt. rend.* lxxiii. 114).

DAPHNE. The seeds of *Daphne Mezereum* yield a fat oil, which has a specific gravity of 0.8903 at 15° , dissolves slightly in alcohol, remains fluid at 16° , and dries up on wood. It contains an acid substance, from which it may be freed by digestion with alcohol. By saponification, it yields stearic, palmitic, myristic and linoleic acids. The press-cake yields to ether a resin, and to alcohol of 95 p.c. a resinous substance, which, after treatment with alcohol of 70 p.c. crystallises from hot alcohol in stellate groups. This substance is coccognin (p. 386). 100 parts of mezereum fruit yielded, together with traces of volatile oil, 31 parts fat oil, 3.58 resin and wax soluble in ether, 0.32 acrid resin (soluble in alcohol), 0.38 coccognin, 19.5 proteids, 32.37 mucus, gum, plant-acids, bitter principles, colouring matter and cellulose, 5.46 inorganic matter, and 7.39 water (Casselmann, *Jahresb.* 1870, 883).

DATOLITE. This mineral occurs abundantly in brilliant crystals exhibiting a great variety of combinations, in the Bergen Hill Tunnel, New Jersey. An elaborate description of these crystals, accompanied by figures, is given by E. S. Dana (*Sill. Am. J.* [3], iv. 16), whose measurements show that they are monoclinic, differing but slightly from the orthorhombic form, a result agreeing with the measurements of Kopp (ii. 305). The crystals are referrible to four distinct types, which are represented in the following figures : *

FIG. 12.

DATURA. The following method, devised by Dragondorff, for estimating the amount of alkaloid in *Datura Stramonium*, and *Atropa Belladonna*, is described by N. Günther (*Zeitschr. Anal. Chem.* viii. 4761). The comminuted plant-organs are twice exhausted at 30°-40°, with 10 times their weight of water acidulated with 3 drops of sulphuric acid, and the strained extracts are evaporated to a syrup over a steam-bath. The syrupy liquid is left for 24 hours in contact with three times its volume of alcohol, to separate gummy substances, then filtered; the greater part of the alcohol is removed by distillation, the rest by evaporation over a water-bath; and the residue is agitated with light petroleum oil to free it from colouring and resinous matters. The liquid is then neutralised with ammonia; the alkaloids are dissolved out by repeated treatment with chloroform; the united extracts are freed from ammonia salts by washing with water; and the residue left, after removing the greater part of the chloroform by distillation, and the rest by evaporation, is weighed. The roots, leaves, ripe and unripe fruit of *Belladonna* thus treated, yield the alkaloid as a colourless, spicular, crystalline mass; the stems yield it as an amorphous mass, whereas from all parts of the *Datura*, yellow amorphous daturine is obtained. The amorphous portions treated with water containing sulphuric acid, always leave a slight resinous residue. The weight-determinations may be verified by titration with potassium-mercuric iodide (*1st Suppl.* 86). The results are given on page 117 of this volume.

DECANE, $C^{10}H^{22}$, is the chief product obtained by heating turpentine oil to 275° for 24 hours with 60 parts of hydriodic acid. It boils between 155° and 162°, withstands the action of nitric acid, and is not attacked by bromine at ordinary temperatures. *Pentane* or *Amyl Hydride*, C^5H^{12} , is formed at the same time in smaller quantity (*Berthelot, Bull. Soc. Chim.* [2], xi. 3).

* The notation of the faces in these figures is that used in Dana's *Mineralogy*, for an explanation of which, see the article *Crystallography*, ii. 145, footnote.

DECENE, $C^{10}H^{20}$, and **DECINE**, $C^{10}H^{18}$, are obtained (together with larger quantities of a volatile aromatic hydrocarbon) by heating turpentine oil for some hours to 200° – 250° with 20 parts of hydriodic acid. *Decene* boils at 165° , has a strong alliaceous odour, is not attacked by ordinary sulphuric acid in the cold, but dissolves in the fuming acid when heated, forming a sulpho-acid. Fuming nitric acid in the cold converts it into a nitro-acid, without evolution of red fumes. Bromine converts it, with evolution of hydrobromic acid, into colourless crystalline needles. *Decine* boils at 170° – 175° , withstands the action of sulphuric acid, nitric acid and bromine more obstinately than decene; nevertheless it is gradually oxidised by boiling with nitric acid, and converted into a viscid product by heating with fuming sulphuric acid. Heated to 280° with hydriodic acid, it is converted into decane, with evolution of a gaseous mixture of 57 parts hydrogen and 43 propane (Berthelot, *loc. cit.*).

DECEMENTE. See VANADATES OF LEAD.

DEHYDRATION. A theoretical paper on the dehydration of organic compounds, and the part which this process plays in the formation of sugar, and on fermentation, has been published by A. Baeyer (*Deut. Chem. Ges. Ber.* 1870, 63; *Chem. Centralblatt*, 1871, 27, 38; *Chem. Soc. J.* [2], ix. 331).

DELESSITE. A mineral allied to delessite occurs in cavities of the trapp in the western part of New Caledonia, sometimes filling these cavities alone, sometimes encrusting zeolites. It is green, soft, fusible at the edges, partly soluble in hydrochloric acid. Analysis gave:

SiO ₂	Al ₂ O ₃	FeO.	CaO.	MgO.	Gangue.	H ₂ O.	O. and loss.
40.53	6.95	12.50	0.52	14.15	2.87	13.10	9.38 = 100.

The iron occurs partly as $Fe^{2+}O^2$ (H. How, *Phil. Mag.* [4], xxxvii. 269).

Another mineral allied to delessite, occurring, on the Puy de Montandoux, Auvergne, as a cement of basaltic tufas, and in cavities of the same, has been analysed by v. Lasaulx (*Jahresb.* 1870, 1306), with the following results:

SiO ₂	Al ₂ O ₃	Fe ²⁺ O ²	CaO.	MgO.	H ₂ O.
30.32	18.51	19.82	4.51	11.74	12.30. = 100.20

DEOXYBENZOLIN. See BENZOIN (p. 172).

DEOXYCODEINE. See CODEINE.

DEOXYGLUTANIC ACID, $C^5H^7O^4$. An acid produced by heating glutanic or glutaric acid, $C^5H^7O^3$ (*1st. Suppl.* 637), with four times its weight of concentrated hydriodic acid to 120° for about eight hours. It is very readily soluble in water, alcohol, and ether, and crystallises exceedingly well, forming large, transparent, monoclinic crystals, melting at about 97° , and decomposing above 280° into water and the anhydride.

Acid Ammonium deoxyglutamate, $C^5H^7(NH^4)O^4$, remains, on evaporating a strongly ammoniacal solution of the acid under an exsiccator, in transparent concentrically grouped crystals. *Calcium deoxyglutamate*, $C^5H^7CaO^4 + H^2O$, is sparingly soluble in water, and forms opaque laminae. *Barium deoxyglutamate*, $C^5H^7BaO^4 + 5H^2O$, crystallises in small transparent needles, readily soluble in water. *Lead deoxyglutamate*, $C^5H^7PbO^4$, is a white heavy precipitate, and the silver salt, $C^5H^7Ag^2O^4$, a very bulky precipitate resembling alumina; it is but sparingly soluble in boiling water, and separates on cooling in the crystalline state. It may be obtained in distinct needles by boiling a dilute solution of the acid with silver carbonate; but the greater part of the salt remains behind with the excess of silver carbonate.

Deoxyglutanic acid is isomeric with pyrotartaric acid, from which it follows that glutanic acid is not identical with either of the three homomalic acids derived from acetic acid, as these latter would yield pyrotartaric acid by reduction (Dittmar, *J. pr. Chem.* [2], v. 338).

DESCLOIZITE. See VANADATES OF LEAD.

DESMIN. See STILBENE.

DETONATION. See EXPLOSION.

DEXTRIN. According to Jacobson (*Ann. Ch. Pharm.* clvii. 227) this substance occurs, together with inosite, in the lungs of the porpoise.

According to Musculus (*Bull. Soc. Chim.* [2], xviii. 66) dextrin is formed by the dehydration of glucose. Proceeding on the view that dextrin is the ether of glucose, he prepared sulphoglucosic acid by dissolving dry glucose in concentrated sulphuric acid, mixed the solution with alcohol of 95° , in which dextrin is very nearly insoluble, and set the mixture aside. A deposit, apparently dextrin, continued to form for about three weeks. Freed from adhering acid and alcohol, this deposit possessed the follow-

ing properties:—It was gummy while moist; amorphous and friable when dry; was very soluble in water, insoluble in alcohol; had no sweet taste; did not reduce copper salts; was only very slightly saccharified by diastase; was slowly converted into glucose by boiling with dilute sulphuric acid; and was not coloured by iodine. Its rotatory power, however, although very nearly double that of glucose, was still far below that of ordinary dextrin.

Respecting the formation of dextrin from starch, and the behaviour of dextrin and starch with iodine, see STARCH.

DEXTRONIC ACID, $C^6H^{12}O_7$ (Habermann, *Deut. Chem. Ges. Ber.* v. 167). This acid, which has the same composition as gluconic acid, is obtained from dextrin in the same way as lactic acid from milk-sugar, *i.e.*, by bromination and treatment with silver oxide. The crude acid yields a crystallisable calcium salt, and is best purified by precipitating with lead acetate and treatment with sulphuretted hydrogen; it then forms a sour uncrystallisable syrup. Its ordinary salts are monobasic, but bibasic salts may be prepared in the same way as the corresponding salts of gluconic acid (*q.v.*), with which it is merely isomeric and not identical. The two acids differ by 5° in their molecular rotatory powers, and in the degree of hydration and the solubility of their calcium and barium salts, thus:

Calcium salts.

Dextronate $Ca(C^6H^{11}O_7)^2 + H_2O$, soluble in 34 parts of water at 16° .
Gluconate $Ca(C^6H^{11}O_7)^2 + 2H_2O$, " 25 "

Barium salts.

Dextronate $Ba(C^6H^{11}O_7)^2 + 4H_2O$, soluble in $5\frac{1}{2}$ parts of water at 30° .
Gluconate $Ba(C^6H^{11}O_7)^2 + 3H_2O$, " 6 "

DEYAMITTIN. An indifferent substance obtained, on one occasion, in the preparation of buxino from the roots and stalks of *Cissampelos Pareira*, by extraction with warm water, and precipitation with soda. On treating the precipitate with hydrochloric acid, the dayamittin remained undissolved, and crystallised from hot alcoholic solution in microscopic hexagonal plates. When treated with sulphuric acid, these crystals assumed a splendid blue colour, which quickly passed through green into red, and then disappeared (Flückiger, *Zeitschr. f. Chem.* vi. 251).

DIABANTACHRONNYN. This name was given by K. Liebe (*Jahrbuch f. Mineralogie*, 1870, 1) to the mineral which gives the colour to the green diabases of the Voigtland and the Frankenwald. This mineral was regarded by Liebe, as a distinct species, but Keungott (*ibid.* 1871, 51) has shown that it is identical with chlorite (p. 323).

DIABASE. This rock, belonging to the greenstone family, is a compact mixture of one or two felspathic minerals with augite, and usually also finely divided chlorite. It is especially characterised by the entire absence of quartz, and the rarity of the presence of mica.

The felspathic constituents are the most abundant, and appear, sometimes in crystals more or less distinct, sometimes in tabular particles, sometimes massive, with a white, greenish-white, or greyish-white colour. They consist of a triclinic alkali-felspar, namely oligoclase, and a lime felspar probably labradorite. The augite is next in proportion, and has a granular, prismatic, or acicular structure, and usually a green or black-brown colour. The proportion of lime in diabase is equal to that of the magnesia and ferrous oxide taken together. The chlorite, which is the least abundant constituent, imparts to the rock its green colour, and impregnates it, usually in very fine earthy particles, sometimes in scales. When it is dissolved out by hydrochloric acid, the rock becomes paler in colour. The more fine-grained the mass, the greater is the quantity of chlorite contained in it.

Titaniferous iron ore, magnetic iron ore, and apatite, are also constant constituents of diabase, and calcium carbonate is usually present in imperceptibly small particles. Accessory constituents are iron pyrites, magnetic pyrites, copper pyrites, actinolite, asbestos, ferrous carbonate, axinite, epidote, olivine, hornblende, mica, diallage, and a few zeolites. The titaniferous iron, apatite, and chlorite, are more or less soluble in hydrochloric acid; the felspar and augite are insoluble.

Diabase forms beds and veins in the palaeozoic formations, occurring especially in Nassau, in the Hartz, the Voigtland, Upper Franconia, Westphalia, Devonshire and Norway. It is usually regarded as an eruptive rock, but sometimes occurs in strata, resembling the sedimentary deposits and passing into them.

Transitions from diabase to serpentine have also been observed, and, on the other

hand, alterations of it more or less advanced, are known, forming aphanites and other diabase conglomerates, and almond stones.

Diabase has a specific gravity of 2·8 to 3·1; begins to turn yellow when heated to 200°. It exhibits the following varieties of structure.

1. Fine-grained diabase. 2. Coarse-grained, resembling granite in appearance. 3. Porphyritic, containing crystals of labradorite, oligoclase and augite. 4. Compact, containing a considerable proportion of chlorite, and of grey-green, dirty-green, or blackish-green colour. 5. Slaty diabase, very rich in chlorite, and often very fine-grained.

The table on page 425 contains the most trustworthy analyses that have been made of diabase. (R. Souffier, *J. pr. Chem.* [2], vi. 227.)

DIALLYLENE (L. Henry, *Deut. Chem. Ges. Ber.* v. 449). When diallyl tetrabromide $C^6H^4Br^2$ is heated with solid caustic potash, it is converted into dibromodiallyl, $C^6H^4Br^2$, and this product, heated with alcoholic potash, gives up 2HBr and is converted into the compound C^6H^6 isomeric with benzene. This compound is called by Henry *diallylene*, a name which more properly belongs to the hydrocarbon C^6H^6 , inasmuch as allylene is C^3H^4 .

DIAMIDOHYDRIN. See CHORHYDRINS (p. 319.)

DIAMYLENE. See AMYLENE, (p. 64.)

DIAPHORITE. See FREISLEBENITE.

DIASPORE. R. Hermann (*J. pr. Chem.* [2], vi. 70) has analysed three varieties of diasporo from the emery vein near Miamarsk in the district of Katharinenburg, Russia: *a.* Brown-yellow, strongly lustrous laminae, grown together in cellular groups; *b.* Milk-white, yellowish or brownish, parallel-fibred, in narrow veins or threads in the emery, the fibres at right angles to the walls of the veins; *c.* Broadly laminated groups of grey colour:

	Al^2O^3	Fe^2O^3	H^2O	P^2O^5		Sp. gr.
<i>a</i>	77·95	6·60	15·00	0·45	= 100	3·40
<i>b</i>	77·90	6·50	14·00	1·60	= 100	3·23
<i>c</i>	67·15	5·00	15·00	12·85	= 100	3·35

All three varieties contain phosphoric acid, which has also been found by C. U. Shepard (*Sill. Am. J.* [2], 1, 96) in diasporo from Chester County, Pennsylvania. A well defined crystal of sp. gr. 3·343, semi-transparent, of hair-brown colour passing into violet, was found to contain 83·50 p.c. Al^2O^3 , 0·38 FeO, 15·80 H^2O , and 0·32 P^2O^5 , with traces of manganese.

DIAZOBENZENE, $C^6H^5N^2$. The nitrate of this base dissolves readily in a solution of potassium bisulphite, the liquid becoming hot, and sulphur dioxide being given off. On cooling, the liquid solidifies to a magma of yellow crystals, which, by recrystallisation from boiling water, are obtained in the form of colourless shining scales, having the composition $C^6H^5KN^2SO^3 + H^2O$. This salt does not explode when heated, and yields neither ammonia nor aniline when heated with soda-lime. Heated with nitric acid it yields sulphuric acid. When barium chloride is added to the hot solution, the salt $Ba(C^6H^5N^2SO^3)^2$ separates, on cooling, in colourless hydrated crystals. When silver nitrate is added to the solution of the potassium salt, metallic silver is precipitated, and the yellow solution yields, on evaporation, fine yellow shining plates of a silver salt which explodes gently when heated (Strecker, *Deut. Chem. Ges. Ber.* iv. 784).

When diazobenzene-sulphonic acid is treated with potassium bisulphite, the acid $C^6H^5N^2SO^3$ is formed according to the equation:

This acid crystallises from boiling water in colourless shining needles or plates; does not yield sulphuric acid when boiled with nitric acid; and gives off only half its nitrogen as aniline (or ammonia) when heated with soda-lime. Its *barium salt* $Ba(C^6H^5N^2SO^3)^2 + 5H^2O$, obtained by boiling the solution with barium carbonate, crystallises in long, lance-shaped, light yellow needles. The *lead salt* $Pb(C^6H^5N^2SO^3)^2 + 2H^2O$ forms small white crystals. The acid reduces silver and mercury salts; its salts are isomeric with those obtained by the action of bisulphites on diazobenzene nitrate (Strecker).

DIAZOCYANOBENZENE, $C^6H^5N^4$ = $C^6H^5(CN)N^2$ (Griess, *Deut. Chem. Ges. Ber.* ii. 369). This compound is formed as a nitrate, $C^6H^5N^4NO^3H$, when amidobenzonitril (1st Suppl. 526) is treated with excess of nitric acid containing nitrous

DIAZOCYANOBENZENIMIDE—DIBENZYL-SULPHUREA. 427

acid. The nitrate forms explosive needles or prisms, sparingly soluble in cold water. The solution gives, with platinum chloride, reddish-yellow needles of a platinumchloride, and with auric chloride an oil which solidifies in delicate laminae. With a solution of bromine in hydrobromic acid it forms a perbromide $C^6H^4(CN)N^+HBr^-$ which crystallises in indistinct yellowish-red prisms, and when treated with aqueous ammonia is converted into diazocyanobenzonimide, $C^6H^4(CN)N^+NH^-$:

The platinumchloride, distilled with dry sodium carbonate, yields chlorobenzonitril, $C^6H^4(CN)Cl$ (i. 564), in white needles melting at 39° .

The aqueous solution of the nitrate, mixed with hydriodic acid, deposits iodobenzonitril or iodocyanobenzene, $C^6H^4(CN)I$, in white needles melting at 41° , smelling like bitter almond oil, insoluble in water, easily soluble in alcohol and in ether.

DIAZOCYANOBENZENIMIDE, $C^6H^4(CN)N^+NH^-$, formed by the action of aqueous ammonia on diazocyanobenzene-perbromide, is nearly insoluble in water but easily soluble in warm alcohol, from which it crystallises in long sulphur-yellow needles melting at 57° , and detonating when strongly heated (Griess).

DIAZOPHENOL. See PHENOL DERIVATIVES.

DIAZOPHENYL-PROPIONIC ACID. See PHENYL-PROPIONIC ACID.

DIBENZYL CARBOXYLIC ACID, $C^{12}H^{10}O_2 = C^{12}H^{12}.COOH$ (Wurtz, *Comp. rend.* lxx. 350). An acid produced by the action of sodium-amalgam on a mixture of benzyl chloride and ethyl chlorocarbonate, 2 mols. benzyl chloride probably uniting together, with evolution of hydrogen chloride, to form chlorodibenzyl, $C^{12}H^{11}Cl$:

and this compound being converted by the sodium and chlorocarbonic ether into the ethylic ether of dibenzylcarboxylic acid:

252 grams of benzyl chloride, 108 grams of chlorocarbonic ether, and 8 kilograms of 1 p.c. sodium-amalgam are placed in a flask provided with reversed condenser and heated in a salt-water bath till the mass becomes solid; water is then added, the whole shaken with ether, the ether distilled off, and the residuo saponified by heating it with potash to 180° . On adding an acid to the alkaline liquid a viscid mass separates, from which boiling water extracts dibenzylcarboxylic acid, to be purified by recrystallisation from water and alcohol.

Dibenzylcarboxylic acid is nearly insoluble in cold water, slightly soluble in boiling water, easily soluble in alcohol and ether. It melts at 84° , gives off aromatic and irritating vapours, and volatilises at a higher temperature. Its salts have but little inclination to crystallise. The calcium salt, $Ca(C^{12}H^{12}O_2)^2$, is soluble, and the solution when heated becomes covered with a film. The lead salt, $Pb(C^{12}H^{12}O_2)^2$, forms a thick white precipitate melting at 146° . The silver salt, $C^{12}H^{12}AgO_2$, exhibits similar characters. The calcium salt distilled with an equal weight of quick-lime gives off a mixture of stilbene and dibenzyl:

DIBENZYLIC ACID, $C^{12}H^{12}O_2$, is formed, together with other products, by heating benzoic acid to 180° for some hours. A deep red liquid then distils over, which solidifies on cooling to an amorphous mass. This substance dissolves easily in alcohol, and the solution yields a number of crystallised bodies, amongst which are dibenzyllic acid, benzophenone, and a body having the composition $C^{12}H^{12}O_2$. Benzoic acid heated with phosphoric anhydride, also yields dibenzyllic acid, together with a viscid non-crystallising oil which, when heated with water to 200° , or when boiled, is reconverted into benzoic acid (Jena, *Ann. Ch. Pharm.* clv. 77).

DIBENZYL-GUANIDINE. See GUANIDINE.

DIBENZYL-PHOSPHINE. See PHOSPHINES.

DIBENZYL-UREA. See BENZYL UREAS (p. 181).

DIBENZYL-SULPHUREA, or **DIBENZYL-SULPHOCARBAMIDE**, $CS(NH.C^6H^5)_2$, is formed by heating an alcoholic solution of benzylamine in a flask

428 DIBROMODIPHENYLCARBAMIDE—DIDYMIUM.

with reversed condenser as long as hydrogen sulphide is given off. On evaporating and repeatedly crystallising the residue from alcohol, dibenzyl-sulphurea is obtained in large four-sided shining plates. It melts at 114° , dissolves in alcohol and ether, but is insoluble in water. When heated with mercuric oxide, it is converted into dibenzyl-urea (Strakosch, *Deut. Chem. Ges. Ber.* v. 692).

DIBROMODIPHENYLCARBAMIDE. See PHENYLCARBAMIDES.

DIBROMONITROPHENOLS. See PHENOL DERIVATIVES.

DIBUTYRALDINE, $C^6H^{11}NO$. A base formed by the union of 2 mols. butyric aldehyde C^4H^8O , and 1 mol. ammonia NH^3 , with elimination of H^2O . It is obtained, together with tetrabutyraldine, by treating butyraldehyde with alcoholic ammonia for two months at 30° , or for one day at 100° . The mode of separating these bases and obtaining coneine from the dibutyraldine has been already described (p. 380). Neither dibutyraldine nor tetrabutyraldine appears to have been obtained in the pure state (Schiff, *Ann. Ch. Pharm.* clvii. 352; *Deut. Chem. Ges. Ber.* v. 42).

DICARBONAPHTHALIC ACID, $C^{10}H^6(CO^2H^2)^2$, is obtained by boiling diquinonaphthalene (from bromonaphthalene-sulphonic acid) with potash-ley, and precipitating with hydrochloric acid. In the pure state it forms microscopic nearly colourless needles, which do not melt at temperatures near 240° . It is nearly insoluble in boiling water, but dissolves more easily in alcohol. Its barium salt, $C^{10}H^4(CO^2)^2Ba + 2H^2O$, forms small granular crystals, very soluble in water. The solution gives, with ferric chloride, a light yellow precipitate of an iron salt nearly insoluble in hot water. The copper salt separated in like manner forms groups of small needles; the lead and silver salts are sparingly soluble precipitates (Darminstädter u. Wichelhaus, *Jahresb.* 1869, 477).

DIDYMIUM. This metal has been detected in pyremorphite from Cumberland (C. Horne, *Chem. News*, xxvi. 109).

This method given by Erk (*Zeitschr. f. Chem.* [2], vii. 100), for the separation of cerium from didymium and lanthanum has been already described (p. 273). To separate didymium from lanthanum, the solution containing the two metals is precipitated to the extent of one half with ammonia, and the washed precipitate is left for a day at the ordinary temperature in contact with the rest of the solution, the whole being frequently stirred: the lanthanum, being the stronger base, then passes into the solution in predominant quantity. The lanthanum solution thus obtained is again half precipitated and treated as above. After the second treatment, the solution gives but slight indications with the spectroscopic of the absorption-bands of didymium, and after four such fractional precipitations, the didymium lines are no longer visible in a column of the solution 30 centimeters long. The solutions rich in didymium are treated in the same manner, and the intermediate solutions are mixed together and separately treated. A didymium solution is regarded by Erk as free from lanthanum, when, on precipitating the greater part of the oxide with ammonia, and treating it as above, no difference of colour or of atomic weight can be found between this precipitate and the oxide precipitated from the filtrate.

For the separation of didymium and the other cerium metals from yttrium, Erk makes use of the property possessed by the cerium metals of forming sparingly soluble double sulphates, whereas the corresponding yttrium salt is easily soluble (i. 833). The whole of the cerium, and the greater part of the lanthanum having been separated as above, the didymium oxide is dissolved in nitric acid, and boiled with a moderately concentrated solution of sodium sulphate, and the same treatment is repeatedly applied both to the precipitated didymium sulphate, and to the oxides which remain in solution, whereby the whole of the didymium is ultimately obtained in the precipitate, and the yttrium in the solution. In the separation of didymium from lanthanum, the yttrium is found chiefly in the solutions of didymium most free from lanthanum.

Salts.—The chloride crystallises from aqueous solution, according to Hermann (*J. pr. Chem.* lxxxii. 385), in granular masses containing $DiCl^2 + 4H^2O$. Zschiesche, on the

other hand (*ibid.* cvii. 65), obtained distinct monoclinic crystals which, after drying over oil of vitriol, had the composition $\text{DiCl}^2 + 5\text{H}^2\text{O}$. The *nitrate* crystallises with $4\text{H}^2\text{O}$. The *sulphate* crystallised from warm water has, according to Zschiescho, the composition $\text{DiSO}^4 + 3\text{H}^2\text{O}$, whereas, according to Hermann, Marignac and Rammelsberg, it contains $\text{DiSO}^4 + \frac{1}{2}\text{H}^2\text{O}$. To the dark brown *peroxide* Hermann assigned the formula Di^2H^{21} . Zschiescho doubts this formula, especially as this oxide is converted by strong ignition into the ash-grey monoxide—so that it is scarcely possible to obtain the peroxide quite pure by ignition in the air.

Absorption-spectrum.—A concentrated solution of pure didymium nitrate, 4 centimeters deep, exhibits a spectrum containing seven dark bands, the relative positions of which are seen in figure 13, the letters in the upper line indicating some of the principal Fraunhofer lines, D coinciding with 42 on the scale.

This spectrum agrees in the main with that described by Bahr and Bunsen (*Ann. Ch. Pharm.* cxxvii. 1).

The smaller the quantity of didymium in solution, the fewer are the dark bands seen. In very dilute solutions, only the band 45 in the yellow and 64 in the green (observed some time ago by Gladstone, ii. 322), are visible, and of these the former is always the stronger. These two bands afford the best indication of the presence of didymium in a lanthanum solution (Erk).

Equivalent and Atomic Weights.—To determine the equivalent weight of didymium, Erk precipitated a weighed quantity of the anhydrous sulphate with ammonium oxalate, and ignited the oxalate strongly before a gas blowpipe flame till it acquired a constant weight (the loss of weight of the platinum crucible by ignition being taken into account). The equivalent weight thus determined was $\text{Di} = 47.45, 47.43$ and 47.82 . Zschiescho (*J. pr. Chem.* cvii. 65), from the analysis of the sulphate, found the numbers 46.885, 46.72, 47.68, 47.93 and 48.08, the highest of which he regards as the most exact. As a mean of all these determinations the number 47.5 may be regarded as a very near approximation to the true equivalent weight of didymium.

If, then, didymium be regarded, according to the ordinary view, as a dyad metal, forming the compounds DiCl^2 , DiO , &c., its atomic weight will be 95. Mendelejeff, however, for reasons already explained (see CERITE METALS, p. 273), regards the sulfifiable oxide of didymium as a sesquioxide, Di^2O^3 , and accordingly assigns to didymium an atomic weight equal to three times its equivalent weight, that is $3 \times 47.5 = 142.5$ [or 138, if the older equivalent 46 be adopted]. According to this view the hydrate of didymium will be $\text{Di}(\text{OH})^3$ instead of $\text{Di}(\text{OH})^2$; the chloride $\text{DiCl}^3.6\text{H}^2\text{O}$ instead of $\text{DiCl}^2.4\text{H}^2\text{O}$, the sulphate $\text{Di}^2(\text{SO}^4)^2.8\text{H}^2\text{O}$ instead of $3\text{DiSO}^4.8\text{H}^2\text{O}$, and the double sulphates will have formulæ analogous to the alums, e.g. $\text{DiK}(\text{SO}^4)^2.\text{H}^2\text{O}$.

Mendelejeff's reasons for the proposed alterations in the atomic weights of the cerium metals, together with Rammelsberg's objections to them, have been already considered (p. 273).

DIGESTION, ANIMAL. (Kühne, *Physiologische Chemie*, Bd. I.; Schiff, *Sur la Physiologie de la Digestion*).

The action of saliva upon raw starch is very incomplete (Schiff), for while it is capable of converting boiled starch completely into dextrose, it acts only upon the 'granulose' of raw starch, leaving the 'cellulose' layers of the granules quite unchanged.

In spite of much attention during the last few years, the digestion of proteids in the stomach is still very imperfectly understood, neither the exact products nor the theory of the process being at all clear. The products vary somewhat with the proteid digested, and with the quantity of pepsin or free acid in the digestive fluid, but, speaking broadly, they consist of several diffusible forms of proteid, known as *peptones*, and an indiffusible form—*parapeptone*—which is insoluble in water, but soluble in dilute acids or alkalis, and, in fact, appears to agree in all its properties with syntonin, except that it is incapable of undergoing peptic digestion. Thus, if boiled blood fibrin be submitted to artificial peptic digestion, a solution is obtained, which is at first opalescent, but by longer digestion becomes clear, and on neutralisation yields a precipitate of parapeptone.

The filtrate from this precipitate contains three forms of peptones—known as Meissner's *a*, *b*, and *c* peptones. The *a*-peptone is characterised by being precipitated by nitric acid, and, in a solution slightly acidulated with acetic acid, by potassic ferrocyanide; the *b*-peptone is not precipitated by nitric acid, and by potassic ferrocyanide only in a solution strongly acidulated with acetic acid; and the *c*-peptone is precipitated by neither of the above reagents. (For the general properties common to all peptones, see **PROTEIDS**.) Sometimes an additional, non-diffusible form of proteid—*metapeptone*, is present in the solution; it appears to be imperfectly formed peptone; by prolonged digestion, part of the parapeptone is converted into another body, *dyspeptone*, which is insoluble in solutions containing the same percentage of free acid as gastric juice, and is accordingly precipitated as it is formed.

According to Meissner, the process of peptic digestion consists first, in the formation of a solution containing a form of proteid insoluble in pure water, whether or not the original proteid was soluble, and then in the splitting up of this product, into parapeptone and the *a*, *b*, and *c* peptones, of which latter he considers the *c*-peptone the final or most complete form. This view is, however, opposed by the fact that the quantities of parapeptone and peptones bear no constant ratio to one another, but vary almost indefinitely with the strength of the digestive fluid, the temperature at which the process is carried on, &c.; and as all the products of peptic digestion can be obtained from proteids by simple prolonged boiling with pure water, the pepsin is, perhaps, rather to be regarded as a ferment, active in acid solutions only, and capable of adding the elements of water to proteid bodies, and causing them to break up in various ways.

With other proteids than blood fibrin the process of peptic digestion is similar in the main, though in some cases the peptones and parapeptone produced present slight differences. Raw white of egg digests only after previous conversion into syntonin, a process which is very slow under the conditions obtaining in the stomach (Kühne), boiled white of egg digests without undergoing this previous change. Syntonin under peptic digestion yields, besides the *a*, *b*, and *c* peptones, a fourth form which differs from them in being precipitated from its solution by cupric sulphate. The coagulation of the casein of milk which occurs in the stomach is not due to the free acid, for it is produced equally well by neutralised gastric juice (Schiff); neither is it due to the pepsin, but as boiled gastric juice loses this power, it is probably due to some other ferment not yet isolated.

Peptic digestion is at once checked when the food enters the intestine; this is due chiefly to the bile, which not only renders the chyme alkaline, but precipitates any peptones it may contain in solution, and these, in falling, carry the pepsin down with them mechanically (Burkard).

In the small intestine the digestion of proteids is mainly carried on by the pancreatic secretion, which, besides its ferments converting starch into glucose and breaking

up fats, contains a third, which in alkaline solution first converts ordinary proteids into peptones, and then by further action breaks them up, tyrosin being one of the chief products.

The secretion of the mucous membrane of the small intestine, which is obtained pure by Thiry's method (*Wien. Akad. Ber.*, Bd. I.), according to most observers, dissolves fibrin, but no other proteid (Thiry, Leube, Schiff); it also readily converts starch into glucose, and in the dog, rabbit, and pig contains an additional ferment which converts cane-sugar into glucose, but which is absent in the sheep and calf (Paschutin).

The question of the changes which fats undergo in the alimentary canal is still very obscure; a part of them is no doubt saponified, but it seems probable that the greater portion will ultimately be found to undergo no chemical decomposition, but to be simply emulsified by the bile and pancreatic juice and then directly ingested as small molecules by the epithelial cells, and passed on by them to the commencing lacteals.

DINONYL KETONE. Syn. with CAPRONE (p. 251).

DIOPSIDE. Chrome-diopside from the olivine rock of the basalt of the Dreiser Weiher in the Eifel, contains, according to Rammelsberg (*Pogg. Ann.* cxli. 516),

SiO ²	Al ² O ³	Cr ² O ³	MgO	CaO	FeO
49.71	7.42	2.61	17.84	17.39	5.03 = 100.

These numbers may be represented by the formula $11\text{RSiO}^2(\text{Al}; \text{Cr})^2\text{O}^3$, in which $11\text{R} = \text{Fe} + 6\text{Mg} + 4\text{Ca}$.

DIOSMOSE. See OSMOSE.

DIOXYBENZOIC ACIDS, C₇H₄O₄. This formula includes protocatechuic, carlohydroquinonic, and hypogallic acids (iii. 239).

(1.) *Protocatechuic acid* has been shown by Barth to be producible both from oxybenzoic and from paraoxybenzoic acid (1st Suppl. 976; also *Deut. Chem. Ges. Ber.* v. 633; *Chem. Soc. J.* [2], ix. 829), namely, by converting the oxybenzoic into a sulphybenzoic acid by treatment with sulphuric acid, and decomposing the latter with potash. The quantity of protocatechuic acid produced from paraoxybenzoic acid is, however, much less than that from oxybenzoic acid, a less soluble acid, which gives a red reaction with ferric salts, being formed at the same time, probably by the action of the potash on an isomeric sulpho-acid.

Assuming, now, that the radicals CO²H and OH occupy in paraoxybenzoic acid the positions 1 : 4, and in oxybenzoic acid 1 : 3, the positions in protocatechuic acid must be 1 : 3 : 4, thus :

		6	5	4	3	2	1
Oxybenzoic	C ⁶	H	H	H	OH	H	CO ² H
Paraoxybenzoic	C ⁶	H	H	OH	H	H	CO ² H
Protocatechuic	C ⁶	H	H	OH	OH	H	CO ² H.

Now protocatechuic acid, when subjected to dry distillation, yields always, and solely, pyrocatechin. Hence, if the above formula of protocatechuic acid be correct, the two hydroxyls in pyrocatechin must be attached to contiguous carbon-atoms (3 : 4 or 1 : 2), and in that case, since these radicals occupy in resorcin the positions 1 : 4, they must have, in hydroquinone, the positions 1 : 3. On the other hand, if, as Gräbe supposes, the position formula of hydroquinone is 1 : 2, then that of pyrocatechin must be 1 : 3 (or 2 : 4), that of pyrocatechuic acid must be 1 : 2 : 4, and that of oxybenzoic acid 1 : 2. The latter view, however, is contradicted by Meyer's experiments (p. 133), which have shown that the position-formula of salicylic acid is 1 : 2, and that of oxybenzoic acid 1 : 3.

Dimethylprotocatechuic acid is prepared by heating 1 gram of protocatechuic acid, 4 grams of methyl iodide, and 1 gram of pure potassium hydrate with methyl alcohol, in a sealed tube to 140° for some hours. The liquid portion is filtered from the

potassium iodide, the alcohol evaporated off, and the oily residue boiled for some time with dilute soda-ley. After cooling, the liquid is acidulated with sulphuric acid, by which means a flocculent deposit of the new acid is produced. This is shaken up with ether, and the insoluble residue repeatedly crystallised from water. It is obtained in

glistening white needles having the composition $C^6H^3 \begin{cases} COOH \\ OCH^3 \\ OCH^3 \end{cases}$. It melts at $170^\circ-171^\circ$,

and does not show the characteristic iron reaction of protocatechuic acid. By distillation with lime, it gives rise to an oil, boiling between 210° and 215° , and having the composition of dimethyl-pyrocatechin: $C^6H^4(OCH^3)_2$.

The acid is converted by bromine into bromodimethyl-protocatechuic acid, $C^6H^2Br.(OCH^3)_2.COOH$, which crystallises from water in needles.

Diethylprotocatechuic acid $C^6H^3 \begin{cases} COOH \\ OC^2H^5 \\ OC^2H^5 \end{cases}$ is prepared in a similar manner to the

dimethyl-acid. It melts at 149° , and gives no reaction with ferric chloride. By dry distillation it yields an oil, probably consisting of diethyl-pyrocatechin. With bromine, it forms a crystalline product, exhibiting the composition of a mixture of mono- and di-bromodimethyl-pyrocatechuic acid (R. Koelle, *Ann. Ch. Pharm.* clix. 249).

(2.) *Dioxybenzoic acid*, 1 : 2 : 4 (Max Ascher, *Deut. Chem. Ges. Ber.* iv. 649). This modification is produced by a series of transformations from paranitrotoluene, $C^6H^4(NO^2)HH(CH^3)$. This body, treated with fuming sulphuric acid, is converted

into nitrotoluene-sulphonic acid $C^6H^3 \begin{cases} CH^3 \\ SO^3H \\ NO^2 \end{cases}$, in which, also, the radicles CH^3 and

NO^2 occupy the paraposition 1 : 4. To determine the relative positions of the radicles CH^3 and SO^3H , the nitrosulpho-acid was converted into the corresponding amido-sulpho-acid, and this into the diazo-compound by treatment with nitrous acid under alcohol; and the diazo-compound was boiled with absolute alcohol under pressure, whereby the nitrogen was eliminated and replaced by hydrogen. By this means, a toluene-sulphonic acid is produced, the potassium salt of which, when fused with potash, yields a liquid cresol, and this, when extracted with ether and repeatedly fused with potash, is converted into salicylic acid. Now in salicylic acid, as appears from Meyer's experiments (p. 133), the relative position of the radicles CH^3 and OH is 1 : 2; this, therefore, must also be the position of the CH^3 and SO^3H in the toluenesulphonic acid from which it was obtained, and therefore, the position of the CH^3 , SO^3H , and NO^2 in the nitrotoluenesulphonic acid must be 1 : 2 : 4.

		6	5	4	3	2	1.
Salicylic acid	C^6	H	H	H	H	(OH)	(CH^3)
Toluenesulphonic acid .	C^6	H	H	H	H	(SO^3H)	(CH^3)
Nitrotoluenesulphonic acid	C^6	H	H	(NO^2)	H	(SO^3H)	(CH^3)

To convert this nitro-acid into dioxybenzoic acid, it was first converted, as above, into the corresponding amido-acid, then into the diazo-compound. The latter is soluble in water, insoluble in alcohol, not easily acted upon by alkalis, detonates slightly when heated upon platinum foil. When boiled with water, it gives off nitrogen, and is converted into a cresolsulphonic acid $C^6H^4(OH)H(SO^3H)(CH^3)$ or 1 : 2 : 4; and by fusing the potassium salt of this acid with potash, the sulphuric acid residue SO^3H is replaced by OH , and at the same time the methyl-group CH^3 is oxidised to carboxyl, the product being the corresponding dioxybenzoic acid $C^6H^4(OH)_2(COOH)$.

To extract the acid, the fused mass is acidulated and shaken with ether, and the ether left to evaporate, whereby the acid is obtained in needles still retaining phenolic impurities. To purify it, the ethereal residue is dissolved in water, the filtered solution precipitated with lead acetate, and the lead precipitated by hydrogen sulphide, the impurities being thereby removed from the solution, together with the lead sulphide. The filtrate is a colourless liquid from which the para-dioxybenzoic acid may be extracted with ether. It crystallises in stellate groups of needles which contain 3 mols. water, and melt at 148° . When dried at 120° it gives off all its water of crystallisation, and the dehydrated acid melts at 194° . It sublimes readily in small white needles, which also melt at 194° ; dissolves readily in water, alcohol, and ether, and produces with ferric chloride a fine red-brown coloration. These characters sufficiently distinguish this modification of dioxybenzoic acid from protocatechuic acid, which crystallises with 1 mol. water, gives off its water at 100° , melts in the dehydrated state at 199° , and gives with ferric chloride a dark blue-green reaction. *Hypogallie acid* (iii. 239°), also gives a blue colour with ferric chloride, crystallises with $1\frac{1}{2}$ mol. water, becomes anhydrous at 100° , and melts at about 180° . *Carbohydro-*

quinonic acid (iii. 214), crystallises with 1 mol. water, which it gives off at 100° , melts at 207° (corr.) and is insoluble in ether. *Oxy-salicylic acid*, obtained by boiling mono-iodo-salicylic acid with potash (iv. 320), crystallises in anhydrous needles which melt at 193° , and gives a deep blue coloration with ferric chloride. All these acids are, therefore, distinct from dioxybenzoic acid 1 : 2 : 4.

Karst n. Senhofer (*Ann. Ch. Pharm.* clix. 217; clxiv. 109), have obtained another modification of dioxybenzoic acid, probably 1 : 3 : 6, by the action of melting potash on the potassium salt of disulphobenzoic acid (produced by heating benzoic acid with hydrogen sulphate and phosphoric anhydride to 250° in sealed tubes). On treating the fused mass with an acid, exhausting with ether, and evaporating the ethereal solution, the dioxybenzoic acid is obtained in long prisms very soluble in hot water, also in alcohol and ether. It is distinguished from protocatechuic acid by its crystalline form, by not giving the blue-green coloration with ferric chloride, and not being precipitated by neutral lead acetate. In the air-dried state it contains $(C^6H^4(OH)_2.COOH + 14H^2O)$; it gives off its water at 105° , and melts at a temperature above 220° . Heated with strong sulphuric acid, it dissolves to a red liquid, which deposits a green powder on addition of water. Its salts crystallise moderately well; most of them give off their water of crystallisation at 105° , the copper salt, however, retains a portion of it even at 110° ;

The *ethyl ether* $C^6H^4(C^2H^5O)^4$ prepared by passing hydrogen chloride into an alcoholic solution of the acid, remains on evaporation as a syrup which crystallises from water in groups of long prisms having a vitreous lustre. It melts at 100° , and remains transparent and amorphous for a long time after cooling.

This modification of dioxybenzoic acid differs from all those previously known, in not yielding by dry distillation any of the known dihydroxylbenzenes, but a yellow body called anthrachryson, $C^{14}H^8O^6$, formed from it by dehydration and condensation: $2C^6H^4O^4 - 2H^2O = C^{14}H^8O^6$. This body, which is also formed by heating the dioxybenzoic acid to 120° – 140° with sulphuric acid, is, in fact, a tetra-oxyanthraquinone, and its formation is analogous to that of rufigallie acid from gallic acid, and that of rufopin from opianic acid (p. 86).

Monobromodioxybenzoic acid, $C^6H^3BrO^4$, is produced by adding a sufficient quantity of bromine-water to a cold aqueous solution of the last-mentioned modification of dioxybenzoic acid. On evaporating the solution and crystallising the residue from hot water, monobromodioxybenzoic acid is obtained in colourless needles an inch long, melting at 253° . Its solution gives a brownish precipitate with ferric chloride, but it is not precipitated by lead acetate. The crystallised acid contains one molecule of water, which it loses at 120° . It is tribasic. Its *silver salt*, $C^6H^3Ag^3BrO^4$, is a yellow amorphous precipitate obtained by adding silver nitrate to the ammonium salt. The *barium salt* is readily soluble in water, and crystallises in long needles. The *copper salt* separates from a hot solution in light green, microscopic, but well-defined prisms $(C^6H^3BrO^4)_2Cu + 8H^2O$. The *potassium salt* crystallises in needles and dissolves very readily in water.

By fusing the monobrominated acid with potash, a large quantity is converted into dioxybenzoic acid, and a smaller quantity into gallic, trioxybenzoic, or dioxy-salicylic acid.

Tribromodioxybenzoic acid, $C^6H^3Br^3O^4$, is produced, together with a small quantity of the monobrominated acid, by tritulating dioxybenzoic acid with bromine. The mass becomes semifluid, hydrogen bromide is given off, and after the excess of bromine has been expelled over the water bath, the tribrominated acid remains as a yellowish crystalline mass, which dissolves easily in water, and separates therefrom in large tabular, anhydrous crystals melting at 183° . By fusion with potash, it is almost wholly reconverted into dioxybenzoic acid, together with a small quantity of a compound which gives a green colour with ferric chloride.
